About the Author

Laura E. Berk is a distinguished professor of psychology at Illinois State University, where she has taught child and human development to both undergraduate and graduate students for more than three decades. She received her bachelor's degree in psychology from the University of California, Berkeley, and her master's and doctoral degrees in child development and educational psychology from the University of Chicago. She has been a visiting scholar at Cornell University, UCLA, Stanford University, and the University of South Australia.

Berk has published widely on the effects of school environments on children's development, the development of private speech, and recently, the role of make-believe play in development. Her research has been funded by the U.S. Office of Education and the National Institute of Child Health and Human Development. It has appeared in many prominent journals, including *Child Development, Developmental Psychology, Merrill-Palmer Quarterly, Journal of Abnormal Child Psychology, Development and Psychopathology,* and *Early Childhood Research Quarterly.* Her empirical studies have attracted the attention of the general public, leading to contributions to *Psychology Today* and *Scientific American*. She has also been featured on National Public Radio's *Morning Edition* and in *Parents Magazine, Wondertime,* and *Reader's Digest*.

Berk has served as research editor of *Young Children* and consulting editor of *Early Childhood Research Quarterly.* Currently, she is associate editor of the *Journal of Cognitive Education and Psychology.* She is a frequent contributor to edited volumes on early childhood development, having recently authored chapters on the importance of parenting, on make-believe play and self-regulation, and on the kindergarten child. She has also written the chapter on development for *The Many Faces of Psychological Research in the Twenty-First Century* (Society for the Teaching of Psychology); the article on social development for *The Child: An Encyclopedic Companion;* the article on Vygotsky for the *Encyclopedia of Cognitive Science;* and the chapter on storytelling as a teaching strategy for *Voices of Experience: Memorable Talks from the National Institute on the Teaching of Psychology* (Association for Psychological Science).

Berk's books include *Private Speech: From Social Interaction to Self-Regulation; Scaffolding Children's Learning: Vygotsky and Early Childhood Education; Landscapes of Development: An Anthology of Readings*; and *A Mandate for Playful Learning in Preschool: Presenting the Evidence.* In addition to *Child Development,* she is author of the best-selling texts *Infants, Children, and Adolescents; Development Through the Lifespan;* and *Exploring Lifespan Development,* published by Pearson. Her book for parents and teachers is *Awakening Children's Minds: How Parents and Teachers Can Make a Difference*.

Berk is active in work for children's causes. In addition to service in her home community, she is a member of the national board of directors and chair of the Chicago advisory board of Jumpstart, a nonprofit organization that provides intensive literacy intervention to thousands of low-income preschoolers across the United States, using college and university students as interveners. Berk is a fellow of the American Psychological Association, Division 7: Developmental Psychology.

Brief Contents

I THEORY AND RESEARCH IN CHILD DEVELOPMENT

1 History, Theory, and Applied Directions 2
2 Research Strategies 40

II FOUNDATIONS OF DEVELOPMENT

3 Biological Foundations, Prenatal Development, and Birth 72
4 Infancy: Early Learning, Motor Skills, and Perceptual Capacities 128
5 Physical Growth 174

III COGNITIVE AND LANGUAGE DEVELOPMENT

6 Cognitive Development: Piagetian, Core Knowledge, and Vygotskian Perspectives 224
7 Cognitive Development: An Information-Processing Perspective 276
8 Intelligence 318
9 Language Development 358

IV PERSONALITY AND SOCIAL DEVELOPMENT

10 Emotional Development 400
11 Self and Social Understanding 446
12 Moral Development 484
13 Development of Sex Differences and Gender Roles 528

V CONTEXTS FOR DEVELOPMENT

14 The Family 566
15 Peers, Media, and Schooling 606

Features at a Glance

BIOLOGY AND ENVIRONMENT

Resilient Children 10
Prenatal Iron Deficiency and Memory Impairments in Infants of Diabetic Mothers: Findings of ERP Research 49
A Case of Epigenesis: Smoking During Pregnancy Alters Gene Expression 125
"Tuning In" to Familiar Speech, Faces, and Music: A Sensitive Period for Culture-Specific Learning 156
Brain Plasticity: Insights from Research on Brain-Damaged Children and Adults 188
Low-Level Lead Exposure and Children's Development 193
Children with Attention-Deficit Hyperactivity Disorder 290
Infantile Amnesia 301
Deaf Children Invent Language 362
Language Development in Children with Williams Syndrome 366
Parental Depression and Child Development 404
Development of Shyness and Sociability 422
"Mindblindness" and Autism 457
Two Routes to Adolescent Delinquency 520
Sex Differences in Spatial Abilities 556
Does Parenting Really Matter? 578
Bullies and Their Victims 621

CULTURAL INFLUENCES

!Kung Infancy: Acquiring Culture 26
Immigrant Youths: Adapting to a New Land 53
Cultural Variation in Infant Sleeping Arrangements 134
Social Origins of Make-Believe Play 270
Children in Village and Tribal Cultures Observe and Participate in Adult Work 273
The Powerful Role of Paternal Warmth in Development 439
Cultural Variations in Personal Storytelling: Implications for Early Self-Concept 451
Identity Development among Ethnic Minority Adolescents 475
Ethnic Differences in the Consequences of Physical Punishment 493
Impact of Ethnic and Political Violence on Children 524
Sweden's Commitment to Gender Equality 536
The African-American Extended Family 583

SOCIAL ISSUES: HEALTH

Family Chaos Undermines Children's Well-Being 29
Welfare Reform, Poverty, and Child Development 36
Children's Research Risks: Developmental and Individual Differences 68
The Pros and Cons of Reproductive Technologies 86
A Cross-National Perspective on Health Care and Other Policies for Parents and Newborn Babies 118
The Mysterious Tragedy of Sudden Infant Death Syndrome 136
Lesbian, Gay, and Bisexual Youth: Coming Out to Oneself and Others 216
Does Child Care Threaten Infant Attachment Security and Later Adjustment? 442
Adolescent Suicide: Annihilation of the Self 472
The Transition to Parenthood 570
Child Sexual Abuse 601
Adolescent Substance Use and Abuse 626

SOCIAL ISSUES: EDUCATION

Can Musical Experiences Enhance Intelligence? 59
Development of Infants with Severe Visual Impairments 162
Sex Differences in Gross-Motor Development 180
Baby Learning from TV and Video: The Video Deficit Effect 237
Speech–Gesture Mismatches: Using the Hand to Read the Mind 285
Media Multitasking Disrupts Learning 293
Emotional Intelligence 327
High-Stakes Testing 343
The Head Start REDI Program: Strengthening School Readiness in Economically Disadvantaged Preschoolers 351
Parent–Child Interaction: Impact on Language and Cognitive Development of Deaf Children 372
Two Approaches to Bilingual Education: Canada and the United States 397
Development of Civic Responsibility 508
Children Learn About Gender Through Mother–Child Conversations 540
Teaching Children to Challenge Peers' Sexist Remarks 545
School Recess—A Time to Play, a Time to Learn 639
Magnet Schools: Equal Access to High-Quality Education 645

APPLYING WHAT WE KNOW

Do's and Don'ts for a Healthy Pregnancy 107
Soothing a Crying Baby 137
Reasons to Breastfeed 195
Communicating with Adolescents About Sexual Issues 213
Enhancing Make-Believe Play in Early Childhood 241
Handling Consequences of Teenagers' New Cognitive Capacities 255
Promoting Children's Cognitive Self-Regulation 305
Supporting Emergent Literacy in Early Childhood 309
Features of a High-Quality Home Life in Infancy and Toddlerhood, Early Childhood, and Middle Childhood: The HOME Subscales 344
Promoting Children's Creativity 355
Supporting Early Language Learning 373
Helping Children Manage Common Fears of Early Childhood 411
Signs of Developmentally Appropriate Infant and Toddler Child Care 443
Fostering a Mastery-Oriented Approach to Learning 468
Supporting Healthy Identity Development 474
Positive Parenting 495
Reducing Children's Gender Stereotyping and Gender-Role Conformity 563
Helping Children Adjust to Their Parents' Divorce 594
Signs of Developmentally Appropriate Early Childhood Programs 598
Regulating TV, Computer, and Cell Phone Use 636

Contents

A Personal Note to Students xiii
Preface for Instructors xiv

PART I
Theory and Research in Child Development

CHAPTER 1

History, Theory, and Applied Directions 2

The Field of Child Development 4
- Domains of Development 4
- Periods of Development 5

Basic Issues 6
- Continuous or Discontinuous Development? 7
- One Course of Development or Many? 8
- Relative Influence of Nature and Nurture? 8
- A Balanced Point of View 9

BIOLOGY AND ENVIRONMENT *Resilient Children* *10*

Historical Foundations 10
- Medieval Times 10
- The Reformation 11
- Philosophies of the Enlightenment 12
- Scientific Beginnings 13

Mid-Twentieth-Century Theories 14
- The Psychoanalytic Perspective 15
- Behaviorism and Social Learning Theory 17
- Piaget's Cognitive-Developmental Theory 19

Recent Theoretical Perspectives 21
- Information Processing 21
- Developmental Cognitive Neuroscience 23
- Ethology and Evolutionary Developmental Psychology 23
- Vygotsky's Sociocultural Theory 24

CULTURAL INFLUENCES *!Kung Infancy: Acquiring Culture* *26*
- Ecological Systems Theory 26

SOCIAL ISSUES: HEALTH *Family Chaos Undermines Children's Well-Being* *29*
- New Directions: Development as a Dynamic System 30

Comparing Child Development Theories 31

Applied Directions: Child Development and Social Policy 32
- Culture and Public Policies 34
- Contributions of Child Development Research 35

SOCIAL ISSUES: HEALTH *Welfare Reform, Poverty, and Child Development* *36*
- Looking Toward the Future 37

Summary 38

Important Terms and Concepts 39

CHAPTER 2

Research Strategies 40

From Theory to Hypothesis 41

Common Research Methods 42
- Systematic Observation 42
- Self-Reports: Interviews and Questionnaires 46
- Neurobiological Methods 47

BIOLOGY AND ENVIRONMENT *Prenatal Iron Deficiency and Memory Impairments in Infants of Diabetic Mothers: Findings of ERP Research* *49*
- The Clinical, or Case Study, Method 50
- Methods for Studying Culture 51

CULTURAL INFLUENCES *Immigrant Youths: Adapting to a New Land* *53*

Reliability and Validity: Keys to Scientifically Sound Research 54
- Reliability 54
- Validity 54

General Research Designs 55
- Correlational Design 55
- Experimental Design 56
- Modified Experimental Designs 58

SOCIAL ISSUES: EDUCATION *Can Musical Experiences Enhance Intelligence?* *59*

Designs for Studying Development 60
- The Longitudinal Design 60
- The Cross-Sectional Design 62
- Improving Developmental Designs 63

Ethics in Research on Children 66

SOCIAL ISSUES: HEALTH *Children's Research Risks: Developmental and Individual Differences* *68*

Summary 70

Important Terms and Concepts 71

PART II
Foundations of Development

CHAPTER 3

Biological Foundations, Prenatal Development, and Birth 72

Genetic Foundations 73
- The Genetic Code 74
- The Sex Cells 75
- Boy or Girl? 76

Multiple Offspring 76
Patterns of Genetic Inheritance 77
Chromosomal Abnormalities 82

Reproductive Choices 84

Genetic Counseling 84
Prenatal Diagnosis and Fetal Medicine 84

SOCIAL ISSUES: HEALTH *The Pros and Cons of Reproductive Technologies 86*

Prenatal Development 88

Conception 88
Period of the Zygote 89

MILESTONES *Prenatal Development 90*

Period of the Embryo 91
Period of the Fetus 92

Prenatal Environmental Influences 94

Teratogens 95
Other Maternal Factors 103

Childbirth 107

The Baby's Adaptation to Labor and Delivery 108
The Newborn Baby's Appearance 109
Assessing the Newborn's Physical Condition: The Apgar Scale 109

Approaches to Childbirth 109

Natural, or Prepared, Childbirth 110
Home Delivery 111
Labor and Delivery Medication 112

Birth Complications 112

Oxygen Deprivation 112
Preterm and Low-Birth-Weight Infants 113
Birth Complications, Parenting, and Resilience 117

SOCIAL ISSUES: HEALTH *A Cross-National Perspective on Health Care and Other Policies for Parents and Newborn Babies 118*

Heredity, Environment, and Behavior: A Look Ahead 118

The Question, "How Much?" 120
The Question, "How?" 121

BIOLOGY AND ENVIRONMENT *A Case of Epigenesis: Smoking During Pregnancy Alters Gene Expression 125*

Summary 126

Important Terms and Concepts 127

CHAPTER 4

Infancy: Early Learning, Motor Skills, and Perceptual Capacities 128

The Organized Infant 129

Reflexes 130
States 132

CULTURAL INFLUENCES *Cultural Variation in Infant Sleeping Arrangements 134*

SOCIAL ISSUES: HEALTH *The Mysterious Tragedy of Sudden Infant Death Syndrome 136*

Neonatal Behavioral Assessment 138
Learning Capacities 139

Motor Development in Infancy 147

The Sequence of Motor Development 147

MILESTONES *Some Gross- and Fine-Motor Attainments of the First Two Years 148*

Motor Skills as Dynamic Systems 148
Fine-Motor Development: Reaching and Grasping 150

Perceptual Development in Infancy 152

Touch 153
Taste and Smell 154
Hearing 155

BIOLOGY AND ENVIRONMENT *"Tuning In" to Familiar Speech, Faces, and Music: A Sensitive Period for Culture-Specific Learning 156*

MILESTONES *Development of Touch, Taste, Smell, and Hearing 158*

Vision 158

SOCIAL ISSUES: EDUCATION *Development of Infants with Severe Visual Impairments 162*

Intermodal Perception 166

MILESTONES *Visual Development in Infancy 167*

Understanding Perceptual Development 168

Early Deprivation and Enrichment: Is Infancy a Sensitive Period of Development? 169

Summary 172

Important Terms and Concepts 173

CHAPTER 5

Physical Growth 174

The Course of Physical Growth 176

Changes in Body Size 176
Changes in Body Proportions 176
Changes in Muscle–Fat Makeup 177
Skeletal Growth 178
Gains in Gross-Motor Skills 178

MILESTONES *Gross-Motor Development in Early and Middle Childhood 179*

SOCIAL ISSUES: EDUCATION *Sex Differences in Gross-Motor Development 180*

Hormonal Influences on Physical Growth 181
Worldwide Variations in Body Size 183
Secular Trends 184

Brain Development 184

Development of Neurons 185
Development of the Cerebral Cortex 186

BIOLOGY AND ENVIRONMENT *Brain Plasticity: Insights from Research on Brain-Damaged Children and Adults 188*

Advances in Other Brain Structures 189
Brain Development in Adolescence 190
Sensitive Periods in Brain Development 191

Factors Affecting Physical Growth 192

Heredity 192

BIOLOGY AND ENVIRONMENT *Low-Level Lead Exposure and Children's Development* 193
  Nutrition 194
  Infectious Disease 201
  Emotional Well-Being 202
Puberty: The Physical Transition to Adulthood 203
  Sexual Maturation in Girls 203
  Sexual Maturation in Boys 203
MILESTONES *Pubertal Development in North American Boys and Girls* 204
  Individual and Group Differences in Pubertal Growth 204
The Psychological Impact of Pubertal Events 205
  Is Puberty Inevitably a Period of Storm and Stress? 205
  Reactions to Pubertal Changes 206
  Pubertal Change, Emotion, and Social Behavior 207
  Pubertal Timing 208
Puberty and Adolescent Health 210
  Eating Disorders 210
  Sexuality 212
SOCIAL ISSUES: HEALTH *Lesbian, Gay, and Bisexual Youths: Coming Out to Oneself and Others* 216
  Sexually Transmitted Disease 217
  Adolescent Pregnancy and Parenthood 217
  A Concluding Note 221
Summary 221
Important Terms and Concepts 223

PART III
Cognitive and Language Development

CHAPTER 6
Cognitive Development: Piagetian, Core Knowledge, and Vygotskian Perspectives 224

Piaget's Cognitive-Developmental Theory 226
  Basic Characteristics of Piaget's Stages 226
  Piaget's Ideas About Cognitive Change 226
The Sensorimotor Stage: Birth to 2 Years 228
  Sensorimotor Development 228
  Follow-Up Research on Infant Cognitive Development 230
  Evaluation of the Sensorimotor Stage 236
SOCIAL ISSUES: EDUCATION *Baby Learning from TV and Video: The Video Deficit Effect* 237
MILESTONES *Some Cognitive Attainments of Infancy and Toddlerhood* 238
The Preoperational Stage: 2 to 7 Years 239
  Advances in Mental Representation 239
  Limitations of Preoperational Thought 243
  Follow-Up Research on Preoperational Thought 245
MILESTONES *Some Cognitive Attainments of Early Childhood* 248
  Evaluation of the Preoperational Stage 248
The Concrete Operational Stage: 7 to 11 Years 249
  Concrete Operational Thought 249
  Limitations of Concrete Operational Thought 252
  Follow-Up Research on Concrete Operational Thought 252
MILESTONES *Some Cognitive Attainments of Middle Childhood and Adolescence* 253
The Formal Operational Stage: 11 Years and Older 253
  Hypothetico-Deductive Reasoning 253
  Propositional Thought 254
  Consequences of Adolescent Cognitive Changes 255
  Follow-up Research on Formal Operational Thought 257
Piaget and Education 259
Overall Evaluation of Piaget's Theory 260
  Is Piaget's Account of Cognitive Change Clear and Accurate? 260
  Does Cognitive Development Take Place in Stages? 260
  Piaget's Legacy 261
The Core Knowledge Perspective 261
  Infancy: Physical and Numerical Knowledge 262
  Children as Naïve Theorists 264
  Evaluation of the Core Knowledge Perspective 265
Vygotsky's Sociocultural Theory 266
  Children's Private Speech 266
  Social Origins of Cognitive Development 267
  Vygotsky's View of Make-Believe Play 269
Vygotsky and Education 269
CULTURAL INFLUENCES *Social Origins of Make-Believe Play* 270
  Reciprocal Teaching 271
  Cooperative Learning 271
Evaluation of Vygotsky's Theory 272
CULTURAL INFLUENCES *Children in Village and Tribal Cultures Observe and Participate in Adult Work* 273
Summary 273
Important Terms and Concepts 275

CHAPTER 7
Cognitive Development: An Information-Processing Perspective 276

The Information-Processing Approach 278
A General Model of Information Processing 278
  Components of the Mental System 278
  Implications for Development 280
Developmental Theories of Information Processing 282
  Case's Neo-Piagetian Theory 283
  Siegler's Model of Strategy Choice 284
SOCIAL ISSUES: EDUCATION *Speech–Gesture Mismatches: Using the Hand to Read the Mind* 285
Attention 286
  Sustained, Selective, and Adaptable Attention 286
  Planning 289

- **BIOLOGY AND ENVIRONMENT** *Children with Attention-Deficit Hyperactivity Disorder 290*
- **Memory 292**
  - Strategies for Storing Information 292
- **SOCIAL ISSUES: EDUCATION** *Media Multitasking Disrupts Learning 293*
  - Retrieving Information 294
  - Knowledge and Semantic Memory 296
  - Episodic Memory 297
  - Eyewitness Memory 300
- **BIOLOGY AND ENVIRONMENT** *Infantile Amnesia 301*
- **Metacognition 303**
  - Metacognitive Knowledge 303
  - Cognitive Self-Regulation 304
- **MILESTONES** *Development of Information Processing 306*
- **Applications of Information Processing to Academic Learning 307**
  - Reading 307
  - Mathematics 310
  - Scientific Reasoning 313
- **Evaluation of the Information-Processing Approach 314**
- **Summary 316**
- **Important Terms and Concepts 317**

CHAPTER 8

Intelligence 318

- **Definitions of Intelligence 320**
  - Alfred Binet: A Holistic View 320
  - The Factor Analysts: A Multifaceted View 321
- **Recent Advances in Defining Intelligence 323**
  - Combining Psychometric and Information-Processing Approaches 323
  - Sternberg's Triarchic Theory 323
  - Gardner's Theory of Multiple Intelligences 325
- **Measuring Intelligence 326**
- **SOCIAL ISSUES: EDUCATION** *Emotional Intelligence 327*
  - Some Commonly Used Intelligence Tests 327
  - Aptitude and Achievement Tests 328
  - Tests for Infants 329
  - Computation and Distribution of IQ Scores 330
- **What Do Intelligence Tests Predict, and How Well? 330**
  - Stability of IQ Scores 330
  - IQ as a Predictor of Academic Achievement 331
  - IQ as a Predictor of Occupational Attainment 332
  - IQ as a Predictor of Psychological Adjustment 333
- **Ethnic and Socioeconomic Variations in IQ 334**
- **Explaining Individual and Group Differences in IQ 335**
  - Genetic Influences 335
  - Adoption Studies: Joint Influence of Heredity and Environment 337
- **CULTURAL INFLUENCES** *The Flynn Effect: Massive Generational Gains in IQ 338*
  - Race and Ethnicity: Genetic or Cultural Groupings? 339
  - Cultural Bias in Testing 339
  - Reducing Cultural Bias in Testing 342
- **SOCIAL ISSUES: EDUCATION** *High-Stakes Testing 343*
  - Home Environment and Mental Development 344
- **Early Intervention and Intellectual Development 347**
  - Benefits of Early Intervention 347
  - Strengthening Early Intervention 349
- **Giftedness: Creativity and Talent 350**
  - The Psychometric View 350
- **SOCIAL ISSUES: EDUCATION** *The Head Start REDI Program: Strengthening School Readiness in Economically Disadvantaged Preschoolers 351*
  - A Multifaceted View 352
- **Summary 356**
- **Important Terms and Concepts 357**

CHAPTER 9

Language Development 358

- **Components of Language 360**
- **Theories of Language Development 360**
  - The Nativist Perspective 360
- **BIOLOGY AND ENVIRONMENT** *Deaf Children Invent Language 362*
- **BIOLOGY AND ENVIRONMENT** *Language Development in Children with Williams Syndrome 366*
  - The Interactionist Perspective 366
- **Prelinguistic Development: Getting Ready to Talk 368**
  - Receptivity to Language 368
  - First Speech Sounds 370
  - Becoming a Communicator 370
- **SOCIAL ISSUES: EDUCATION** *Parent–Child Interaction: Impact on Language and Cognitive Development of Deaf Children 372*
- **Phonological Development 373**
  - The Early Phase 373
  - Phonological Strategies 374
  - Later Phonological Development 375
- **Semantic Development 376**
  - The Early Phase 376
  - Later Semantic Development 380
  - Ideas About How Semantic Development Takes Place 381
- **Grammatical Development 384**
  - First Word Combinations 384
  - From Simple Sentences to Complex Grammar 385
  - Development of Complex Grammatical Forms 387
  - Later Grammatical Development 388
  - Ideas About How Grammatical Development Takes Place 388
- **Pragmatic Development 390**
  - Acquiring Conversational Skills 390
  - Communicating Clearly 391
  - Narratives 392
  - Sociolinguistic Understanding 393

Development of Metalinguistic Awareness 394

Bilingualism: Learning Two Languages in Childhood 394

MILESTONES *Language Development 395*

SOCIAL ISSUES: EDUCATION *Two Approaches to Bilingual Education: Canada and the United States 397*

Summary 398

Important Terms and Concepts 399

PART IV
Personality and Social Development

CHAPTER 10
Emotional Development 400

Functions of Emotions 401

- Emotions and Cognitive Processing 402
- Emotions and Social Behavior 402
- Emotions and Health 403

BIOLOGY AND ENVIRONMENT *Parental Depression and Child Development 404*

- Other Features of the Functionalist Approach 405

Development of Emotional Expression 405

- Basic Emotions 406
- Self-Conscious Emotions 408
- Emotional Self-Regulation 409
- Acquiring Emotional Display Rules 412

Understanding and Responding to the Emotions of Others 414

- Social Referencing 414
- Emotional Understanding in Childhood 415
- Empathy and Sympathy 416

MILESTONES *Emotional Development 417*

Temperament and Development 418

- The Structure of Temperament 420
- Measuring Temperament 421

BIOLOGY AND ENVIRONMENT *Development of Shyness and Sociability 422*

- Stability of Temperament 423
- Genetic and Environmental Influences 423
- Temperament as a Predictor of Children's Behavior 425
- Temperament and Child Rearing: The Goodness-of-Fit Model 426

Development of Attachment 428

- Bowlby's Ethological Theory 428
- Measuring the Security of Attachment 430
- Stability of Attachment 432
- Cultural Variations 432
- Factors Affecting Attachment Security 433
- Multiple Attachments 437

CULTURAL INFLUENCES *The Powerful Role of Paternal Warmth in Development 439*

- Attachment and Later Development 439

Attachment, Parental Employment, and Child Care 441

SOCIAL ISSUES: HEALTH *Does Child Care Threaten Infant Attachment Security and Later Adjustment? 442*

Summary 444

Important Terms and Concepts 445

CHAPTER 11
Self and Social Understanding 446

Emergence of Self and Development of Self-Concept 448

- Self-Awareness 448
- The Categorical, Remembered, and Enduring Selves 450

CULTURAL INFLUENCES *Cultural Variations in Personal Storytelling: Implications for Early Self-Concept 451*

- The Inner Self: Young Children's Theory of Mind 451
- Self-Concept 456

BIOLOGY AND ENVIRONMENT *"Mindblindness" and Autism 457*

- Cognitive, Social, and Cultural Influences on Self-Concept 459

MILESTONES *Emergence of Self and Development of Self-Concept 460*

Self-Esteem: The Evaluative Side of Self-Concept 461

- The Structure of Self-Esteem 461
- Changes in Level of Self-Esteem: The Role of Social Comparisons 462
- Influences on Self-Esteem 463
- Achievement-Related Attributions 464

Constructing an Identity: Who Should I Become? 468

MILESTONES *Development of Self-Esteem 469*

- Paths to Identity 470
- Identity Status and Psychological Well-Being 471

SOCIAL ISSUES: HEALTH *Adolescent Suicide: Annihilation of the Self 472*

- Factors Affecting Identity Development 472

CULTURAL INFLUENCES *Identity Development Among Ethnic Minority Adolescents 475*

Thinking About Other People 476

- Understanding People as Personalities 476

A Personal Note to Students

My more than 30 years of teaching child development have brought me in contact with thousands of students like you—students with diverse majors, future goals, interests, and needs. Some are affiliated with my own field, psychology, but many come from other related fields—education, sociology, anthropology, family studies, social service, nursing, and biology, to name just a few. Each semester, my students' aspirations have proven to be as varied as their fields of study. Many look toward careers in applied work with children—teaching, caregiving, nursing, counseling, social service, school psychology, and program administration. Some plan to teach child development, and a few want to do research. Most hope someday to become parents, whereas others are already parents who come with a desire to better understand and rear their children. And almost all arrive with a deep curiosity about how they themselves developed from tiny infants into the complex human beings they are today.

My goal in preparing this ninth edition of *Child Development* is to provide a textbook that meets the instructional goals of your course as well as your personal interests and needs. To achieve these objectives, I have grounded this book in a carefully selected body of classic and current theory and research brought to life with stories and vignettes about children and families, most of whom I have known personally. In addition, the text highlights the joint contributions of biology and environment to the developing child, explains how the research process helps solve real-world problems, illustrates commonalities and differences between ethnic groups and cultures, discusses the broader social contexts in which children develop, and pays special attention to policy issues that are crucial for safeguarding children's well-being in today's world. Woven throughout the text is a unique pedagogical program that will assist you in mastering information, integrating the various aspects of development, critically examining controversial issues, applying what you have learned, and relating the information to real life.

I hope that learning about child development will be as rewarding for you as I have found it over the years. I would like to know what you think about both the field of child development and this book. I welcome your comments; please feel free to send them to me at Department of Psychology, Box 4620, Illinois State University, Normal, IL 61790, or in care of the publisher, who will forward them to me.

Laura E. Berk

Preface for Instructors

My decision to write *Child Development* was inspired by a wealth of professional and personal experiences. First and foremost were the interests and needs of thousands of students of child development in my classes in more than three decades of college teaching. I aimed for a text that is intellectually stimulating, that provides depth as well as breadth of coverage, that portrays the complexities of child development with clarity and excitement, and that is relevant and useful in building a bridge from theory and research to children's everyday lives.

Today, *Child Development* reaches around the globe, with editions published in six languages: English, Chinese, Georgian, Japanese, Russian, and Spanish. Instructor and student enthusiasm for the book not only has been among my greatest sources of pride and satisfaction but also has inspired me to rethink and improve each edition. I am honored and humbled to have entrusted to me the awesome responsibility of introducing the field of child development to so many students.

The 23 years since *Child Development* first appeared have been a period of unprecedented expansion and change in theory and research. This ninth edition represents these rapid transformations, with a wealth of new content and teaching tools:

- ***Diverse pathways of change are highlighted.*** Investigators have reached broad consensus that variations in biological makeup, everyday tasks, and the people who support children in mastery of those tasks lead to wide individual differences in children's paths of change and resulting competencies. This edition pays more attention to variability in development and to recent theories—including ecological, sociocultural, and dynamic systems—that attempt to explain it. Multicultural and cross-cultural findings, including international comparisons, are enhanced throughout the text and in revised and expanded Cultural Influences boxes.

- ***The complex, bidirectional relationship between biology and environment is given greater attention.*** Accumulating evidence on development of the brain, motor skills, cognitive and language competencies, temperament, emotional and social understanding, and developmental problems underscores the way biological factors emerge in, are modified by, and share power with experience. The interconnection between biology and environment is revisited throughout the text narrative and in the Biology and Environment boxes with new and updated topics.

- ***Inclusion of interdisciplinary research is expanded.*** The move toward viewing thoughts, feelings, and behavior as an integrated whole, affected by a wide array of influences in biology, social context, and culture, has motivated developmental researchers to strengthen their ties with other fields of psychology and with other disciplines. Topics and findings included in this edition increasingly reflect the contributions of educational psychology, social psychology, health psychology, clinical psychology, neurobiology, pediatrics, sociology, anthropology, social service, and other fields.

- ***The links among theory, research, and applications—a theme of this book since its inception—are strengthened.*** As researchers intensify their efforts to generate findings relevant to real-life situations, I have placed even greater weight on social policy issues and sound theory- and research-based practices. Further applications are provided in the Applying What We Know tables, which give students concrete ways of building bridges between their learning and the real world.

- ***Both health and education are granted increased attention.*** The home, school, community, and larger culture are featured as contexts that powerfully influence children's health and education, with lifelong consequences for their well-being. Research on effective health- and education-related policies and practices appears throughout the text narrative and in new and revised Social Issues: Health and Social Issues: Education boxes.

- ***The role of active student learning is made more explicit.*** **TAKE A MOMENT...**, a feature built into the chapter narrative, asks students to think deeply and critically as they read. Ask Yourself questions at the end of each major section have been thoroughly revised and expanded to promote four approaches to engaging actively with the subject matter: *Review, Connect, Apply,* and *Reflect*. This feature assists students in reflecting on what they have learned from multiple vantage points. A new Look and Listen feature, appearing periodically in the margins, presents students with opportunities to observe what real children say and do and attend to influences on children in their everyday environments.

Text Philosophy

The basic approach of this book has been shaped by my own professional and personal history as a teacher, researcher, and parent. It consists of seven philosophical ingredients that I regard as essential for students to emerge from a course with a thorough understanding of child development:

1. ***An understanding of major theories and the strengths and shortcomings of each.*** The first chapter begins by emphasizing that only knowledge of multiple theories can do justice to the richness of child development. In each topical domain, I present a variety of theoretical perspectives, indicate how each highlights previously overlooked facets of development, and discuss research that evaluates it. If one or two theories have emerged as especially prominent in a particular area, I indicate why, in terms of the theory's broad explanatory power. Consideration of contrasting theories also serves as the basis for an evenhanded analysis of many controversial issues throughout the text.

2. ***An appreciation of research strategies for investigating child development.*** To evaluate theories, students need a firm grounding in research methods and designs. I devote an entire chapter

to a description and critique of research strategies. Throughout the book, numerous studies are discussed in sufficient detail for students to use what they have learned to critically assess the findings, conclusions, and implications of research.

3. *Knowledge of both the sequence of child development and the processes that underlie it.* Students are provided with a description of the organized sequence of development along with processes of change. An understanding of process—how complex combinations of biological and environmental events produce development—has been the focus of most recent research. Accordingly, the text reflects this emphasis. But new information about the timetable of change has also emerged. In many ways, children have proved to be far more competent than they were believed to be in the past. Current evidence on the sequence and timing of development, along with its implications for process, is presented throughout the book.

4. *An appreciation of the impact of context and culture on child development.* A wealth of research indicates that children live in rich physical and social contexts that affect all aspects of development. In each chapter, the student travels to distant parts of the world as I review a growing body of cross-cultural evidence. The text narrative also discusses many findings on socioeconomically and ethnically diverse children within the United States and on children with varying abilities and disabilities. Besides highlighting the role of immediate settings, such as family, neighborhood, and school, I underscore the impact of larger social structures—societal values, laws, and government programs—on children's well-being.

5. *An understanding of the joint contributions of biology and environment to development.* The field recognizes more powerfully than ever before the joint impact of hereditary/constitutional and environmental factors—that these contributions to development combine in complex ways and cannot be separated in a simple manner. Numerous examples of how biological dispositions can be maintained as well as transformed by social contexts are presented throughout the book.

6. *A sense of the interdependency of all aspects of development—physical, cognitive, emotional, and social.* Every chapter takes an integrated approach to understanding children. I show how physical, cognitive, emotional, and social development are interwoven. Within the text narrative and in a special series of Ask Yourself *Connect* questions at the end of major sections, students are referred to other parts of the book to deepen their grasp of relationships among various aspects of change.

7. *An appreciation of the interrelatedness of theory, research, and applications.* Throughout this book, I emphasize that theories of child development and the research stimulated by them provide the foundation for sound, effective practices with children. The links among theory, research, and applications are reinforced by an organizational format in which theory and research are presented first, followed by practical implications. In addition, a current focus in the field—harnessing child development knowledge to shape social policies that support children's needs—is reflected in every chapter. The text addresses the current condition of children in the United States and around the world and shows how theory and research have sparked successful interventions.

New Coverage in the Ninth Edition

Child development is a fascinating and ever-changing field of study, with constantly emerging new discoveries and refinements in existing knowledge. The ninth edition represents this burgeoning contemporary literature, with more than 1,400 new citations. Cutting-edge topics throughout the text underscore the book's major themes. Here is a sampling:

■ **CHAPTER 1** ■ Introduction to the concept of plasticity within the section on basic issues of development • Revised and updated section on developmental cognitive neuroscience as a new area of investigation • New Social Issues: Health box on how family chaos undermines children's well-being, illustrating the power of the exosystem to affect development • Expanded and updated section on child development and social policy • Updated Social Issues: Health box on the impact of welfare reform on children's development, with U.S. welfare reform policies compared to those of other Western nations

■ **CHAPTER 2** ■ Attention throughout to the advantages of combining research methods and designs • New examples of research using systematic observation, structured interviews, correlational design, field experimentation, and microgenetic design • Expanded and updated section on neurobiological methods, including salivary cortisol as a measure of stress reactivity and new approaches to assessing brain functioning, including the geodesic sensor net (GSN) and near-infrared spectroscopy (NIRS) • Updated Biology and Environment box on prenatal iron deficiency and memory impairments in infants of diabetic mothers, illustrating research using event-related potentials (ERPs) • Updated Cultural Influences box on immigrant youths

■ **CHAPTER 3** ■ Updated Social Issues: Health box on the pros and cons of reproductive technologies • Enhanced attention to fetal brain development and behavior • Updated consideration of a wide range of teratogens • New evidence on the long-term consequences of emotional stress during pregnancy • New findings on older maternal age and prenatal and birth complications • Updated Social Issues: Health box on health care and other policies for parents and newborn babies, including the importance of generous parental leave • Introduction to the concept of gene–environment interaction, with illustrative research findings • Expanded section on epigenesis, including new examples of environmental influences on gene expression

■ **CHAPTER 4** ■ Enhanced attention to cultural influences—including infant sleep, gross- and fine-motor development, and perceptual development • New evidence on the impact of "proximal care"—extensive holding of young babies—on reducing infant crying • Updated findings on how environmental factors, including caregiving practices and the baby's physical surroundings, contribute to motor development • New evidence on the perceptual narrowing effect in speech, music, and species-related face perception and in gender- and race-related face perception • New research on development of object perception, including the role of object manipulation • Expanded and updated research on intermodal perception and its contributions to all aspects of psychological development • New findings on children adopted from Romanian orphanages bearing on the question of whether infancy is a sensitive period of development

■ **CHAPTER 5** ■ Updated Social Issues: Education box on sex differences in gross motor development, including the role of physical education • Updated consideration of advances in brain development, with special attention to the prefrontal cortex and the amygdala • New section on adolescent brain development • Updated Biology and Environment box on low-level lead exposure and children's development • Expanded attention to the impact of adult mealtime practices on children's eating behaviors • Revised and updated section on overweight and obesity, including current U.S. prevalence rates, international comparisons, and coverage of contributing factors and health and psychological consequences • New research on infants with growth faltering, highlighting the joint contributions of feeding difficulties and a disturbed parent–infant relationship • New findings on media exposure to sexual content and teenage sexual activity • New evidence on key elements of effective sex education programs • Updated research on adolescent parenthood, including long-term adjustment of adolescent parents and their children and effective interventions

■ **CHAPTER 6** ■ Updated section on infant and toddler imitation, revealing toddlers' ability to infer others' intentions • New section on symbolic understanding, including toddlers' developing grasp of words and pictures as symbolic tools • New Social Issues: Education box on baby learning from TV and video, including discussion of the video deficit effect and the negative impact of extensive early TV viewing • Updated Cultural Influences box on social origins of make-believe play • New evidence on preschoolers' magical beliefs • Enhanced discussion of school-age children's spatial reasoning, with special attention to map skills • Expanded consideration of infants' numerical knowledge, including capacity to discriminate ratios and to represent approximate large-number values • Expanded and updated research on adolescent decision making • New evidence on cultural variations in parental scaffolding of young children's mastery of challenging tasks • New findings on benefits of cooperative learning

■ **CHAPTER 7** ■ Enhanced and updated consideration of working memory, its assessment, and its implications for learning and academic achievement • New section on executive function and its component processes • Expanded section on inhibition and its contribution to many information-processing skills • Updated Biology and Environment box on children with attention-deficit hyperactivity disorder (ADHD) • New Social Issues: Education box on the impact of "media multitasking" on learning • Revised and enhanced attention to development of episodic memory, including the relationship between semantic and episodic memory • New research on children's eyewitness memory • Enhanced discussion of differences between preschoolers from middle-income and low-income families in emergent literacy and math knowledge, including interventions that reduce the gap

■ **CHAPTER 8** ■ Updated Social Issues: Education box on emotional intelligence • Updated evidence on neurobiological correlates of mental test performance • New findings on IQ as a predictor of psychological adjustment • New evidence on how culturally acquired knowledge affects reasoning on mental test items • Enhanced Social Issues: Education box on high-stakes testing, including the impact of the U.S. No Child Left Behind Act on quality of American education • Enhanced consideration of the potential for supplementary programs to strengthen the impact of Head Start and other preschool programs serving low-income children

■ **CHAPTER 9** ■ Updated research on categorical speech perception in humans and other animals • New evidence on the contributions of joint attention and preverbal gestures to early language development • Updated findings on toddlers' earliest spoken words, including cultural variations • New findings on how phonological features of the child's native language influence early vocabulary growth • Enhanced consideration of research on young children's grammatical knowledge, including the influence of native-language syntactic forms • Updated research on consequences of bilingualism for cognitive and language development • Enhanced attention to the impact of bilingual education on academic achievement and long-term educational and occupational attainment

■ **CHAPTER 10** ■ Updated consideration of the dynamic systems perspective on development of emotional expression • Updated evidence on contributions of language development and parenting to preschoolers' emotional self-regulation • New research on consequences of effortful control for cognitive, emotional, and social development • New findings on goodness of fit, with special attention to the interacting roles of genotype and parenting on child difficultness • Updated section on consequences of early availability of a consistent caregiver for attachment security, emotion processing, and adjustment, highlighting studies of children adopted from Eastern European orphanages • New findings on the joint contributions of infant genotype, temperament, and parenting to disorganized/disoriented attachment • New evidence on contributions of fathers' play to attachment security and emotional and social adjustment • Revised and updated Social Issues: Health box on child care, attachment, and later adjustment • New section on grandparents as primary caregivers

■ **CHAPTER 11** ■ New findings on development of explicit body self-awareness in the second year, including scale errors •

New evidence on cognitive attainments and social experiences that contribute to preschoolers' mastery of false belief • Updated research on the school-age child's theory of mind, including development of recursive thought • Expanded section on implications of theory-of-mind development for social skills • Updated Biology and Environment box on "mindblindness" and autism • New evidence on preschoolers' self-concepts, including their emerging grasp of personality traits • New findings on the contribution of parent–child conversations about the past to early self-concept • Enhanced attention to cultural variations in self-concept • New research on personal and social factors contributing to identity development in adolescence • Updated Social Issues: Health box on adolescent suicide • Enhanced section on children's understanding of social groups, racial and ethnic prejudice, and strategies for reducing prejudice • New evidence on the Promoting Alternative Thinking Strategies (PATHS) curriculum, a widely applied intervention for enhancing preschoolers' social problem solving

■ **CHAPTER 12** ■ New evidence on the relationship of early corporal punishment to later behavior problems, including cross-cultural findings • Enhanced consideration of factors that promote moral identity, along with its relationship to moral commitment • Updated Social Issues: Education box on development of civic responsibility • New findings on social-cognitive deficits and distortions of aggressive children • Updated Cultural Influences box on the impact of ethnic and political violence on children, with expanded attention to the September 11, 2001, terrorist attacks • New section on parent training programs to reduce child conduct problems, with special attention to Incredible Years

■ **CHAPTER 13** ■ New evidence on parents' differential expectations for boys' and girls' academic achievement • Revised Cultural Influences box on Sweden's commitment to gender equality, with coverage of Swedish "daddy-months" aimed at encouraging fathers' involvement in child rearing • Updated findings on teachers' differential treatment of boys and girls • New research on the power of observed sex differences in adults' occupations to affect children's occupational interests • New Social Issues: Education box on teaching children to challenge peers' sexist remarks • Updated evidence on gender intensification in adolescence • Updated consideration of factors contributing to sex differences in verbal, mathematical, and spatial abilities • New findings on sex differences in adolescent depression

■ **CHAPTER 14** ■ Updated evidence on the impact of neighborhood poverty on family functioning, including community-wide prevention efforts of the Better Beginnings, Better Futures Project • New research on long-term, favorable consequences of authoritative child rearing • Updated section on parenting and adolescent autonomy, including research on immigrant families • New evidence on socioeconomic variations in parenting • Updated research on family size and parenting quality • New findings on sibling relationships, including cultural influences and interventions to reduce sibling animosity • Updated discussion of the one-child policy in China • New research on gay and lesbian families, including children's adjustment and gender identity • Expanded attention to the role of fathers in children's development, with special attention to the transition to parenthood, blended families, and dual-career families • Updated consideration of the consequences of child maltreatment

■ **CHAPTER 15** ■ Updated research on parental influences on peer sociability • New findings on the role of positive peer relations in school readiness • New research on characteristics of adolescent friendships, including implications of other-sex friends for adjustment • Updated findings on Internet friendships, with special attention to teenagers' use of social networking sites • Updated Biology and Environment box on bullies and their victims • Expanded consideration of the impact of biased teacher judgments on ethnic minority children's academic achievement • New statistics on U.S. children and adolescents' use of diverse media forms, including TV, computers, and cell phones • Updated evidence on the influence of various media activities, including TV, video games, texting, and social networking sites, on development and adjustment • New research on the educational consequences of widespread SES and ethnic segregation in American schools • New Social Issues: Education box on magnet schools as a means of attaining equal access to high-quality education • Revised and updated section on U.S. academic achievement in international perspective, including education in the high-performing nations of Finland, Korea, Japan, and Taiwan

Acknowledgments

The dedicated contributions of many individuals helped make this book a reality and contributed to refinements and improvements in each edition. An impressive cast of reviewers provided many helpful suggestions, constructive criticisms, and encouragement and enthusiasm for the organization and content of the book. I am grateful to each one of them.

An outstanding editorial staff in my home community contributed immeasurably to the entire project. Sara Harris, Supplements Editor and visiting assistant professor of psychology, Bradley University, coordinated the preparation of the teaching ancillaries and wrote major sections of the Instructor's Resource Manual, bringing to these tasks great depth of knowledge, impressive writing skill, enthusiasm, and imagination. Amelia Benner and Rachel Trapp, Editorial Assistants, spent countless hours searching, gathering, and organizing scholarly literature. Rachel also assisted with specifications for several highly creative MyDevelopmentLab simulations, contributed to the Explorations in Child Development video guide, designed the text's back cover, and expertly handled many additional tasks as they arose.

I have been fortunate to work with a highly capable editorial team at Pearson Education. It has been a great pleasure to work once again with Tom Pauken, Managing Editor, who oversaw the preparation of the sixth edition of *Child Development* and who returned to edit its ninth edition. His careful review of manuscript, keen organizational skills, responsive day-to-day communication, insightful suggestions, astute problem solving, interest in the subject matter, and thoughtfulness have greatly enhanced the quality of the text and made its preparation especially enjoyable and rewarding. Judy Ashkenaz and Lisa McLellan, Development Editors, carefully reviewed and commented on each chapter, helping to ensure that every thought and concept would be clearly expressed and well-developed.

My appreciation, also, to Jessica Mosher, Editor in Chief of Psychology, for reorganizing the management of my projects to enable the focused work that is vital for precise, inspired writing. The supplements package benefited from the talents and diligence of several other individuals. Leah Shiro carefully revised the chapter summaries and outlines in the Instructor's Resource Manual. Kimberly Michaud and Cheryl Wilms prepared the superb Test Bank and MyDevelopmentLab assessments. Diana Murphy designed and wrote a highly attractive PowerPoint presentation. Maria Henneberry and Phil Vandiver of Contemporary Visuals in Bloomington, IL, prepared an extraordinarily artistic and inspiring set of new video segments covering diverse topics in child development.

Donna Simons, Senior Production Project Manager, coordinated the complex production tasks that resulted in an exquisitely beautiful ninth edition. I am grateful for her keen aesthetic sense, attention to detail, flexibility, efficiency, and thoughtfulness. I thank Sarah Evertson for obtaining the exceptional photographs that so aptly illustrate the text narrative. I am also grateful for Judy Ashkenaz's fine contributions to the photo specifications and captions. Margaret Pinette, Bill Heckman, and Julie Hotchkiss provided outstanding copyediting and proofreading.

Wendy Albert, Executive Marketing Manager, prepared the beautiful print ads and informative e-mails to the field about *Child Development,* Ninth Edition. She has also ensured that accurate and clear information reached Pearson Education's sales force and that the needs of prospective and current adopters were met.

A final word of gratitude goes to my family, whose love, patience, and understanding have enabled me to be wife, mother, teacher, researcher, and text author at the same time. My sons, David and Peter, grew up with my texts, passing from childhood to adolescence and then to adulthood as successive editions were written. David has a special connection with the books' subject matter as an elementary school teacher, and Peter is now an experienced attorney and married to his vivacious, talented, and caring Melissa. All three continue to enrich my understanding through reflections on events and progress in their own lives. My husband, Ken, willingly made room for yet another time-consuming endeavor in our life together and communicated his belief in its importance in a great many unspoken, caring ways.

About the Cover and Chapter-Opening Art

I would like to extend grateful acknowledgments to the International Museum of Children's Art, Oslo, Norway, and to the International Child Art Foundation, Washington, D.C.; to the World Awareness Children's Museum, Glens Falls, New York; and to the International Collection of Child Art, Milner Library, Illinois State University, for the exceptional cover image and chapter-opening art, which depict the talents, concerns, and viewpoints of child and adolescent artists from around the world. The awe-inspiring collection of children's art gracing this text expresses family, school, and community themes; good times and personal triumphs; profound appreciation for beauty; and great depth of emotion. I am pleased to share with readers this window into children's creativity, insightfulness, sensitivity, and compassion.

CHAPTER 1

“Untitled”

Patrick, 15 years, New Mexico

This artist represents his Taos Pueblo culture with intricate patterns and rainbows of color. As the theories reviewed in this chapter reveal, a similarly complex blend of genetic, family, community, and societal forces influences child development.

History, Theory, and Applied Directions

Not long ago, I left my Midwestern home to live for a year near the small city in northern California where I spent my childhood. One morning, I visited the neighborhood where I grew up—a place I had not seen since I was 12 years old.

I stood at the entrance to my old schoolyard. Buildings and grounds that had looked large to me as a child now seemed strangely small. I peered through the window of my first-grade classroom. The desks were no longer arranged in rows but grouped in intimate clusters. Computers rested against the far wall, near where I once sat. I walked my old route home from school, the distance shrunken by my longer stride. I stopped in front of my best friend Kathryn's house, where we once drew sidewalk pictures, crossed the street to play kickball, and produced plays in the garage. In place of the small shop where I had purchased penny candy stood a child-care center, filled with the voices and vigorous activity of toddlers and preschoolers.

As I walked, I reflected on early experiences that contributed to who I am and what I am like today—weekends helping my father in his downtown clothing shop, the year my mother studied to become a high school teacher, moments of companionship and rivalry with my sister and brother, Sunday outings to museums and the seashore, and visits to my grandmother's house, where I became someone extra special.

As I passed the homes of my childhood friends, I thought of what I knew about the course of their lives. Kathryn, star pupil and president of our sixth-grade class—today a successful corporate lawyer and mother of two. Shy, withdrawn Phil, cruelly teased because of his cleft lip—now owner of a thriving chain of hardware stores and member of the city council. Julio, immigrant from Mexico who joined our class in third grade—today director of an elementary school bilingual education program and single parent of an adopted Mexican boy. And finally, my next-door neighbor Rick, who picked fights at recess, struggled with reading, repeated fourth grade, dropped out of high school, and (so I heard) moved from one job to another over the following 10 years.

As you begin this course in child development, perhaps you, too, are wondering about some of the same questions that crossed my mind during that nostalgic neighborhood walk:

- In what ways are children's home, school, and neighborhood experiences the same today as they were in generations past, and in what ways are they different?
- How are the infant's and young child's perceptions of the world the same as the adult's, and how are they different?
- What determines the features that humans have in common and those that make each of us unique—physically, mentally, and behaviorally?
- How did Julio, transplanted at age 8 to a new culture, master its language and customs and succeed in its society, yet remain strongly identified with his ethnic community?
- Why do some of us, like Kathryn and Rick, retain the same styles of responding that characterized us as children, whereas others, like Phil, change in essential ways?
- How do cultural changes—employed mothers, child care, divorce, smaller families, and new technologies—affect children's characteristics?

Comparing Child Development Theories

Applied Directions: Child Development and Social Policy
Culture and Public Policies • Contributions of Child Development Research • Looking Toward the Future

■ **SOCIAL ISSUES: HEALTH:** *Welfare Reform, Poverty, and Child Development*

These are central questions addressed by **child development,** an area of study devoted to understanding constancy and change from conception through adolescence. Child development is part of a larger, interdisciplinary field known as **developmental science,** which includes all changes we experience throughout the lifespan (Lerner, 2006). Great diversity characterizes the interests and concerns of the thousands of investigators who study child development. But all have a common goal: to describe and identify those factors that influence the consistencies and changes in young people during the first two decades of life. ■

- What is the field of child development, and what factors stimulated its expansion?
- How is child development typically divided into domains and periods?

The Field of Child Development

The questions just listed are not just of scientific interest. Each has *applied,* or practical, importance as well. In fact, scientific curiosity is just one factor that led child development to become the exciting field of study it is today. Research about development has also been stimulated by social pressures to improve the lives of children. For example, the beginning of public education in the early twentieth century led to a demand for knowledge about what and how to teach children of different ages. Pediatricians' interest in improving children's health required an understanding of physical growth and nutrition. The social service profession's desire to treat children's anxieties and behavior problems required information about personality and social development. And parents have continually sought advice about child-rearing practices and experiences that would promote their children's development and well-being.

Our large storehouse of information about child development is *interdisciplinary*. It has grown through the combined efforts of people from many fields. Because of the need to solve everyday problems concerning children, researchers from psychology, sociology, anthropology, biology, and neuroscience have joined forces with professionals from education, family studies, medicine, public health, and social service—to name just a few. The field of child development, as it exists today, is a monument to the contributions of these many disciplines. Its body of knowledge is not just scientifically important but also relevant and useful.

Domains of Development

To make the vast, interdisciplinary study of human constancy and change more orderly and convenient, development is often divided into three broad domains: *physical, cognitive,* and *emotional and social*. Refer to Figure 1.1 for a description and illustration of each. In this book, we will largely consider the domains of development in the order just mentioned. Yet the domains are not really distinct. Rather, they combine in an integrated, holistic fashion to yield the living, growing child. Furthermore, each domain influences and is influenced by the others. For example, in Chapter 4, you will see that new motor capacities, such as reaching, sitting, crawling, and walking (physical), contribute greatly to infants' understanding of their surroundings (cognitive). When babies think and act more competently, adults stimulate them more with games, language, and expressions of delight at their new achievements (emotional and social). These enriched experiences, in turn, promote all aspects of development.

You will encounter instances of the interwoven nature of all domains on almost every page of this book. In the margins of the text, you will find occasional *Look and Listen* activities—opportunities for you to see everyday illustrations of development by observing what real children say and do or by attending to everyday influences on children. Through these experiences, I hope to make your study of development more authentic and meaningful.

Physical Development
Changes in body size, proportions, appearance, functioning of body systems, perceptual and motor capacities, and physical health

Cognitive Development
Changes in intellectual abilities, including attention, memory, academic and everyday knowledge, problem solving, imagination, creativity, and language

Emotional and Social Development
Changes in emotional communication, self-understanding, knowledge about other people, interpersonal skills, friendships, intimate relationships, and moral reasoning and behavior

FIGURE 1.1 **Major domains of development.** The three domains are not really distinct. Rather, they overlap and interact.

Also, look for the *Ask Yourself* feature at the end of major sections, designed to deepen your understanding. Within it, I have included *Review* questions, which help you recall and think about information you have just read; *Connect* questions, which help you form a coherent, unified picture of child development; *Apply* questions, which encourage you to apply your knowledge to controversial issues and problems faced by parents, teachers, and children; and *Reflect* questions, which invite you to reflect on your own development and that of people you know well.

Periods of Development

Besides distinguishing and integrating the three domains, another dilemma arises in discussing development: how to divide the flow of time into sensible, manageable parts. Researchers usually use the following age periods, as each brings new capacities and social expectations that serve as important transitions in major theories:

1. *The prenatal period: from conception to birth.* In this nine-month period, the most rapid time of change, a one-celled organism is transformed into a human baby with remarkable capacities for adjusting to life in the surrounding world.
2. *Infancy and toddlerhood: from birth to 2 years.* This period brings dramatic changes in the body and brain that support the emergence of a wide array of motor, perceptual, and intellectual capacities; the beginnings of language; and first intimate ties to others. Infancy spans the first year; toddlerhood spans the second, during which children take their first independent steps, marking a shift to greater autonomy.
3. *Early childhood: from 2 to 6 years.* The body becomes longer and leaner, motor skills are refined, and children become more self-controlled and self-sufficient. Make-believe play blossoms, supporting every aspect of psychological development. Thought and language

expand at an astounding pace, a sense of morality becomes evident, and children establish ties with peers.

4. *Middle childhood: from 6 to 11 years.* Children learn about the wider world and master new responsibilities that increasingly resemble those they will perform as adults. Hallmarks of this period are improved athletic abilities; participation in organized games with rules; more logical thought processes; mastery of fundamental reading, writing, math, and other academic knowledge and skills; and advances in understanding the self, morality, and friendship.
5. *Adolescence: from 11 to 18 years.* This period initiates the transition to adulthood. Puberty leads to an adult-sized body and sexual maturity. Thought becomes abstract and idealistic, and schooling is increasingly directed toward preparation for higher education and the world of work. Young people begin to establish autonomy from the family and to define personal values and goals.

© UWE OMMER, *1,000 FAMILIES*, TASCHEN ED

Child development is so dramatic that researchers divide it into periods. This large family of the Ivory Coast includes children in infancy, early childhood (boy in front row, girl seated in second row), middle childhood (girl in front row, girl standing in second row), and adolescence (girl standing in center).

For many contemporary youths in industrialized nations, the transition to adult roles has become increasingly prolonged—so much so that some researchers have posited a new period of development called *emerging adulthood,* which spans ages 18 to 25. Although emerging adults have moved beyond adolescence, they have not yet fully assumed adult roles. Rather, during higher education and sometimes beyond, these young people intensify their exploration of options in love, career, and personal values before making enduring commitments. Because emerging adulthood first became apparent during the past few decades, researchers have just begun to study it (Arnett, 2007; Arnett & Tanner, 2006). Perhaps it is *your* period of development. In later chapters, we will touch on milestones of emerging adulthood, which build on adolescent attainments. To find out more about this period, consult the mini-chapter entitled “Emerging Adulthood,” available as an online supplement to this text.

With this introduction in mind, let’s turn to some basic issues that have captivated, puzzled, and sparked debate among child development theorists. Then our discussion will trace the emergence of the field and survey major theories.

Basic Issues

▶ Identify three basic issues on which child development theories take a stand.

Research on child development did not begin until the late nineteenth and early twentieth centuries. But ideas about how children grow and change have a much longer history. As these speculations combined with research, they inspired the construction of *theories* of development. A **theory** is an orderly, integrated set of statements that describes, explains, and predicts behavior. For example, a good theory of infant–caregiver attachment would (1) *describe* the behaviors of babies around 6 to 8 months of age as they seek the affection and comfort of a familiar adult, (2) *explain* how and why infants develop this strong desire to bond with a caregiver, and (3) *predict* the consequences of this emotional bond for future relationships.

Theories are vital tools for two reasons. First, they provide organizing frameworks for our observations of children. In other words, they *guide and give meaning* to what we see. Second, theories that are verified by research often serve as a sound basis for practical action. Once a theory helps us *understand* development, we are in a much better position *to know how to improve* the welfare and treatment of children.

As we will see later, theories are influenced by cultural values and belief systems of their times. But theories differ in one important way from mere opinion and belief: A theory's continued existence depends on *scientific verification*. This means that the theory must be tested using a fair set of research procedures agreed on by the scientific community, and its findings must endure, or be replicated over time. (We will consider research strategies in Chapter 2.)

Within the field of child development, many theories offer very different ideas about what children are like and how they change. The study of child development provides no ultimate truth because investigators do not always agree on the meaning of what they see. Also, children are complex beings; they change physically, cognitively, emotionally, and socially. No single theory has explained all these aspects. But the existence of many theories helps advance knowledge as researchers continually try to support, contradict, and integrate these different points of view.

Although there are many theories, we can easily organize them by looking at the stand they take on three basic issues: (1) Is the course of development continuous or discontinuous? (2) Does one course of development characterize all children, or are there many possible courses? (3) What are the roles of genetic and environmental factors—nature and nurture—in development? Let's look closely at each of these issues.

Continuous or Discontinuous Development?

Recently, the mother of 20-month-old Angelo reported to me with amazement that her young son had pushed a toy car across the living room floor while making a motorlike sound, "Brrmmmm, brrmmmm," for the first time. When he hit a nearby wall with a bang, Angelo let go of the car, exclaimed, "C'ash," and laughed heartily.

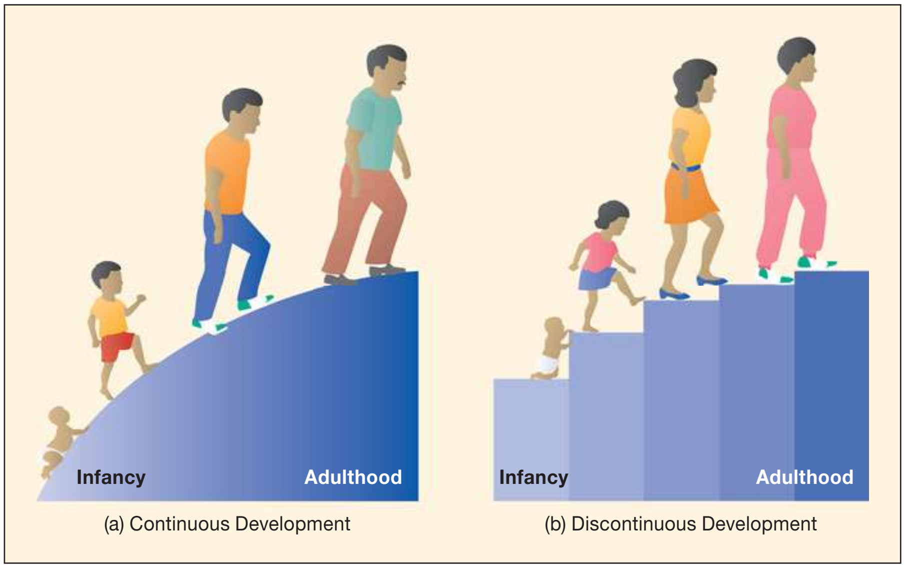
"How come Angelo can pretend, but he couldn't a few months ago?" his mother asked. "And I wonder what 'Brrmmmm, brmmmm' and 'Crash!' mean to Angelo? Does he understand motorlike sounds and collision the same way I do?"

Angelo's mother has raised a puzzling issue about development: How can we best describe the differences in capacities and behavior among small infants, young children, adolescents, and adults? As Figure 1.2 illustrates, major theories recognize two possibilities.

One view holds that infants and preschoolers respond to the world in much the same way as adults do. The difference between the immature and the mature being is simply one of *amount or complexity*. For example, little Angelo's thinking might be just as logical and well-organized as our own. Perhaps (as his mother reports) he can sort objects into simple categories, recognize whether he has more of one kind than another, and remember where he left his favorite toy at child care the week before. Angelo's only limitation may be that he cannot perform these skills with as much information and precision as we can. If this is so, then Angelo's development is **continuous**—a process of gradually adding more of the same types of skills that were there to begin with.

According to a second view, Angelo's thoughts, emotions, and behavior differ considerably from those of adults. His development is **discontinuous**—a process in which new ways of understanding and responding to the world emerge at specific times. From this perspective, Angelo is not yet able to

FIGURE 1.2 Is development continuous or discontinuous? (a) Some theorists believe that development is a smooth, continuous process. Children gradually add more of the same types of skills. (b) Other theorists think that development takes place in discontinuous stages. Children change rapidly as they step up to a new level of development and then change very little for a while. With each step, the child interprets and responds to the world in a qualitatively different way.



(a) Continuous Development

(b) Discontinuous Development

organize objects or remember and interpret experiences as we do. Instead, he will move through a series of developmental steps, each with unique features, until he reaches the highest level of functioning.

Theories that accept the discontinuous perspective regard development as taking place in **stages**—*qualitative* changes in thinking, feeling, and behaving that characterize specific periods of development. In stage theories, development is much like climbing a staircase, with each step corresponding to a more mature, reorganized way of functioning. The stage concept also assumes that children undergo periods of rapid transformation as they step up from one stage to the next, alternating with plateaus during which they stand solidly within a stage. In other words, change is fairly sudden rather than gradual and ongoing.

Does development actually occur in a neat, orderly sequence of stages? This ambitious assumption has faced significant challenges. Later in this chapter, we will review some influential stage theories.

One Course of Development or Many?

Stage theorists assume that people everywhere follow the same sequence of development. For example, in the domain of cognition, a stage theorist might try to identify the common influences that lead children to represent their world through language and make-believe play in early childhood, to think more logically in middle childhood, and to reason more systematically and abstractly in adolescence.

At the same time, the field of child development is becoming increasingly aware that children grow up in distinct **contexts**—unique combinations of personal and environmental circumstances that can result in different paths of change. For example, a shy child who fears social encounters develops in very different contexts from those of a sociable agemate who readily seeks out other people (Kagan, 2003, 2008). Children in non-Western village societies encounter experiences in their families and communities that differ sharply from those of children in large Western cities. These different circumstances foster different cognitive capacities, social skills, and feelings about the self and others (Shweder et al., 2006).

© ELIZABETH CREWS/THE IMAGE WORKS

Will this toddler's tantrums extend into a lifelong pattern of difficult behavior? Some theorists, stressing the importance of heredity, believe she will remain hard to manage. Others think that change is possible, depending on how the mother handles her child's emotional outbursts.

As you will see, contemporary theorists regard the contexts that mold development as many-layered and complex. On the personal side, these include heredity and biological makeup. On the environmental side, they include both immediate settings—home, child-care center, school, and neighborhood—and circumstances that are more remote from children's everyday lives: community resources, societal values and priorities, and historical time period. Finally, researchers today are more conscious than ever before of cultural diversity in development.

Relative Influence of Nature and Nurture?

In addition to describing the course of development, each theory takes a stand on a major question about its underlying causes: Are genetic or environmental factors more important in influencing development? This is the age-old **nature–nurture controversy.** By *nature,* we mean inborn biological givens—the hereditary information we receive from our parents at the moment of conception. By *nurture,* we mean the complex forces of the physical and social world that influence our biological makeup and psychological experiences before and after birth.

Although all theories grant roles to both nature and nurture, they vary in emphasis. Consider the following questions: Is the older child's ability to think in more complex ways largely the result of an inborn timetable of growth, or is it primarily influenced by stimulation from parents and teachers? Do children acquire language because they are genetically predisposed to do so or because parents intensively teach them from an early age? And what accounts for the vast individual differences among children—in height, weight, physical coordination, intelligence, personality, and social skills? Is nature or nurture more responsible?

A theory's position on the roles of nature and nurture affects how it explains individual differences. Some theorists emphasize *stability*—that children who are high or low in a characteristic (such as verbal ability, anxiety, or sociability) will remain so at later ages. These theorists typically stress the importance of *heredity*. If they regard environment as important, they usually point to *early experiences* as establishing a lifelong pattern of behavior. Powerful negative events in the first few years, they argue, cannot be fully overcome by later, more positive ones (Bowlby, 1980; Johnson, 2000; Sroufe, 2005). Other theorists, taking a more optimistic view, see development as having substantial **plasticity** throughout life—as open to change in response to influential experiences (Baltes, Lindenberger, & Staudinger, 2006; Lerner & Overton, 2008; Lester, Masten, & McEwen, 2006).

Throughout this book, you will see that investigators disagree, often sharply, on the question of *stability versus plasticity*. Their answers have great applied significance. If you believe that development is largely due to nature, then providing experiences aimed at promoting change would seem to be of little value. If, on the other hand, you are convinced of the supreme importance of early experience, then you would intervene as soon as possible, offering high-quality stimulation and support to ensure that children develop at their best. Finally, if you think that environment is profoundly influential throughout development, you would provide assistance any time children or adolescents face difficulties, in the belief that, with the help of favorable life circumstances, they can recover from early negative events.

A Balanced Point of View

So far, we have discussed the basic issues of child development in terms of extremes—solutions favoring one side or the other. But as we trace the unfolding of the field in the rest of this chapter, you will see that the positions of many theorists have softened. Today, some theorists believe that both continuous and discontinuous changes occur. Many acknowledge that development has both universal features and features unique to each individual and his or her contexts. And a growing number regard heredity and environment as inseparably interwoven, each affecting the potential of the other to modify the child's traits and capacities (Cole, 2006; Gottlieb, Wahlsten, & Lickliter, 2006; Lerner, 2006; Rutter, 2007). We will discuss these new ideas about nature and nurture in Chapter 3.

Finally, as you will see later in this book, the relative impact of early and later experiences varies greatly from one domain of development to another and even—as the Biology and Environment box on pages 10–11 indicates—across individuals! Because of the complex network of factors contributing to human change and the challenge of isolating the effects of each, many theoretical viewpoints have gathered research support. Although debate continues, this circumstance has also sparked more balanced visions of child development.

ASK YOURSELF

Review ■ What is meant by a *stage* of development? Provide your own example of stagewise change. What stand do stage theorists take on the issue of continuous versus discontinuous development?

Connect ■ Provide an example of how one domain of development (physical, cognitive, or emotional/social) can affect development in another domain.

Apply ■ Anna, a high school counselor, has devised a program that integrates classroom learning with vocational training to help adolescents at risk for school dropout stay in school and transition smoothly to work life. What is Anna's position on *stability versus plasticity* in development? Explain.

Reflect ■ Cite an aspect of your development that differs from a parent's or grandparent's when he or she was your age. How might *contexts* explain this difference?

BIOLOGY and ENVIRONMENT

Resilient Children

John and his best friend, Gary, grew up in a run-down, crime-ridden inner-city neighborhood. By age 10, each had experienced years of family conflict followed by parental divorce. Reared for the rest of childhood and adolescence in mother-headed households, John and Gary rarely saw their fathers. Both dropped out of high school and were in and out of trouble with the police.

Then their paths diverged. By age 30, John had fathered two children with women he never married, had spent time in prison, was unemployed, and drank alcohol heavily. In contrast, Gary had returned to finish high school, had studied auto mechanics at a community college, and became manager of a gas station and repair shop. Married with two children, he had saved his earnings and bought a home. He was happy, healthy, and well-adapted to life. A wealth of evidence shows that environmental risks—poverty, negative family interactions and parental divorce, job loss, mental illness, and drug abuse—predispose children to future problems (Masten & Gewirtz, 2006; Sameroff, 2006; Wadsworth & Santiago, 2008). Why did Gary "beat the odds" and come through unscathed? Research on **resilience**—the ability to adapt effectively in the face of threats to development—is receiving increasing attention as investigators look for ways to protect young people from the damaging effects of stressful life conditions. This interest has been inspired by several long-term studies on the relationship of life stressors in childhood to competence and adjustment in adolescence and adulthood (Fergusson & Horwood, 2003; Masten et al., 1995; Werner & Smith, 2001). In each study, some individuals were shielded from negative outcomes, whereas others had lasting problems. Four broad factors seemed to offer protection from the damaging effects of stressful life events.

Personal Characteristics

A child's biologically endowed characteristics can reduce exposure to risk or lead to experiences that compensate for early stressful events. High intelligence and socially valued talents (in music or athletics, for example) increase the chances that a child will have rewarding experiences in school and in the community that offset the impact of a stressful home life. Temperament is particularly powerful.

© ROBERT BRENNER/PHOTOEDIT

This boy's close, affectionate relationship with his father promotes resilience. A strong bond with at least one parent who combines warmth with appropriate expectations for maturity can shield children from the damaging effects of stressful life conditions.

- Describe major historical influences on theories of child development.

Historical Foundations

Contemporary theories of child development are the result of centuries of change in Western cultural values, philosophical thinking about children, and scientific progress. To understand the field as it exists today, we must return to its early beginnings—to ideas about children that long preceded scientific child study but that linger as important forces in current theory and research.

Medieval Times

Childhood was regarded as a separate period of life as early as medieval Europe—the sixth through the fifteenth centuries. Medieval painters often depicted children wearing loose, comfortable gowns, playing games, and looking up to adults. Written texts contained terms that distinguished children under age 7 or 8 from other people and that recognized even young teenagers as not fully mature. By the fourteenth century, manuals offering advice on many aspects of child care, including health, feeding, clothing, and games, were common

Children who have easygoing, sociable dispositions and who can readily inhibit negative emotions and impulses tend to have an optimistic outlook on life and a special capacity to adapt to change—qualities that elicit positive responses from others. In contrast, emotionally reactive and irritable children often tax the patience of people around them (Mathiesen & Prior, 2006; Vanderbilt-Adriance & Shaw, 2008; Wong et al., 2006). For example, both John and Gary moved several times during their childhoods. Each time, John became anxious and angry. Gary looked forward to making new friends and exploring a new neighborhood.

A Warm Parental Relationship

A close relationship with at least one parent who provides warmth, appropriately high expectations, monitoring of the child's activities, and an organized home environment fosters resilience (Masten & Shaffer, 2006; Taylor, 2010). But this factor (as well as the next one) is not independent of children's personal characteristics. Children who are relaxed, socially responsive, and able to deal with change are easier to rear and more likely to enjoy positive relationships with parents and other people. At the same time, some children may develop more attractive dispositions as a result of parental warmth and attention (Conger & Conger, 2002; Gulotta, 2008).

Social Support Outside the Immediate Family

The most consistent asset of resilient children is a strong bond with a competent, caring adult. For children who do not have a close bond with either parent, a grandparent, aunt, uncle, or teacher who forms a special relationship with the child can promote resilience (Masten & Reed, 2002). Gary received support from his grandfather, who listened to Gary's concerns and helped him solve problems. Gary's grandfather had a stable marriage and work life and handled stressors skillfully. Consequently, he served as a model of effective coping.

Associations with rule-abiding peers who value school achievement are also linked to resilience (Tiet, Huizinga, & Byrnes, 2010). But children who have positive relationships with adults are far more likely to establish these supportive peer ties.

Community Resources and Opportunities

Community supports—good schools, convenient and affordable health care and social services, libraries, and recreation centers—foster both parents' and children's well-being. In addition, opportunities to participate in community life help older children and adolescents overcome adversity. Extracurricular activities at school, religious youth groups, scouting, and other organizations teach important social skills, such as cooperation, leadership, and contributing to others' welfare. As participants acquire these competencies, they gain in self-reliance, self-esteem, and community commitment (Benson et al., 2006). As a college student, Gary volunteered for Habitat for Humanity, joining a team building affordable housing in low-income neighborhoods. Community involvement offered Gary additional opportunities to form meaningful relationships, which further strengthened his resilience.

Research on resilience highlights the complex connections between heredity and environment. Armed with positive characteristics stemming from innate endowment, favorable rearing experiences, or both, children and adolescents can act to reduce stressful situations.

But when many risks pile up, they are increasingly difficult to overcome (Obradović et al., 2009). To inoculate children against the negative effects of risk, interventions must not only reduce risks but also enhance children's protective relationships at home, in school, and in the community. This means attending to both the person and the environment—strengthening children's capacities while also reducing hazardous experiences.

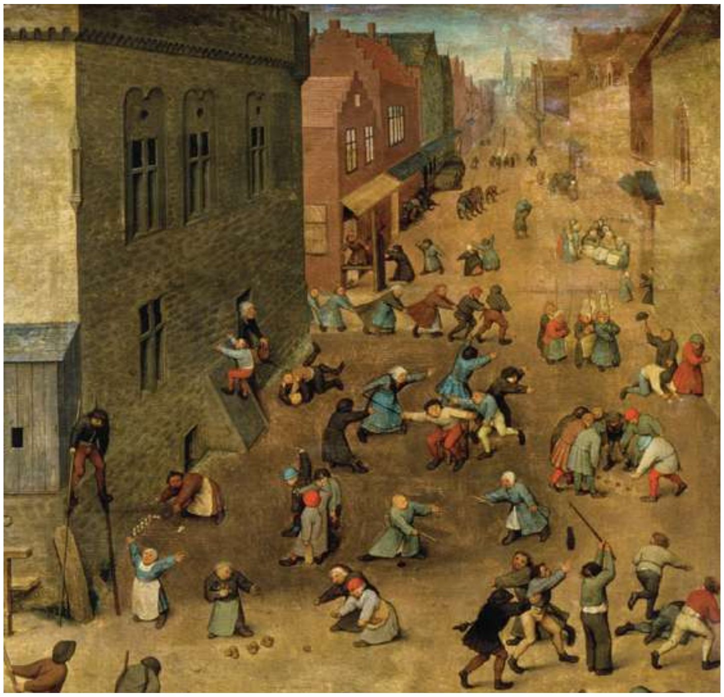
(Alexandre-Bidon & Lett, 1997; Lett, 1997). Laws recognized that children needed protection from people who might mistreat them, and courts exercised leniency with lawbreaking youths because of their tender years (Hanawalt, 1993).

In sum, in medieval times, if not before, clear awareness existed of children as vulnerable beings. Religious writings, however, contained contradictory depictions of children's basic nature, sometimes portraying them as possessed by the devil and in need of purification, at other times as innocent and close to angels (Hanawalt, 2003). Both ideas foreshadowed later views of childhood.

The Reformation

In the sixteenth century, the Puritan belief in original sin gave rise to the view that children were born evil and stubborn and had to be civilized (Shahar, 1990). Harsh, restrictive child-rearing practices were recommended to tame the depraved child. Children were dressed in stiff, uncomfortable clothing that held them in adultlike postures, and disobedient students were routinely beaten by their schoolmasters. Nevertheless, love and affection for their children prevented most Puritan parents from using extremely repressive measures (Moran & Vinovskis, 1986).

As the Puritans emigrated from England to the New World, they brought the belief that child rearing was one of their most important obligations. Although they continued to regard the child's soul as tainted by original sin, they tried to teach their sons and daughters to use reason to tell right from wrong (Clarke-Stewart, 1998). As they trained their children in self-reliance and self-control, Puritan parents gradually adopted a moderate balance between severity and permissiveness.



KUNSTHISTORISCHES MUSEUM, VIENNA, AUSTRIA/ALI MEYER/ THE BRIDGEMAN ART LIBRARY INTERNATIONAL

As early as medieval times, adults viewed childhood as a distinct developmental period. In this sixteenth-century painting, *Children's Games,* by Pieter Bruegel the Elder, boys and girls wearing loose, comfortable clothing play lively outdoor games. *[Children's Games (Kinderspiele): Detail of top right-hand corner, 1560 (oil on panel) (detail of 68945), Bruegel, Pieter the Elder (c. 1525–69).]*

Philosophies of the Enlightenment

The seventeenth-century Enlightenment brought new philosophies that emphasized ideals of human dignity and respect. Conceptions of childhood were more humane than those of the past.

John Locke The writings of British philosopher John Locke (1632–1704) served as the forerunner of a twentieth-century perspective that we will discuss shortly: behaviorism. Locke viewed the child as a *tabula rasa*—Latin for "blank slate." According to this idea, children begin as nothing at all; their characters are shaped entirely by experience. Locke (1690/1892) saw parents as rational tutors who can mold the child in any way they wish through careful instruction, effective example, and rewards for good behavior. He was ahead of his time in recommending child-rearing practices that present-day research supports—for example, the use of praise and approval as rewards, rather than money or sweets. He also opposed physical punishment: "The child repeatedly beaten in school cannot look upon books and teachers without experiencing fear and anger." Locke's philosophy led to a change from harshness toward children to kindness and compassion.

Look carefully at Locke's ideas, and you will see that he regarded development as *continuous:* Adultlike behaviors are gradually built up through the warm, consistent teachings of parents. His view of the child as a tabula rasa led him to champion *nurture*—the power of the environment to shape the child. And his faith in nurture suggests the possibility of *many courses of development* and of *high plasticity at later ages* due to new experiences. Finally, Locke's philosophy characterizes children as doing little to influence their own destiny; rather, the child is the "blank slate" on which others write. This vision of a passive child has been discarded. All contemporary theories view children as active, purposeful beings who contribute substantially to their own development.

Jean-Jacques Rousseau In the eighteenth century, French philosopher Jean-Jacques Rousseau (1712–1778) introduced a new view of childhood. Children, Rousseau claimed, are not blank slates or empty containers to be filled by adult instruction. Instead, they are *noble savages,* naturally endowed with a sense of right and wrong and an innate plan for orderly, healthy growth. Unlike Locke, Rousseau believed that children's built-in moral sense and unique ways of thinking and feeling would only be harmed by adult training. His was a child-centered philosophy in which the adult should be receptive to the child's needs at each of four stages: infancy, childhood, late childhood, and adolescence.

Rousseau's philosophy includes two influential concepts. The first is the concept of *stage,* which we discussed earlier. The second is the concept of **maturation**, which refers to a genetically determined, naturally unfolding course of growth. In contrast to Locke, Rousseau saw children as determining their own destinies. And he viewed development as a *discontinuous, stagewise* process that follows a *single, unified course* mapped out by *nature*.

Scientific Beginnings

The study of child development evolved quickly in the late nineteenth and early twentieth centuries. Early observations of children were soon followed by improved methods and theories. Each advance contributed to the firm foundation on which the field rests today.

Darwin: Forefather of Scientific Child Study

A century after Rousseau, British naturalist Charles Darwin (1809–1882) joined an expedition to distant parts of the world, where he observed infinite variation among plant and animal species. He also saw that within a species, no two individuals are exactly alike. From these observations, he constructed his famous *theory of evolution*.

The theory emphasized two related principles: *natural selection* and *survival of the fittest*. Darwin explained that certain species survive in particular parts of the world because they have characteristics that fit with, or are adapted to, their surroundings. Other species die off because they are not as well-suited to their environments. Individuals within a species who best meet the environment's survival requirements live long enough to reproduce and pass on their more beneficial characteristics to future generations. Darwin's emphasis on the adaptive value of physical characteristics and behavior eventually found its way into important twentieth-century theories.

During his explorations, Darwin discovered that early prenatal growth is strikingly similar in many species. Other scientists concluded from Darwin's observation that the development of the human child follows the same general plan as the evolution of the human species. Although this belief eventually proved inaccurate, efforts to chart parallels between child growth and human evolution prompted researchers to make careful observations of all aspects of children's behavior. Out of these first attempts to document an idea about development, scientific child study was born.

The Normative Period

G. Stanley Hall (1844–1924), one of the most influential American psychologists of the early twentieth century, is generally regarded as the founder of the child-study movement (Cairns & Cairns, 2006). Inspired by Darwin's work, Hall and his well-known student Arnold Gesell (1880–1961) developed theories based on evolutionary ideas. These early leaders regarded development as a *maturational process*—a genetically determined series of events that unfold automatically, much like a flower (Gesell, 1933; Hall, 1904).

Hall and Gesell are remembered less for their one-sided theories than for their intensive efforts to describe all aspects of child development. They launched the **normative approach,** in which measures of behavior are taken on large numbers of individuals and age-related averages are computed to represent typical development. Using this procedure, Hall constructed elaborate questionnaires asking children of different ages almost everything they could tell about themselves—interests, fears, imaginary playmates, dreams, friendships, everyday knowledge, and more. Similarly, through observations and parental interviews, Gesell collected detailed normative information on the motor achievements, social behaviors, and personality characteristics of infants and children.

Gesell was also among the first to make knowledge about child development meaningful to parents by informing them of what to expect at each age. If, as he believed, the timetable of development is the product of millions of years of evolution, then children are naturally knowledgeable about their needs. His child-rearing advice, in the tradition of Rousseau, recommended sensitivity to children's cues (Thelen & Adolph, 1992). Along with Benjamin Spock's *Baby and Child Care,* Gesell's books became a central part of a rapidly expanding child development literature for parents.

LOOK and LISTEN

Examine several parenting-advice books in your local bookstore or library, and identify the stand each takes on the three basic issues about child development.

The Mental Testing Movement

While Hall and Gesell were developing their theories and methods in the United States, French psychologist Alfred Binet (1857–1911) was also taking a normative approach to child development, but for a different reason. In the early 1900s, Binet and his colleague Theodore Simon were asked by Paris school officials to find a way to identify children with learning problems who needed to be placed in special classes.

To address these practical educational concerns, Binet and Simon constructed the first successful intelligence test.

Binet began with a well-developed theory of intelligence. Capturing the complexity of children's thinking, he defined intelligence as good judgment, planning, and critical reflection (Sternberg & Jarvin, 2003). Then he created age-graded test items that directly measured these abilities.

In 1916, at Stanford University, Binet's test was adapted for use with English-speaking children. Since then, the English version has been known as the *Stanford-Binet Intelligence Scale*. Besides providing a score that could successfully predict school achievement, the Binet test sparked tremendous interest in individual differences in development. Comparisons of the scores of children who vary in gender, ethnicity, birth order, family background, and other characteristics became a major focus of research. And intelligence tests rose quickly to the forefront of the nature–nurture controversy.

James Mark Baldwin: Early Developmental Theorist A final important figure, long overlooked in the history of child development, is American psychologist James Mark Baldwin (1861–1934). A theorist and keen observer of children's behavior, Baldwin's (1897) rich interpretations of development are experiencing a revival today. He believed that children's understanding of their physical and social worlds develops through a sequence of stages, beginning with the simplest behavior patterns of the newborn infant and concluding with the adult's capacity to think abstractly and reflectively (Cairns & Cairns, 2006).

Yet in Baldwin's view, neither the child nor the environment controlled development. Instead, he granted nature and nurture equal importance. Children, he argued, actively revise their ways of thinking about the world, but they also learn through habit, or by copying others' behaviors. As development proceeds, the child and her social surroundings influence each other, forming an inseparable, interwoven network.

Consider these ideas, and you will see why Baldwin (1895) argued that heredity and environment should not be viewed as distinct, opposing forces. Instead, he claimed, most human characteristics are "due to both causes working together" (p. 77). As we turn now to an overview of modern theories of child development, you will find Baldwin's ideas represented in several, especially the more recent ones.

ASK YOURSELF

Review ■ Imagine a debate between John Locke and Jean-Jacques Rousseau on the nature–nurture controversy. Summarize the argument that each historical figure is likely to present.

Connect ■ What do the ideas of Rousseau, Darwin, and Hall have in common?

Reflect ■ Find out whether your parents read any child-rearing advice books when you were growing up. What questions most concerned them? Do you think the concerns of today's parents differ from those of your parents' generation? Explain.

▶ What theories influenced child development research in the mid-twentieth century?

Mid-Twentieth-Century Theories

In the mid-twentieth century, the field of child development expanded into a legitimate discipline. Specialized research centers and professional societies devoted to the scientific study of children were founded. A leader among these is the Society for Research in Child Development (SRCD), established in 1933 to promote interdisciplinary research, dissemination of information, and applications of research findings. The society's inaugural membership of 425 grew rapidly. Today, approximately 5,500 researchers, applied professionals, and students from more than 50 countries are members.

As child development attracted increasing interest, a variety of theories emerged, each of which continues to have followers today. In these theories, the European concern with the child's inner thoughts and feelings contrasts sharply with the North American academic focus on scientific precision and concrete, observable behavior.

The Psychoanalytic Perspective

By the 1930s and 1940s, parents were increasingly seeking professional help in dealing with children's emotional difficulties. The earlier normative movement had answered the question, What are children like? Now another question had to be addressed: How and why do children become the way they are? To treat psychological problems, psychiatrists and social workers turned to an emerging approach to personality development that emphasized the unique history of each child.

According to the **psychoanalytic perspective,** children move through a series of stages in which they confront conflicts between biological drives and social expectations. How these conflicts are resolved determines the person's ability to learn, to get along with others, and to cope with anxiety. Among the many individuals who contributed to the psychoanalytic perspective, two were especially influential: Sigmund Freud, founder of the psychoanalytic movement, and Erik Erikson.

Freud's Theory

Freud (1856–1939), a Viennese physician, sought a cure for emotionally troubled adults by having them talk freely about painful events of their childhoods. Working with these recollections, Freud examined the unconscious motivations of his patients and constructed his **psychosexual theory,** which emphasizes that how parents manage their child's sexual and aggressive drives in the first few years is crucial for healthy personality development.

In Freud's theory, three parts of the personality—id, ego, and superego—become integrated during a sequence of five stages, summarized in Table 1.1 on page 16. The *id,* the largest portion of the mind, is the source of basic biological needs and desires. The *ego,* the conscious, rational part of personality, emerges in early infancy to redirect the id's impulses so they are discharged in acceptable ways. Between 3 and 6 years of age, the *superego,* or conscience, develops through interactions with parents, who insist that children conform to the values of society. Now the ego faces the increasingly complex task of reconciling the demands of the id, the external world, and conscience (Freud, 1923/1974). For example, when the id impulse to grab an attractive toy from a playmate confronts the superego's warning that such behavior is wrong, the ego must mediate between these two forces, deciding which will win the inner struggle or, alternatively, working out a compromise, such as asking for a turn with the toy. According to Freud, the relations established among id, ego, and superego during the preschool years determine the individual's basic personality.

Freud (1938/1973) believed that during childhood, sexual impulses shift their focus from the oral to the anal to the genital regions of the body. In each stage, parents walk a fine line between permitting too much or too little gratification of their child's basic needs. If parents strike an appropriate balance, then children grow into well-adjusted adults with the capacity for mature sexual behavior and investment in family life.

Freud's theory was the first to stress the influence of the early parent–child relationship on development—an emphasis that continues to play a role in many contemporary theories. But his perspective was eventually criticized. First, it overemphasized the influence of sexual feelings in development. Second, because it was based on the problems of sexually repressed, well-to-do adults in nineteenth-century Victorian society, it did not apply in other cultures. Finally, Freud had not studied children directly.

Erikson's Theory

Several of Freud's followers took what was useful from his theory and improved on his vision. The most important of these neo-Freudians is Erik Erikson (1902–1994), who expanded the picture of development at each stage. In his **psychosocial theory,** Erikson emphasized that in addition to mediating between id impulses and superego

TABLE 1.1 Freud’s Psychosexual Stages and Erikson’s Psychosocial Stages Compared

APPROXIMATE AGE	FREUD’S PSYCHOSEXUAL STAGE	ERIKSON’S PSYCHOSOCIAL STAGE
Birth–1 year	***Oral:*** If oral needs are not met through sucking from breast or bottle, the individual may develop such habits as thumb sucking, fingernail biting, overeating, or smoking.	***Basic trust versus mistrust:*** From warm, responsive care, infants gain a sense of trust, or confidence, that the world is good. Mistrust occurs if infants are neglected or handled harshly.
1–3 years	***Anal:*** Toddlers and preschoolers enjoy holding and releasing urine and feces. If parents toilet train before children are ready or make too few demands, conflicts about anal control may appear in the form of extreme orderliness or disorder.	***Autonomy versus shame and doubt:*** Using new mental and motor skills, children want to decide for themselves. Parents can foster autonomy by permitting reasonable free choice and not forcing or shaming the child.
3–6 years	***Phallic:*** As preschoolers take pleasure in genital stimulation, Freud’s Oedipus conflict for boys and Electra conflict for girls arise: Children feel a sexual desire for the other-sex parent. To avoid punishment, they give up this desire and adopt the same-sex parent’s characteristics and values. As a result, the superego is formed, and children feel guilty when they violate its standards.	***Initiative versus guilt:*** Through make-believe play, children gain insight into the person they can become. Initiative—a sense of ambition and responsibility—develops when parents support their child’s sense of purpose. But if parents demand too much self-control, children experience excessive guilt.
6–11 years	***Latency:*** Sexual instincts die down, and the superego strengthens as the child acquires new social values from adults and same-sex peers.	***Industry versus inferiority:*** At school, children learn to work and cooperate with others. Inferiority develops when negative experiences at home, at school, or with peers lead to feelings of incompetence.
Adolescence	***Genital:*** With puberty, sexual impulses reappear. Successful development during earlier stages leads to marriage, mature sexuality, and child rearing.	***Identity versus role confusion:*** By exploring values and vocational goals, the young person forms a personal identity. The negative outcome is confusion about future adult roles.
Young adulthood	© OLIVE PIERCE/BLACK STAR **Erik Erikson**	***Intimacy versus isolation:*** Young adults establish intimate relationships. Because of earlier disappointments, some individuals cannot form close bonds and remain isolated.
Middle adulthood		***Generativity versus stagnation:*** Generativity means giving to the next generation through child rearing, caring for others, or productive work. The person who fails in these ways feels an absence of meaningful accomplishment.
Old age		***Integrity versus despair:*** Integrity results from feeling that life was worth living as it happened. Older people who are dissatisfied with their lives fear death.

demands, the ego makes a positive contribution to development, acquiring attitudes and skills that make the individual an active, contributing member of society. A basic psychosocial conflict, which is resolved along a continuum from positive to negative, determines healthy or maladaptive outcomes at each stage. As Table 1.1 shows, Erikson’s first five stages parallel Freud’s stages, but Erikson added three adult stages. He was one of the first to recognize the lifespan nature of development.

Unlike Freud, Erikson pointed out that normal development must be understood in relation to each culture’s life situation. For example, in the 1940s, he observed that Yurok Indians of the U.S. northwest coast deprived babies of breastfeeding for the first 10 days after birth and instead fed them a thin soup. At age 6 months, infants were abruptly weaned—if necessary, by having the mother leave for a few days. From our cultural vantage point, these practices may seem cruel. But Erikson explained that because the Yurok depended on salmon, which fill the river just once a year, the development of considerable self-restraint was essential for survival. In this way, he showed that child rearing is responsive to the competencies valued and needed by the child’s society.

Contributions and Limitations of the Psychoanalytic Perspective A special strength of the psychoanalytic perspective is its emphasis on the individual's unique life history as worthy of study and understanding. Consistent with this view, psychoanalytic theorists accept the *clinical,* or *case study, method,* which synthesizes information from a variety of sources into a detailed picture of the personality of a single child. (We will discuss this method further in Chapter 2.) Psychoanalytic theory has also inspired a wealth of research on many aspects of emotional and social development, including infant–caregiver attachment, aggression, sibling relationships, child-rearing practices, morality, gender roles, and adolescent identity.

Despite its extensive contributions, the psychoanalytic perspective is no longer in the mainstream of child development research. Psychoanalytic theorists may have become isolated from the rest of the field because they were so strongly committed to in-depth study of individual children that they failed to consider other methods. In addition, many psychoanalytic ideas, such as psychosexual stages and ego functioning, are too vague to be tested empirically (Crain, 2005; Thomas, 2005). Nevertheless, Erikson's broad outline of psychosocial change captures the essence of psychosocial attainments at each age period. Consequently, we will return to it in later chapters.

Children of the Lacandon Mayan people of southern Mexico learn from their father how to make arrows like those of their hunter-gatherer ancestors. As Erikson recognized, this parenting practice is best understood in relation to the competencies valued and needed in Lacandon culture.

Behaviorism and Social Learning Theory

As the psychoanalytic perspective gained in prominence, child study was also influenced by a very different perspective. According to **behaviorism,** directly observable events—stimuli and responses—are the appropriate focus of study. North American behaviorism began in the early twentieth century with the work of psychologist John Watson (1878–1958), who wanted to create an objective science of psychology.

Traditional Behaviorism Watson was inspired by Russian physiologist Ivan Pavlov's studies of animal learning. Pavlov knew that dogs release saliva as an innate reflex when they are given food. But he noticed that his dogs started salivating before they tasted any food—when they saw the trainer who usually fed them. The dogs, Pavlov reasoned, must have learned to associate a neutral stimulus (the trainer) with another stimulus (food) that produces a reflexive response (salivation). Because of this association, the neutral stimulus alone could bring about a response resembling the reflex. Eager to test this idea, Pavlov successfully taught dogs to salivate at the sound of a bell by pairing it with the presentation of food. He had discovered *classical conditioning*.

Watson wanted to find out if classical conditioning could be applied to children's behavior. In a historic experiment, he taught Albert, an 11-month-old infant, to fear a neutral stimulus—a soft white rat—by presenting it several times with a sharp, loud sound, which naturally scared the baby. Little Albert, who at first had reached out eagerly to touch the furry rat, began to cry and turn his head away at the sight of it (Watson & Raynor, 1920). In fact, Albert's fear was so intense that researchers eventually challenged the ethics of studies like this one. Consistent with Locke's tabula rasa, Watson concluded that environment is the supreme force in development and that adults can mold children's behavior by carefully controlling stimulus–response associations. He viewed development as a continuous process—a gradual increase with age in the number and strength of these associations.

Another form of behaviorism was B. F. Skinner's (1904–1990) *operant conditioning theory*. According to Skinner, the frequency of a behavior can be increased by following it with a wide variety of *reinforcers*—food, drink, praise, a friendly smile, or a new toy—or decreased through *punishment,* such as disapproval or withdrawal of privileges. As a result of Skinner's work, operant conditioning became a broadly applied learning principle, which we will consider further when we explore the infant's learning capacities in Chapter 4.

Social Learning Theory

Psychologists wondered whether behaviorism might offer a more direct and effective explanation of the development of children's social behavior than the less precise concepts of psychoanalytic theory. This sparked approaches that built on the principles of conditioning, offering expanded views of how children and adults acquire new responses.

Several kinds of **social learning theory** emerged. The most influential, devised by Albert Bandura (1977), emphasized *modeling*, otherwise known as *imitation* or *observational learning*, as a powerful source of development. The baby who claps her hands after her mother does so, the child who angrily hits a playmate in the same way that he has been punished at home, and the teenager who wears the same clothes and hairstyle as her friends at school are all displaying observational learning. In his early work, Bandura found that diverse factors influence children's motivation to imitate—their own history of reinforcement or punishment for the behavior, the promise of future reinforcement or punishment, and even vicarious reinforcement or punishment (observing the model being reinforced or punished).

© BOB DAEMMRICH/THE IMAGE WORKS

Social learning theory recognizes that children acquire many skills through modeling. By observing and imitating her mother's behavior, this 19-month-old learns an important skill.

Bandura's work continues to influence much research on children's social development. But today, like the field of child development as a whole, his theory stresses the importance of *cognition,* or thinking. Bandura has shown that children's ability to listen, remember, and abstract general rules from complex sets of observed behaviors affects their imitation and learning. In fact, the most recent revision of Bandura's (1992, 2001) theory places such strong emphasis on how children think about themselves and other people that he calls it a *social-cognitive* rather than a social learning approach.

In Bandura's revised view, children gradually become more selective in what they imitate. From watching others engage in self-praise and self-blame and through feedback about the worth of their own actions, children develop *personal standards* for behavior and a *sense of self-efficacy*—the belief that their own abilities and characteristics will help them succeed. These cognitions guide responses in particular situations (Bandura, 1999, 2001). For example, imagine a parent who often remarks, "I'm glad I kept working on that task, even though it was hard," who explains the value of persistence, and who encourages it by saying, "I know you can do a good job on that homework!" Soon the child starts to view herself as hardworking and high-achieving and selects people with these characteristics as models. In this way, as children acquire attitudes, values, and convictions about themselves, they control their own learning and behavior.

LOOK and LISTEN

Describe an event you observed in which feedback from a parent or teacher likely strengthened a child's self-efficacy. How might the adult's message have influenced the child's self-image and choice of models?

Contributions and Limitations of Behaviorism and Social Learning Theory

Behaviorism and social learning theory have had a major impact on practices with children. **Behavior modification** consists of procedures that combine conditioning and modeling to eliminate undesirable behaviors and increase desirable responses. It has been used to relieve a wide range of serious developmental problems, such as persistent aggression, language delays, and extreme fears (Martin & Pear, 2007).

Behavior modification is also effective in dealing with common, everyday difficulties, including poor time management; unwanted habits such as nail biting and thumb sucking; and anxiety over such recurrent events as test-taking, public speaking, and medical and dental treatments. In one study, researchers reduced 4- and 5-year-olds' unruliness in a preschool classroom by reinforcing them with tokens (which they could exchange for treats) when they behaved appropriately and punishing them by taking away tokens when they screamed, threw objects, attacked other children, or refused to comply with a teacher's request (Conyers et al., 2004). In another investigation, children with acute burn injuries played a virtual reality game while nurses engaged in the painful process of changing their bandages. Visual images and sound effects delivered through a headset made the children feel as if they were in a fantasy world. As the game reinforced children's concentration and pleasure, it distracted them from the medical procedure, causing their pain and anxiety to drop sharply compared with dressing changes in which the game was unavailable (Das et al., 2005).

Nevertheless, many theorists believe that behaviorism and social learning theory offer too narrow a view of important environmental influences. These extend beyond immediate reinforcements, punishments, and modeled behaviors to children's rich physical and social worlds. Behaviorism and social learning theory have also been criticized for underestimating children's contributions to their own development. Bandura, with his emphasis on cognition, is unique among theorists whose work grew out of the behaviorist tradition in granting children an active role in their own learning.

Piaget's Cognitive-Developmental Theory

If one individual has influenced the contemporary field of child development more than any other, it is Swiss cognitive theorist Jean Piaget (1896–1980). North American investigators had been aware of Piaget's work since 1930. But they did not grant it much attention until the 1960s, mainly because Piaget's ideas were at odds with behaviorism, which dominated North American psychology in the mid-twentieth century (Cairns & Cairns, 2006). Piaget did not believe that children's learning depends on reinforcers, such as rewards from adults. According to his **cognitive-developmental theory,** children actively construct knowledge as they manipulate and explore their world.

Piaget's Stages

Piaget's view of development was greatly influenced by his early training in biology. Central to his theory is the biological concept of *adaptation* (Piaget, 1971). Just as structures of the body are adapted to fit with the environment, so structures of the mind develop to better fit with, or represent, the external world. In infancy and early childhood, Piaget claimed, children's understanding is different from adults'. For example, he believed that young babies do not realize that an object hidden from view—a favorite toy or even the mother—continues to exist. He also concluded that preschoolers' thinking is full of faulty logic. For example, children younger than age 7 commonly say that the amount of liquid changes when it is poured into a different-shaped container. According to Piaget, children eventually revise these incorrect ideas in their ongoing efforts to achieve an *equilibrium,* or balance, between internal structures and information they encounter in their everyday worlds.

In Piaget's theory, as the brain develops and children's experiences expand, they move through four broad stages, each characterized by qualitatively distinct ways of thinking. Table 1.2 on page 20 provides a brief description of Piaget's stages. Cognitive development begins in the *sensorimotor stage* with the baby's use of the senses and movements to explore the world. These action patterns evolve into the symbolic but illogical thinking of the preschooler in the *preoperational stage*. Then cognition is transformed into the more organized, logical reasoning of the

In Piaget's preoperational stage, preschool children represent their earlier sensorimotor discoveries with symbols, and language and make-believe play develop rapidly. With a few props, this 5-year-old creates an imaginary doctor's office.

TABLE 1.2 Piaget's Stages of Cognitive Development

STAGE	PERIOD OF DEVELOPMENT	DESCRIPTION
Sensorimotor	Birth–2 years	Infants "think" by acting on the world with their eyes, ears, hands, and mouth. As a result, they invent ways of solving sensorimotor problems, such as pulling a lever to hear the sound of a music box, finding hidden toys, and putting objects into and taking them out of containers.
Preoperational	2–7 years	Preschool children use symbols to represent their earlier sensorimotor discoveries. Development of language and make-believe play takes place. However, thinking lacks the logic of the two remaining stages.
Concrete operational	7–11 years	Children's reasoning becomes logical and better organized. School-age children understand that a certain amount of lemonade or play dough remains the same even after its appearance changes. They also organize objects into hierarchies of classes and subclasses. However, thinking falls short of adult intelligence. It is not yet abstract.
Formal operational	11 years on	The capacity for abstract, systematic thinking enables adolescents, when faced with a problem, to start with a hypothesis, deduce testable inferences, and isolate and combine variables to see which inferences are confirmed. Adolescents can also evaluate the logic of verbal statements without referring to real-world circumstances.

In Piaget's concrete operational stage, school-age children think in an organized, logical fashion about concrete objects. This 7-year-old understands that the quantity of pie dough remains the same after he changes its shape from a ball to a flattened circle.

school-age child in the *concrete operational stage*. Finally, in the *formal operational stage,* thought becomes the abstract, systematic reasoning system of the adolescent and adult.

Piaget devised special methods for investigating how children think. Early in his career, he carefully observed his three infant children and presented them with everyday problems, such as an attractive object that could be grasped, mouthed, kicked, or searched for. From their responses, Piaget derived his ideas about cognitive changes during the first two years. To study childhood and adolescent thought, Piaget adapted the clinical method of psychoanalysis, conducting open-ended *clinical interviews* in which a child's initial response to a task served as the basis for Piaget's next question. We will look more closely at this technique in Chapter 2.

Contributions and Limitations of Piaget's Theory Piaget convinced the field that children are active learners whose minds consist of rich structures of knowledge. Besides investigating children's understanding of the physical world, Piaget explored their reasoning about the social world. His stages have sparked a wealth of research on children's conceptions of themselves, other people, and human relationships. In practical terms, Piaget's theory encouraged the development of educational philosophies and programs that emphasize children's discovery learning and direct contact with the environment.

Despite Piaget's overwhelming contributions, his theory has been challenged. Research indicates that Piaget underestimated the competencies of infants and preschoolers. We will see in Chapter 6 that when young children are given tasks scaled down in difficulty and relevant to their everyday experiences, their understanding appears closer to that of the older child and adult than Piaget assumed. Also, adolescents generally reach their full intellectual potential only in areas of endeavor in which they have had extensive education and experience (Kuhn, 2008). These discoveries have led many researchers to conclude that the maturity of thinking depends heavily on the complexity of knowledge sampled and the individual's familiarity with the task. Furthermore, many studies show that children's performance on Piagetian problems can be improved with training—findings that call into question Piaget's assumption that discovery learning rather than adult teaching is the best way to foster development (Klahr & Nigam, 2004; Siegler & Svetina, 2006). Critics also point out that Piaget's stagewise account pays insufficient attention to social and cultural influences—and the resulting wide variation in thinking among children and adolescents of the same age.

Today, the field of child development is divided over its loyalty to Piaget's ideas (Desrochers, 2008). Those who continue to find merit in Piaget's stages often accept a modified view—one in which changes in children's thinking take place more gradually than Piaget believed (Case, 1998; Demetriou et al., 2002; Fischer & Bidell, 2006; Halford & Andrews, 2006). Among those who disagree with Piaget's stage sequence, some have embraced an approach that emphasizes continuous gains in children's cognition: information processing. And still others have been drawn to theories that highlight the role of children's social and cultural contexts. We take up these approaches in the next section.

ASK YOURSELF

Review ■ What aspect of behaviorism made it attractive to critics of the psychoanalytic perspective? How did Piaget's theory respond to a major limitation of behaviorism?

Connect ■ Although social learning theory focuses on social development and Piaget's theory on cognitive development, each has enhanced our understanding of other domains. Mention an additional domain addressed by each theory.

Apply ■ A 4-year-old becomes frightened of the dark and refuses to go to sleep at night. How would a psychoanalyst and a behaviorist differ in their views of how this problem developed?

Reflect ■ Illustrate Bandura's ideas by describing a personal experience in which you observed and received feedback from another person that strengthened your self-efficacy—belief that your abilities and characteristics will help you succeed.

Recent Theoretical Perspectives

▶ Describe recent theoretical perspectives on child development.

New ways of understanding children are constantly emerging—questioning, building on, and enhancing the discoveries of earlier theories. Today, a burst of fresh approaches and research emphases is broadening our understanding of children's development.

Information Processing

In the 1970s and 1980s, researchers turned to the field of cognitive psychology for ways to understand the development of children's thinking. The design of digital computers that use mathematically specified steps to solve problems suggested to psychologists that the human mind might also be viewed as a symbol-manipulating system through which information flows—a perspective called **information processing** (Klahr & MacWhinney, 1998; Munakata, 2006). From the time information is presented to the senses at *input* until it emerges as a behavioral response at *output,* the information is actively coded, transformed, and organized. Information-processing researchers often design flowcharts to map the precise steps individuals use to solve problems and complete tasks, much like the plans devised by programmers to get computers to perform a series of "mental operations." They seek to clarify how

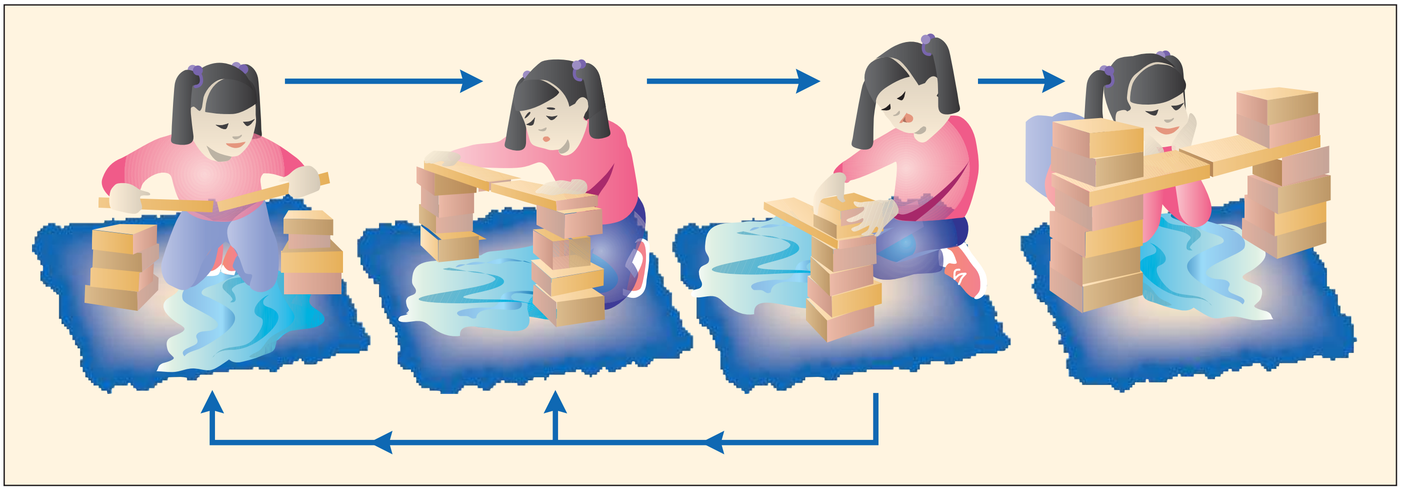

FIGURE 1.3 Information-processing flowchart showing the steps that a 5-year-old used to solve a bridge-building problem. Her task was to use blocks varying in size, shape, and weight, some of which were planklike, to construct a bridge across a "river" (painted on a floor mat) too wide for any single block to span. The child discovered how to counterweight and balance the bridge. The arrows reveal that even after building a successful counterweight, she returned to earlier, unsuccessful strategies, which seemed to help her understand why the counterweight approach worked. (Adapted from Thornton, 1999.)

both task characteristics and cognitive limitations (for example, memory capacity or available knowledge) influence performance (Birney & Sternberg, 2011). To see the usefulness of this approach, let's look at an example.

In a study of problem solving, a researcher provided a pile of blocks varying in size, shape, and weight and asked school-age children to build a bridge across a "river" (painted on a floor mat) that was too wide for any single block to span (Thornton, 1999). Figure 1.3 shows one solution: Two planklike blocks span the water, each held in place by the counterweight of heavy blocks on the bridge's towers. Whereas older children easily built successful bridges, only one 5-year-old did. Careful tracking of her efforts revealed that she repeatedly tried unsuccessful strategies, such as pushing two planks together and pressing down on their ends to hold them in place. But eventually, her experimentation triggered the idea of using the blocks as counterweights. Her mistaken procedures helped her understand why the counterweight approach worked. Although this child had no prior understanding of counterweight and balance, she arrived at just as effective a solution as older children, who started with considerable task-relevant knowledge. Her own actions within the task facilitated problem solving.

Many information-processing models exist. Some, like the one just considered, track children's mastery of one or a few tasks. Others describe the human cognitive system as a whole (Johnson & Mareschal, 2001; Johnson-Laird, 2001; Westermann et al., 2006). These general models are used as guides for asking questions about broad age changes in children's thinking: Does a child's ability to solve problems become more organized and "planful" with age? What strategies do younger and older children use to remember new information, and how do those strategies affect children's recall?

The information-processing approach is also being used to clarify the processing of social information. For example, flowcharts exist that track the steps children use to solve social problems (such as how to enter an ongoing play group) and acquire gender-linked preferences and behaviors (Crick & Dodge, 1994; Liben & Bigler, 2002). If we can identify how social problem solving and gender stereotyping arise in childhood, then we can design interventions that promote more favorable social development.

Like Piaget's theory, the information-processing approach regards children as active, sense-making beings who modify their own thinking in response to environmental demands (Halford, 2005; Munakata, 2006). But unlike Piaget's theory, it does not divide development into stages. Rather, the thought processes studied—perception, attention, memory, categorization of information, planning, problem solving, and comprehension of written and spoken prose—usually are regarded as similar at all ages but present to a lesser or greater extent. Therefore, the view of development is one of continuous change.

A great strength of the information-processing approach is its commitment to rigorous research methods. Because it has provided precise accounts of how children of different ages engage in many aspects of thinking, its findings have led to teaching methods that help children approach academic tasks in more advanced ways (Blumenfeld, Marx, & Harris, 2006; Siegler, 2009). But information processing has fallen short in some respects. It has been better at analyzing thinking into its components than at putting them back together into a comprehensive theory. And it has had little to say about aspects of children's cognition that are not linear and logical, such as imagination and creativity (Birney & Sternberg, 2011).

Developmental Cognitive Neuroscience

Over the past three decades, as information-processing research expanded, a new area of investigation arose, called **developmental cognitive neuroscience.** It brings together researchers from psychology, biology, neuroscience, and medicine to study the relationship between changes in the brain and the developing child's cognitive processing and behavior patterns.

Improved methods for analyzing brain activity while children perform various tasks have greatly enhanced knowledge of relationships between brain functioning, cognitive capacities, and behavior (Johnson, 2005; Pennington, Snyder, & Roberts, 2007; Westermann et al., 2007). Armed with these brain-imaging techniques (which we will consider in Chapter 2), neuroscientists are tackling questions like these: How does genetic makeup combine with specific experiences at various ages to influence the growth and organization of the child's brain? How do changes in brain structures support rapid memory development in infancy and toddlerhood? What transformations in brain systems make it harder for adolescents and adults than for children to acquire a second language?

During infancy and early childhood, the brain is highly plastic—especially open to growth and reorganization as a result of experience. But a revolutionary finding of neuroscience research is that the brain retains considerable plasticity throughout life. Neuroscientists are making especially impressive progress in identifying the types of experiences that support or undermine brain development at diverse ages. They are also clarifying the brain bases of many learning and behavior disorders (Durston & Conrad, 2007; Meltzoff et al., 2009). And they are contributing to effective treatments for children with disabilities by examining the impact of various intervention techniques on both brain functioning and behavior (Luciana, 2007). Although much remains to be discovered, developmental cognitive neuroscience is already transforming our understanding of development and yielding major practical applications.

An advantage of having many theories is that they encourage researchers to attend to previously neglected dimensions of children's lives. The final four perspectives we will discuss all focus on *contexts* for development. The first of these views emphasizes that the development of many capacities is influenced by our long evolutionary history.

Ethology and Evolutionary Developmental Psychology

Ethology is concerned with the adaptive, or survival, value of behavior and its evolutionary history. Its roots can be traced to the work of Darwin. Two European zoologists, Konrad Lorenz and Niko Tinbergen, laid its modern foundations. Watching diverse animal species in their natural habitats, Lorenz and Tinbergen observed behavior patterns that promote survival. The best known of these is *imprinting,* the early following behavior of certain baby birds, such as geese, which ensures that the young will stay close to the mother and be fed and protected from danger (Lorenz, 1952). Imprinting takes place during an early, restricted period of development. If the mother goose is absent during this time but an object resembling her in important features is present, young goslings may imprint on it instead.

Observations of imprinting led to a major concept in child development: the *critical period*. It refers to a limited time during which the child is biologically prepared to acquire certain adaptive behaviors but needs the support of an appropriately stimulating environment. Many researchers have conducted studies to find out whether complex cognitive and social behaviors must be learned during certain periods. For example, if children are deprived of adequate food or physical and social stimulation during their early years, will

AP IMAGES

Ethology focuses on the adaptive, or survival, value of behavior and on similarities between human behavior and that of other species, especially our primate relatives. Observing this chimpanzee mother cuddling her 8-day-old infant helps us understand the human caregiver–infant relationship.

their intelligence be impaired? If language learning is impeded in childhood due to limited parent–child communication, is the capacity to acquire language later reduced?

In later chapters, we will discover that the term *sensitive period* applies better to human development than the strict notion of a critical period (Bornstein, 1989; Knudsen, 2004). A **sensitive period** is a time that is optimal for certain capacities to emerge because the individual is especially responsive to environmental influences. However, its boundaries are less well-defined than those of a critical period. Development can occur later, but it is harder to induce.

Inspired by observations of imprinting, British psychoanalyst John Bowlby (1969) applied ethological theory to understanding the human caregiver–infant relationship. He argued that infant smiling, babbling, grasping, and crying are built-in social signals that encourage the caregiver to approach, care for, and interact with the baby. By keeping the parent near, these behaviors help ensure that the infant will be fed, protected from danger, and provided with stimulation and affection necessary for healthy growth. The development of attachment in human infants is a complex, lengthy process that leads the baby to form a deep affectionate tie with the caregiver (Thompson, 2006). In Chapter 10, we will consider how infant, caregiver, and family context contribute to attachment and how attachment influences later development.

Observations by ethologists have shown that many aspects of children's social behavior, including emotional expressions, aggression, cooperation, and social play, resemble those of our primate relatives. Recently, researchers have extended this effort in a new area of research called **evolutionary developmental psychology.** It seeks to understand the adaptive value of species-wide cognitive, emotional, and social competencies as those competencies change with age (Geary, 2006b; King & Bjorklund, 2010). Evolutionary developmental psychologists ask questions like these: What role does the newborn's visual preference for facelike stimuli play in survival? Does it support older infants' capacity to distinguish familiar caregivers from unfamiliar people? Why do children play in gender-segregated groups? What do they learn from such play that might lead to adult gender-typed behaviors, such as male dominance and female investment in caregiving?

As these examples suggest, evolutionary psychologists are not just concerned with the genetic and biological roots of development. They recognize that humans' large brain and extended childhood resulted from the need to master the complexities of human group life, so they are also interested in learning (Bjorklund, Causey, & Periss, 2009). And they realize that today's lifestyles differ so radically from those of our evolutionary ancestors that certain evolved behaviors, such as life-threatening risk taking in adolescents and male-to-male violence, are no longer adaptive (Blasi & Bjorklund, 2003). By clarifying the origins and development of such behaviors, evolutionary developmental psychology may help spark more effective interventions.

In sum, evolutionary psychologists want to understand the entire *organism–environment system*. The next contextual perspective we will discuss, Vygotsky's sociocultural theory, serves as an excellent complement to the evolutionary viewpoint because it highlights social and cultural dimensions of children's experiences.

Vygotsky's Sociocultural Theory

The field of child development has recently seen a dramatic increase in studies addressing the cultural context of children's lives. Investigations that make comparisons across cultures, and between ethnic groups within cultures, provide insight into whether developmental pathways apply to all children or are limited to particular environmental conditions (Goodnow, 2010).

Today, much research is examining the relationship of *culturally specific beliefs and practices* to development. The contributions of Russian psychologist Lev Vygotsky (1896–1934) have played a major role in this trend. Vygotsky's (1934/1987) perspective, known as **sociocultural theory,** focuses on how *culture*—the values, beliefs, customs, and skills of a social group—is transmitted to the next generation. According to Vygotsky, *social interaction*—in particular, cooperative dialogues between children and more knowledgeable members of society—is necessary for children to acquire the ways of thinking and behaving that make up a community's culture. Vygotsky believed that as adults and more-expert peers help children master culturally meaningful activities, the communication between them becomes part of children's thinking. As children internalize the features of these dialogues, they can use the language within them to guide their own thought and actions and to acquire new skills (Berk & Harris, 2003; Winsler, Fernyhough, & Montero, 2009). The young child instructing herself while working a puzzle or setting a table for dinner has begun to produce the same kind of guiding comments that an adult previously used to help her master important tasks.

COURTESY OF JAMES V. WERTSCH, WASHINGTON UNIVERSITY IN ST. LOUIS

According to Lev Vygotsky, shown here with his daughter, many cognitive processes and skills are socially transferred from more knowledgeable members of society to children. Vygotsky's sociocultural theory helps explain the wide cultural variation in cognitive competencies.

Vygotsky's theory has been especially influential in the study of children's cognition. Vygotsky agreed with Piaget that children are active, constructive beings. But whereas Piaget emphasized children's independent efforts to make sense of their world, Vygotsky viewed cognitive development as a *socially mediated process,* in which children depend on assistance from adults and more-expert peers as they tackle new challenges.

In Vygotsky's theory, children undergo certain stagewise changes. For example, when they acquire language, they gain in ability to participate in dialogues with others, and mastery of culturally valued competencies surges forward. When children enter school, they spend much time discussing language, literacy, and other academic concepts—experiences that encourage them to reflect on their own thinking (Bodrova & Leong, 2007; Kozulin, 2003). As a result, they gain dramatically in reasoning and problem solving.

At the same time, Vygotsky stressed that dialogues with experts lead to continuous changes in cognition that vary greatly from culture to culture. Consistent with this view, a major finding of cross-cultural research is that cultures select different tasks for children's learning (Rogoff, 2003). Social interaction surrounding those tasks leads to competencies essential for success in a particular culture. For example, in industrialized nations, teachers help people learn to read, drive a car, or use a computer. Among the Zinacanteco Indians of southern Mexico, adult experts guide young girls as they master complicated weaving techniques (Greenfield, 2004; Greenfield, Maynard, & Childs, 2000). In Brazil and other developing nations, child candy sellers with little or no schooling develop sophisticated mathematical abilities as the result of buying candy from wholesalers, pricing it in collaboration with adults and experienced peers, and bargaining with customers on city streets (Saxe, 1988). And as the research reported in the Cultural Influences box on page 26 indicates, adults encourage culturally valued skills in children at a remarkably early age.

A Cambodian girl learns traditional dance forms from her grandmother. She acquires a culturally valued skill by interacting with an older, more experienced member of her culture.

© ROGER HUTCHINGS/IN PICTURES/CORBIS

Research stimulated by Vygotsky's theory reveals that children in every culture develop unique strengths. But Vygotsky's emphasis on culture and social experience led him to neglect the biological side of development. Although he recognized the importance of heredity and brain growth, he said little about their role in cognitive change. Furthermore, Vygotsky's focus on social transmission of knowledge meant that, compared with other theorists, he placed less emphasis

CULTURAL INFLUENCES

!Kung Infancy: Acquiring Culture

Interactions between caregivers and infants take different forms in different cultures. Through those interactions, adults start to transmit their society's values and skills to the next generation, channeling the course of future development. Focusing on a culture very different from our own, researchers studied how caregivers respond to infants' play with objects among the !Kung, a hunting-and-gathering society living in the desert regions of Botswana, Africa (Bakeman et al., 1990). Daily foraging missions take small numbers of adults several miles from the campground, but most obtain enough food to contribute to group survival by working only three out of every seven days. A mobile way of life also prevents the !Kung from collecting many possessions that require extensive care and maintenance. Adults have many free hours to relax around the campfire, and they spend this time in intense social contact with one another and with children (Draper & Cashdan, 1988; Konner, 2010).

In this culture of intimate social bonds and minimal property, objects are valued as things to be shared, not as personal possessions. This message is conveyed to !Kung children at a very early age. While carried about on their mother's hip during work hours, babies often pause to play with decorative beads worn around her neck (Konner, 2008). Between 6 and 12 months, grandmothers start to train infants in the importance of exchanging objects by guiding them in handing beads to relatives. The child's first words generally include *i* ("Here, take this") and *na* ("Give it to me"). In !Kung society, no toys are made for babies. Instead, natural objects, such as twigs, grass, stones, and nutshells, are always available, along with cooking implements. However, adults do not encourage babies to play with these objects. In fact, adults are unlikely to interact with infants while they are exploring objects independently. But when a baby offers an object to another person, adults become highly responsive, encouraging and vocalizing much more than at other times. Thus, the !Kung cultural emphasis on the interpersonal rather than physical aspects of existence is reflected in how adults interact with the very youngest members of their community.

!Kung children grow up in a hunting-and-gathering society in which possessions are a burden rather than an asset. From an early age, children experience warm social contact with adults and are taught the importance of sharing.

TAKE A MOMENT... When you next have a chance, observe the conditions under which parents in your own society respond to infants' involvement with objects. How is parental responsiveness linked to cultural values? How does it compare with findings on the !Kung?

on children's capacity to shape their own development. Followers of Vygotsky stress that children strive for social connection, actively participating in the conversations and social activities from which their development springs. From these joint experiences, they not only acquire culturally valued practices but also modify and transform those practices (Nelson, 2007; Rogoff, 2003). Contemporary sociocultural theorists grant the individual and society balanced, mutually influential roles.

Ecological Systems Theory

Urie Bronfenbrenner (1917–2005) is responsible for an approach to child development that has moved to the forefront of the field because it offers the most differentiated and complete account of contextual influences on children's development. **Ecological systems theory** views the child as developing within a complex *system* of relationships affected by multiple levels of the surrounding environment. Because the child's biologically influenced dispositions join with environmental forces to mold development, Bronfenbrenner characterized his perspective as a *bioecological model* (Bronfenbrenner, 2005; Bronfenbrenner & Morris, 2006).

Bronfenbrenner envisioned the environment as a series of nested structures that form a complex functioning whole, or *system*. These include but also extend beyond the home, school, and neighborhood settings in which children spend their everyday lives (see Figure 1.4). Each layer of the environment joins with the others to powerfully affect development.

The Microsystem The innermost level of the environment, the **microsystem,** consists of activities and interaction patterns in the child's immediate surroundings. Bronfenbrenner emphasizes that to understand child development at this level, we must keep in mind that all relationships are *bidirectional:* Adults affect children's behavior, but children's biologically and socially influenced characteristics—their physical attributes, personalities, and capacities—also affect adults' behavior. A friendly, attentive child is likely to evoke positive, patient reactions from parents, whereas an irritable or distractible child is more likely to receive impatience, restriction, and punishment. When these reciprocal interactions occur often over time, they have an enduring impact on development (Collins et al., 2000; Crockenberg & Leerkes, 2003b).

Third parties—other individuals in the microsystem—also affect the quality of any two-person relationship. If they are supportive, interaction is enhanced. For example, when parents encourage each other in their child-rearing roles, each engages in more effective parenting. In contrast, marital conflict is associated with inconsistent discipline and hostile reactions toward children. In response, children often react with fear and anxiety or with anger and aggression, and the well-being of both parent and child suffers (Caldera & Lindsey, 2006; Davies & Lindsay, 2004). Similarly, children can affect their parents' relationship in powerful ways. For example, as Chapter 14 will reveal, divorce is often associated with lasting adjustment problems. Yet long before the marital breakup, some children were impulsive and defiant. These behaviors may have contributed to, as well as been caused by, their parents' marital problems (Strohschein, 2005).

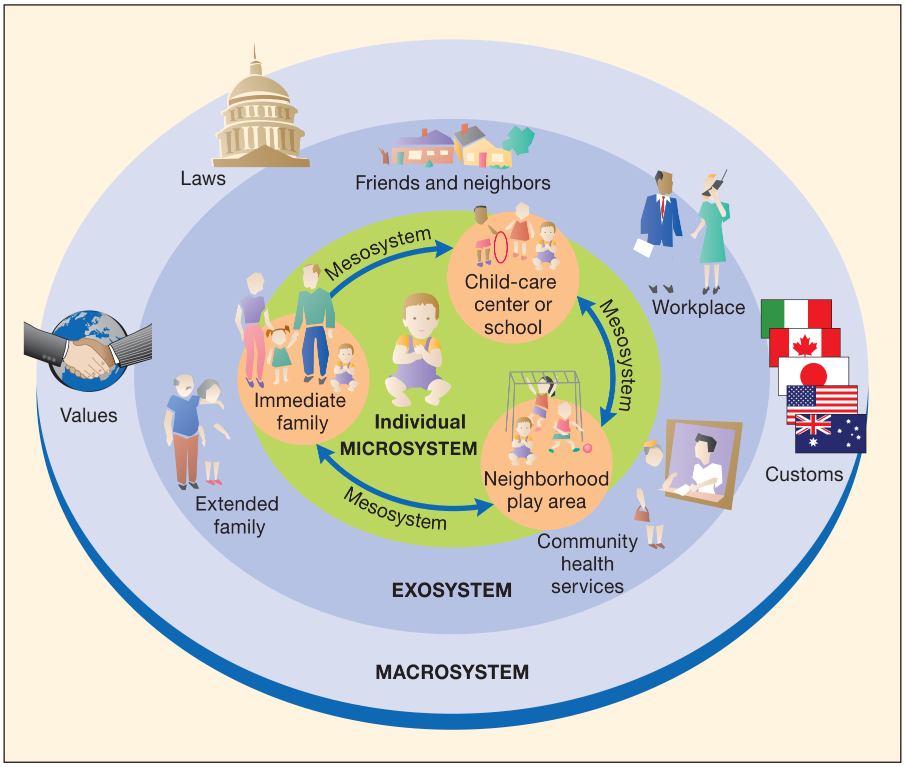

FIGURE 1.4 Structure of the environment in ecological systems theory. The *microsystem* concerns relations between the child and the immediate environment; the *mesosystem*, connections among immediate settings; the *exosystem*, social settings that affect but do not contain the child; and the *macrosystem*, the values, laws, customs, and resources of the culture that affect activities and interactions at all inner layers. The *chronosystem* (not pictured) is not a specific context. Instead, it refers to the dynamic, ever-changing nature of the person's environment.

The Mesosystem The second level of Bronfenbrenner's model, the **mesosystem,** encompasses connections between microsystems, such as home, school, neighborhood, and child-care center. For example, a child's academic progress depends not just on activities that take place in classrooms but also on parent involvement in school life and on the extent to which academic learning is carried over into the home (Gershoff & Aber, 2006). Similarly, parent–child interaction at home is likely to affect caregiver–child interaction in the child-care setting, and vice versa. Each relationship is more likely to support development when there are links between home and child care, in the form of visits and cooperative exchanges of information.

Family–neighborhood connections are especially important for economically disadvantaged children. Affluent families are less dependent on their immediate surroundings for social support, education, and leisure pursuits. They can afford to transport their children to lessons and entertainment and even, if necessary, to better-quality schools in distant parts of the community. In low-income neighborhoods, in-school and after-school programs that substitute for lack of other resources by providing child care and art, music, sports, scouting, and other enrichment activities are associated with improved school performance and a reduction in emotional and behavior problems in middle childhood (Peters, Petrunka, & Arnold, 2003; Vandell & Posner, 1999; Vandell, Reisner, & Pierce, 2007). In adolescence, too, religious youth groups, special-interest clubs, and other neighborhood organizations contribute to favorable development, including self-confidence, school achievement, educational aspirations, and responsible social behavior (Barnes et al., 2007; Kerestes & Youniss, 2003).

Yet in dangerous, disorganized neighborhoods, high-quality activities for children and adolescents are usually scarce, and home and neighborhood obstacles often combine to reduce involvement. Parents faced with financial and other stressors are less likely to encourage their children to participate (Kohen et al., 2008). In an investigation of elementary school students diverse in family income and neighborhood residence, those living in the least stimulating homes and the most disorganized neighborhoods were least likely to participate in after-school enrichment activities (Dearing et al., 2009). Thus, the neediest children were especially likely to miss out on these development-enhancing experiences.

The Exosystem

The **exosystem** consists of social settings that do not contain children but that nevertheless affect children's experiences in immediate settings. These can be formal organizations, such as parents' workplaces, their religious institutions, and health and welfare services in the community. For example, parents' work settings can support child rearing and, indirectly, enhance development through flexible work schedules, paid maternity and paternity leave, and sick leave for parents whose children are ill. Exosystem supports also can be informal, such as parents' social networks—friends and extended-family members who provide advice, companionship, and even financial assistance. Research confirms the negative impact of a breakdown in exosystem activities. Families who are affected by unemployment or who are socially isolated, with few personal or community-based ties, show increased rates of conflict and child abuse (Coulton et al., 2007). Refer to the Social Issues: Health box on the following page for an additional illustration of the power of the exosystem to affect family functioning and children's development.

The Macrosystem

The outermost level of Bronfenbrenner's model, the **macrosystem,** consists of cultural values, laws, customs, and resources. The priority that the macrosystem gives to children's needs affects the support they receive at inner levels of the environment. For example, in countries that require generous workplace benefits for employed parents and set high standards for child care, children are more likely to have favorable experiences in their immediate settings. As you will see later in this chapter and in other parts of this book, such programs are far less available in the United States than in other industrialized nations (Children's Defense Fund, 2009).

LOOK and LISTEN

Ask a parent to explain his or her most worrisome child-rearing challenge. Describe one source of support at each level of Bronfenbrenner's model that might ease the parent's stress and promote favorable child development.

An Ever-Changing System

According to Bronfenbrenner, the environment is not a static force that affects children in a uniform way. Instead, it is ever-changing. Important life events, such as the birth of a sibling, the beginning of school, a move to a new neighborhood, or parents' divorce, modify existing relationships between children and their environments, producing new conditions that affect development. In addition, the timing of environmental change affects its impact. The arrival of a new sibling has very different consequences for a homebound toddler than for a school-age child with many relationships and activities beyond the family.

Bronfenbrenner called the temporal dimension of his model the **chronosystem** (the prefix *chrono-* means "time"). Life changes can be imposed on the child, as in the examples just given. Alternatively, they can arise from within the child, since as children get older they select, modify, and create many of their own settings and experiences. How they do so depends on their physical, intellectual, and personality characteristics and their environmental opportunities. Therefore, in ecological systems theory, development is neither entirely controlled by environmental circumstances nor driven solely by inner dispositions. Rather, children are both products and producers of their environments: The child and the environment form a network of interdependent effects. Notice how our discussion of resilient children on pages 10–11 illustrates this idea. You will see many more examples in this book.

SOCIAL ISSUES: HEALTH

Family Chaos Undermines Children's Well-Being

Virtually all of us can recall days during our childhoods when family routines—regular mealtime, bedtime, homework time, and parent–child reading and playtimes—were disrupted, perhaps because of a change in a parent's job, a family illness, or a busy season of after-school sports. In some families, however, absence of daily structure is nearly constant, yielding a chaotic home life that interferes with healthy development (Fiese & Winter, 2010). An organized family life provides a supportive context for warm, involved parent–child interaction, which is essential to children's well-being.

Family chaos is linked to economic disadvantage—especially, single mothers with limited incomes struggling to juggle transportation challenges, inconvenient shift jobs, unstable child-care arrangements, and other daily hassles. But chaos is not limited to such families.

Survey findings reveal that considering U.S. families as a whole, mothers' time with children has remained fairly stable over the past three decades, and fathers' time has increased (Galinsky, Aumann, & Bond, 2009). But in many families, the way parents spend that time has changed. Across income levels and ethnic groups, both mothers and fathers report more multitasking while caring for children—for example, using mealtimes not just to eat but also to check homework, assign household chores, read to children, and plan family outings and celebrations (Bianchi & Raley, 2005; Serpell et al., 2002). Consequently, disruption in one family routine can disrupt others.

Possibly because of this compression of family routines, today's parents and children consistently say they have too little time together and desire more (Opinion Research Corporation, 2009; Roehlkepartain, 2004). For example, although regular mealtimes affect quality of relationships, only slightly more than half of U.S. families surveyed nationally report eating together from 3 to 5 times per week (CASA, 2006). Frequency of family meals is associated with wide-ranging positive outcomes—in childhood, enhanced language development and academic achievement, fewer behavior problems, and time spent sleeping; and in adolescence, reduced sexual risk taking, alcohol and drug use, and mental health problems. Shared mealtimes also increase the likelihood of a healthy diet and protect against obesity and adolescent eating disorders (Adam, Snell, & Pendry, 2007; Fiese & Schwartz, 2008). As these findings suggest, regular mealtimes are a general indicator of an organized family life and positive parental involvement.

But family chaos can prevail even when families do engage in joint activities. Also vital are the conditions under which these activities occur. Unpredictable, disorganized family meals involving harsh or lax parental discipline and hostile, disrespectful communication are associated with children's adjustment difficulties (Fiese, Foley, & Spagnola, 2006). As family time becomes pressured and overwhelming, its orderly structure diminishes, and warm, relaxed parent–child engagement disintegrates.

Diverse circumstances can trigger a pileup of limited parental emotional resources, breeding family chaos. In addition to *microsystem* and *mesosystem* influences (parents with mental health problems; parental separation and divorce; single parents with few or no supportive relationships), the *exosystem* is powerful: When family time is at the mercy of external forces—parents commuting several hours a day to and from work, child-care arrangements often failing, parents experiencing excessive workplace pressures or job loss—family routines are threatened.

Family chaos contributes to children's behavior problems, above and beyond its negative impact on parenting effectiveness (Coldwell, Pike, & Dunn, 2008). Chaotic surroundings induce in children a sense of being hassled and feelings of powerlessness, which engender anxiety and low self-esteem (Fiese & Winter, 2010).

Exosystem and macrosystem supports—including work settings with favorable family policies and high-quality child care that is affordable and reliable—can help prevent escalating demands on families that give way to chaos (Repetti & Wang, 2010). In one community, a child-care center initiated a take-home dinner program. Busy parents could special-order a healthy, reasonably priced family meal, ready to go at day's end to aid in making the family dinner a routine that enhances children's development.

The dynamic systems perspective views the child's mind, body, and physical and social worlds as a continuously reorganizing, integrated system. In response to the physical and psychological changes of adolescence, this girl and her father must develop a new, more mature relationship.

New Directions: Development as a Dynamic System

Today, researchers recognize both consistency and variability in children's development and want to do a better job of explaining variation. Consequently, a new wave of systems theorists focuses on how children alter their behavior to attain more advanced functioning. According to this **dynamic systems perspective,** the child's mind, body, and physical and social worlds form an *integrated system* that guides mastery of new skills. The system is *dynamic*, or constantly in motion. A change in any part of it—from brain growth to physical and social surroundings—disrupts the current organism–environment relationship. When this happens, the child actively reorganizes her behavior so the components of the system work together again but in a more complex, effective way (Fischer & Bidell, 2006; Spencer & Schöner, 2003; Thelen & Smith, 2006).

Researchers adopting a dynamic systems perspective try to find out just how children attain new levels of organization by studying their behavior while they are in transition (Thelen & Corbetta, 2002). For example, when presented with an attractive toy, how does a 3-month-old baby who engages in many, varied movements discover how to reach for it? On hearing a new word, how does a 2-year-old figure out the category of objects or events to which it refers?

Dynamic systems theorists acknowledge that a common human genetic heritage and basic regularities in children's physical and social worlds yield certain universal, broad outlines of development. But biological makeup, everyday tasks, and the people who support children in mastery of those tasks vary greatly, leading to wide individual differences in specific skills. Even when children master the same skills, such as walking, talking, or adding and subtracting, they often do so in unique ways. And because children build competencies by engaging in real activities in real contexts, different skills vary in maturity within the same child. From this perspective, development cannot be characterized as a single line of change. As Figure 1.5 shows, it is more like a web of fibers branching out in many directions, each representing a different skill area that may undergo both continuous and stagewise transformations (Fischer & Bidell, 2006).

The dynamic systems view has been inspired by other scientific disciplines, especially biology and physics. It also draws on information-processing and contextual theories—evolutionary developmental psychology, sociocultural theory, and ecological systems theory.

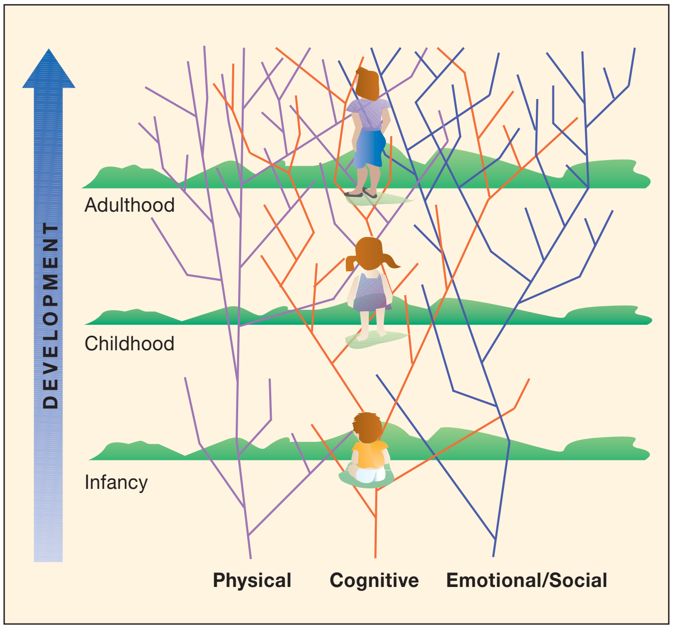

FIGURE 1.5 The dynamic systems view of development. Rather than envisioning a single line of stagewise or continuous change (refer to Figure 1.2 on page 7), dynamic systems theorists conceive of development as a web of fibers branching out in many directions. Each strand in the web represents a skill within the major domains of development—physical, cognitive, and emotional/social. The differing directions of the strands signify possible variations in paths and outcomes as the child masters skills necessary to participate in diverse contexts. The interconnections of the strands at each row of "hills" portray stagelike changes—periods of major transformation in which various skills work together as a functioning whole. As the web expands, skills become more numerous, complex, and effective. (Adapted from Fischer & Bidell, 2006.)

Dynamic systems research is still in its early stages. The perspective has largely been applied to children's motor and cognitive skills, but some investigators have drawn on it to explain emotional and social development as well (Campos, Frankel, & Camras, 2004; Fogel & Garvey, 2007; Lewis, 2000). Consider the young teenager, whose body and reasoning powers are changing massively and who also is confronting the challenges of secondary school. Researchers following parent–child interaction over time found that the transition to adolescence disrupted family communication. It became unstable and variable for several years—a mix of positive, neutral, and negative exchanges (Granic et al., 2003). Gradually, as parent and adolescent devised new, more mature ways of relating to one another, the system reorganized and stabilized. Once again, interaction became predictable and mostly positive.

As dynamic systems research illustrates, today investigators are tracking and analyzing development in all its complexity. In doing so, they hope to move closer to an all-encompassing approach to understanding change.

ASK YOURSELF

Review ■ Explain how each recent theoretical perspective regards children as active contributors to their own development.

Connect ■ Return to the Biology and Environment box on pages 10–11. How does the story of John and Gary illustrate bidirectional influences within the microsystem, as described in ecological systems theory?

Apply ■ Mario wants to find out precisely how children of different ages recall stories. Anna is interested in how adult–child communication in different cultures influences children's storytelling. Which theoretical perspective has Mario probably chosen? How about Anna? Explain.

Reflect ■ To illustrate the chronosystem in ecological systems theory, select an important event from your childhood, such as a move to a new neighborhood, a class with an inspiring teacher, or parental divorce. How did the event affect you? How might its impact have differed had you been five years younger? How about five years older?

Comparing Child Development Theories

▶ Identify the stand taken by each major theory on the basic issues of child development.

In the preceding sections, we reviewed major theoretical perspectives in child development research. They differ in many respects. First, they focus on different domains of development. Some, such as the psychoanalytic perspective and ethology, emphasize emotional and social development. Others, such as Piaget's cognitive-developmental theory, information processing, and Vygotsky's sociocultural theory, stress changes in thinking. The remaining approaches—behaviorism, social learning theory, evolutionary developmental psychology, ecological systems theory, and the dynamic systems perspective—discuss many aspects of children's functioning. Second, every theory contains a point of view about child development. **TAKE A MOMENT...** As we conclude our review of theoretical perspectives, identify the stand each theory takes on the controversial issues presented at the beginning of this chapter. Then check your analysis against Table 1.3 on page 32.

Finally, we have seen that every theory has strengths and limitations. Perhaps you find that you are attracted to some theories but have doubts about others. As you read more about child development in later chapters, you may find it useful to keep a notebook in which you test your theoretical likes and dislikes against the evidence. Don't be surprised if you revise your ideas many times, just as theorists have done since the beginning of systematic child study. By the end of this course, you will have built your own personal perspective on child development. Very likely, it will be an *eclectic position*, or blend of several theories, because every viewpoint we have considered has contributed to what we know about children.

TABLE 1.3 Stances of Major Theories on Basic Issues in Child Development

THEORY	CONTINUOUS OR DISCONTINUOUS DEVELOPMENT?	ONE COURSE OF DEVELOPMENT OR MANY?	RELATIVE INFLUENCE OF NATURE AND NURTURE?
Psychoanalytic perspective	***Discontinuous:*** Psychosexual and psychosocial development takes place in stages.	***One course:*** Stages are assumed to be universal.	***Both nature and nurture:*** Innate impulses are channeled and controlled through child-rearing experiences. *Early experiences* set the course of later development.
Behaviorism and social learning theory	***Continuous:*** Development involves an increase in learned behaviors.	***Many possible courses:*** Behaviors reinforced and modeled may vary from child to child.	***Emphasis on nurture:*** Development results from conditioning and modeling. *Both early and later experiences* are important.
Piaget's cognitive-developmental theory	***Discontinuous:*** Cognitive development takes place in stages.	***One course:*** Stages are assumed to be universal.	***Both nature and nurture:*** Development occurs as the brain grows and children exercise their innate drive to discover reality in a generally stimulating environment. *Both early and later experiences are important.*
Information processing	***Continuous:*** Children gradually improve in perception, attention, memory, and problem-solving skills.	***One course:*** Changes studied characterize most or all children.	***Both nature and nurture:*** Children are active, sense-making beings who modify their thinking as the brain grows and they confront new environmental demands. *Both early and later experiences* are important.
Ethology and evolutionary developmental psychology	***Both continuous and discontinuous:*** Children gradually develop a wider range of adaptive behaviors. Sensitive periods occur, in which qualitatively distinct capacities emerge fairly suddenly.	***One course:*** Adaptive behaviors and sensitive periods apply to all members of a species.	***Both nature and nurture:*** Evolution and heredity influence behavior, and learning lends greater flexibility and adaptiveness to it. In sensitive periods, *early experiences* set the course of later development.
Vygotsky's sociocultural theory	***Both continuous and discontinuous:*** Language acquisition and schooling lead to stagewise changes. Dialogues with more expert members of society also lead to continuous changes that vary from culture to culture.	***Many possible courses:*** Socially mediated changes in thought and behavior vary from culture to culture.	***Both nature and nurture:*** Heredity, brain growth, and dialogues with more expert members of society jointly contribute to development. *Both early and later experiences* are important.
Ecological systems theory	***Not specified.***	***Many possible courses:*** Children's characteristics join with environmental forces at multiple levels to mold development in unique ways.	***Both nature and nurture:*** Children's characteristics and the reactions of others affect each other in a bidirectional fashion. Layers of the environment influence child-rearing experiences. *Both early and later experiences* are important.
Dynamic systems perspective	***Both continuous and discontinuous:*** Change in the system is always ongoing. Stagelike transformations occur as children reorganize their behavior so components of the system work as a functioning whole.	***Many possible courses:*** Biological makeup, everyday tasks, and social experiences vary, yielding wide individual differences in specific skills.	***Both nature and nurture:*** The child's mind, body, and physical and social surroundings form an integrated system that guides mastery of new skills. *Both early and later experiences* are important.

- Explain the importance of social policies for safeguarding children's well-being, and cite factors that affect the policy-making process, noting the role of child development research.

Applied Directions: Child Development and Social Policy

In recent years, the field of child development has become increasingly concerned with applying its vast knowledge base to solving pressing social problems. Today, we know much more than ever before about family, school, and community contexts that foster physically healthy and cognitively and socially competent children. Yet a nation's values, policies, and programs powerfully affect children's experiences in these immediate contexts.

Social policy is any planned set of actions by a group, institution, or governing body directed at attaining a social goal. When widespread social problems arise, nations attempt to solve them through a special type of social policy called **public policy**—laws and government programs designed to improve current conditions. Return to Bronfenbrenner's ecological systems theory, and note how the concept of the macrosystem suggests that sound public policies are essential for protecting children's well-being. For example, when poverty increases and families become homeless, a country might decide to build more low-cost housing, provide economic aid to homeowners having difficulty making mortgage payments, raise the minimum wage, and increase welfare benefits. When reports indicate that many children are not achieving well in school, federal and state governments might grant more tax money to school districts, strengthen teacher preparation, and make sure that help reaches children who need it most at the earliest possible age.

U.S. public policies safeguarding children and youths have lagged behind policies in other developed nations. A striking indicator is that the United States outranks nearly all other economically advanced countries in child poverty (UNICEF, 2007, 2010b). Nearly 21 percent of U.S. children are poor—a rate that climbs to 33 percent for Hispanic children, 34 percent for Native-American children, and 36 percent for African-American children. Families hit hardest are parents under age 25 with young children. For single mothers with infants and preschoolers, the poverty rate in the United States is nearly 50 percent (DeNavas-Walt, Proctor, & Smith, 2009; U.S. Census Bureau, 2011b). These dire statistics are expected to worsen, due to the recent economic recession (Foundation for Child Development, 2010). Historically, a lag of several years typically occurs between the onset of a recession and its worst impact on children.

AP IMAGES/KEVORK DJANSEZIAN

In Los Angeles, a 4-yr-old waits to receive a "back-to-school" give-away of clothing, shoes, and school supplies. Stricken by poverty at such a young age, this boy faces a high risk of lifelong health, cognitive, and social problems.

Furthermore, of all Western nations, the United States has the highest percentage of extremely poor children. Nearly 8 percent of U.S. children live in deep poverty (at less than half the poverty threshold, the income level judged necessary for a minimum living standard). In contrast, in Denmark, Finland, Norway, and Sweden, child poverty rates have remained at 5 percent or less for several decades, and deep child poverty is rare (UNICEF, 2007, 2010b). The earlier poverty begins, the deeper it is, and the longer it lasts, the more devastating are its effects. Children of poverty are more likely than other children to suffer from lifelong poor physical health, persistent deficits in cognitive development and academic achievement, high school dropout, early pregnancy, mental illness, and antisocial behavior (Aber, Jones, & Raver, 2007; Dearing, McCartney, & Taylor, 2006; Morgan et al., 2009; Ryan, Fauth, & Brooks-Gunn, 2006).

As Table 1.4 on page 34 reveals, the United States does not rank well on any key measure of children's health and well-being. And in an international assessment of children's overall well-being, in which each economically advanced country's combined material, health, and educational performance was compared with the average of 24 nations as a whole, the United States ranked at the bottom (see Figure 1.6 on page 34) (UNICEF, 2010b).

The problems of U.S. children and youths extend beyond the indicators in Table 1.4. Despite improved health-care provisions signed into law in 2010, the United States remains the only industrialized nation without a universal, publicly funded health-care system. Approximately 10 percent of U.S. children—most in low-income families—have no health insurance (Kenney, Lynch, & Cook, 2010). Furthermore, the United States has been slow to move toward national standards and funding for child care. Affordable child care is in short supply, and much of it is substandard in quality (Lamb & Ahnert, 2006; Muenchow & Marsland, 2007). In families affected by divorce, weak enforcement of child support payments heightens poverty in mother-headed households. When non-college-bound young

TABLE 1.4 How Does the United States Compare to Other Nations on Indicators of Children's Health and Well-Being?

INDICATOR	U.S. RANK[a]	SOME COUNTRIES THE UNITED STATES TRAILS
Childhood poverty (among 24 industrialized nations considered)	24th	Canada, Czech Republic, Germany, United Kingdom, Norway, Sweden, Poland, Spain[b]
Infant deaths in the first year of life (worldwide)	28th	Canada, Hong Kong, Ireland, Singapore, Spain
Teenage pregnancy rate (among 28 industrialized nations considered)	28th	Australia, Canada, Czech Republic, Denmark, Hungary, Iceland, Poland, Slovakia
Public expenditure on education as a percentage of gross domestic product[c] (among 22 industrialized nations considered)	12th	Belgium, France, Iceland, New Zealand, Portugal, Spain, Sweden
Public expenditure on early childhood education and child care as a percentage of gross domestic product (among 14 industrialized nations considered)	9th	Austria, Germany, Italy, Netherlands, France, Sweden
Public expenditure on health as a percentage of total health expenditure, public plus private (among 27 industrialized nations considered)	26th	Austria, Australia, Canada, France, Hungary, Iceland, Switzerland, New Zealand

[a] 1 = highest, or best, rank.

[b] U.S. childhood poverty and, especially, deep poverty rates greatly exceed poverty in these nations. For example, the poverty rate is 12 percent in United Kingdom, 9.5 percent in Canada, 6 percent in the Czech Republic, 4 percent in Norway, and 2.5 percent in Sweden. Deep poverty affects just 2.5 percent of children in Canada, and a fraction of 1 percent in the other countries just listed.

[c] Gross domestic product is the value of all goods and services produced by a nation during a specified time period. It provides an overall measure of a nation's wealth.

Sources: Canada Campaign 2000, 2009; OECD, 2010a, 2010b; U.S. Census Bureau, 2011b; U.S. Department of Education, 2011b.

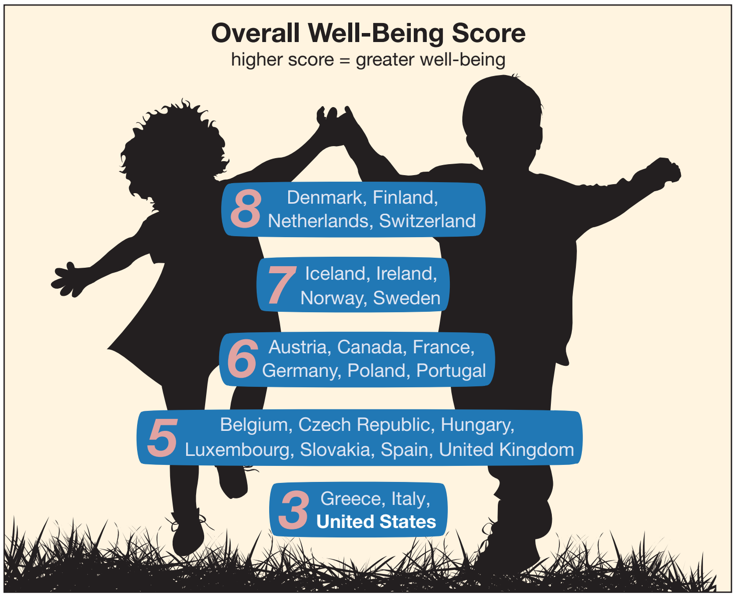

FIGURE 1.6 **Children's overall well-being in 24 economically advanced nations.** Researchers determined the percentage of children in each country who fell below the average for all nations combined on three dimensions of inequality: (1) *material well-being* (prevalence of deep poverty; living space and educational resources in the home); (2) *educational well-being* (high school students' literacy, math, and science achievement); and (3) *health well-being* (adolescents' self-reported healthy eating, physical activity, and health complaints). Then, for each dimension, 3 points were assigned for a better-than-average performance, 2 points for a close-to-average performance, and 1 point for a below-average performance. Thus, the highest score a country could attain was 9, the lowest score 3. (Adapted from UNICEF, 2010, *The Children Left Behind: A League Table of Inequality in the World's Richest Countries, Innocenti Report Card 9*, p. 2, Florence, Italy: Innocenti Research Centre.)

people finish high school, many lack the vocational preparation they need to contribute fully to society. And 8 percent of 16- to 24-year-olds who dropped out of high school have not returned to earn a diploma (U.S. Department of Education, 2011b).

Why have attempts to help children and youths been so difficult to realize in the United States? A complex set of cultural, political, and economic forces is involved.

Culture and Public Policies

TAKE A MOMENT... Consider the question, Who should be responsible for rearing young children? How would you answer it? Here are some typical responses from my students: "If parents decide to have a baby, then they should be ready to care for it." "Most people are not happy about others intruding into family life." "If parents work hard, then they won't need government assistance." These statements reflect a widely held opinion in the United States—that the care and rearing of young children, and paying for that care, are the duty of parents, and only parents. This view has a long history—one in which independence, self-reliance, and the privacy of family life emerged as central American values (Halfon & McLearn, 2002). It is one reason, among others, that the public has been slow to endorse government-supported benefits for all families, such as high-quality child care and paid employment leave for meeting family needs. And it has also contributed to the large number of U.S. children who remain poor, even though their parent or parents are gainfully employed (Gruendel & Aber, 2007; Pohl, 2002; UNICEF, 2007, 2010).

Consider our discussion so far, and you will see that it reflects cultural variation in values that strongly influence public policies: the extent to which *individualism* versus *collectivism* prevails. In **individualistic societies,** people think of themselves as separate entities and are largely concerned with their own personal needs. In **collectivist societies,** people define themselves as part of a group and stress group goals over individual goals (Triandis, 1995, 2005). As these definitions suggest, the two cultural patterns are associated with two distinct views of the self. Individualistic societies value an *independent self,* which emphasizes personal achievement and individual choice. In contrast, collectivist societies value an *interdependent self,* which stresses social harmony, obligations to others, and collaboration. Both independence and interdependence are part of the makeup of every person and occur in varying mixtures (Greenfield et al., 2003; Tamis-LeMonda et al., 2008). But societies vary greatly in the extent to which they emphasize each alternative and—as later chapters will reveal—instill it in their young.

Although individualism tends to increase as cultures become more complex, cross-national differences remain. The United States is strongly individualistic, whereas most Western European countries lean toward collectivism.

Furthermore, less consensus exists among American than among European citizens on issues of child and family policy, resulting in fewer and more limited programs—ones that target the most economically disadvantaged while leaving many needy children unserved (Ripple & Zigler, 2003). And good social programs are expensive; they must compete for a fair share of a country's economic resources. Children can easily remain unrecognized because they cannot vote or speak out to protect their own interests. Instead, they must rely on the goodwill of others to make them an important government priority.

Without vigilance from child advocates, policies directed at solving a particular social problem can work at cross-purposes with children's well-being, leaving them in dire straits or even worsening their condition. Consider, for example, U.S. welfare policy aimed at returning welfare recipients to the workforce. As the Social Issues: Health box on page 36 makes clear, these policies can help or harm children, depending on whether they lift a family out of poverty.

Contributions of Child Development Research

As the evidence in the Social Issues: Health box suggests, for a policy to be effective in meeting children's needs, research must guide it at every step—during design, implementation, and evaluation of the program. Events of the 1960s and 1970s initiated the current trend toward greater involvement of child development researchers in the policy process (Phillips & Styfco, 2007).

For example, in 1965, research on the importance of early experiences for children's intellectual development played a major role in the founding of Project Head Start, the largest educational and family-services intervention program for poverty-stricken preschool children in the United States. In Chapter 8, we will see that several decades of research on early rapid brain growth and plasticity and the short- and long-term benefits of early intervention helped Head Start survive and contributed to repeated increases in government support (Guerra, Graham, & Tolan, 2011). In another instance, findings on the severe impact of malnutrition on early brain development led to the establishment of the U.S. Special Supplemental Food Program for Women, Infants, and Children (WIC). Since the 1970s, WIC has supplied poverty-stricken women and their young children with food packages, nutrition education, breastfeeding support, and referral to health and social services.

At this California resource center, families learn about healthy eating and also receive food. Programs designed to ensure adequate child nutrition are partly shaped by child development research, which recognizes the impact of public policy.

SOCIAL ISSUES: HEALTH

Welfare Reform, Poverty, and Child Development

In 1997, the United States changed its welfare policy, instituting welfare-to-work programs that ended decades of guaranteed government financial aid to needy families. In the revised system, called Temporary Aid to Needy Families (TANF), after time-limited assistance, recipients must go to work or face reduced or terminated benefits. The goal is to encourage families to become self-sufficient. A family can be on TANF for only 24 continuous months, with a lifetime limit of 60 months, and the states can further restrict these benefits. For example, a state can prevent payments from increasing if recipients have more children, and it can deny teenage single mothers any benefits.

Until recently, most evaluations of TANF focused on declines in the number of families on the welfare rolls. By these standards, welfare-to-work seemed to be a resounding success. But as researchers looked more closely, they found that some people made successful transitions to financial independence—typically, those who had more schooling and fewer mental health problems. Others, however, had difficulty meeting work requirements, lost their benefits, and fell deeper into poverty (Lower-Basch, 2010). For example, as welfare caseloads declined, the incomes of low-skilled, less educated single mothers dropped sharply (Lindsey & Martin, 2003).

Designers of welfare-to-work assumed it would be beneficial for children. But moving off welfare without increasing family income poses serious risks to child development. In one study, mothers who left welfare and also left poverty engaged in more positive parenting and had preschoolers who showed more favorable cognitive development, compared with working mothers whose incomes remained below the poverty threshold. Among these mothers, harsh, coercive parenting remained high (Smith et al., 2001). In other research, families who moved from welfare to a combination of welfare and work experienced a greater reduction in young children's behavior problems than families who moved to total reliance on work (Dunifon, Kalil, & Danziger, 2003; Gennetian & Morris, 2003). Why was the welfare–work combination so beneficial? Most welfare recipients must take unstable jobs with erratic work hours, low wages, and minimal or no benefits. Working while retaining some welfare support probably gave mothers an added sense of economic stability. It also sustained government-provided health insurance (Medicaid), a major source of U.S. parents' worry about leaving welfare (Slack et al., 2007). The resulting reduction of financial anxiety seemed to enhance children's adjustment.

In sum, welfare reform promotes children's development only when it results in a more adequate standard of living. Punitive aspects of welfare-to-work that reduce or cut off benefits push families deeper into poverty, with destructive consequences for children's well-being. Because of a shortage of affordable child care in the United States (care for one child can consume 50 percent or more of a minimum-wage earner's income), mothers of young children are least able to earn enough by working. Yet poverty is most harmful to development when it occurs early in life (see page 33).

Welfare policies in other Western nations do not just encourage parents to be better providers. They also protect children from the damaging effects of poverty. Great Britain, for example, reduced its child poverty rate by more than half over the past decade, continuing to do so even during the recent recession. (In contrast, U.S. child poverty is now at its highest level in 20 years.)

How did Britain do so? First, it took steps "to make work pay"—by initiating a minimum wage sufficient to cover a family's basic needs, by reducing taxes for low-income workers, and by providing a tax credit to employed parents with limited incomes (Waldfogel, 2010, p. 4). Second, it raised the economic well-being of families with children, regardless of whether parents were employed, by guaranteeing all a modest minimum income and providing an extra amount for families with young children. Finally, it invested in children in ways that support working parents while preventing the transfer of poverty to the next generation—instituting free universal preschool for all 3- and 4-year-olds, expanding government child-care subsidies, and raising standards for child-care quality. The British success story offers important lessons. To effectively tackle poverty, U.S. policies must help poor families rear children while they move toward financial independence.

AP IMAGES/RICH PEDRONCELLI

A young mother applies for food stamps, health coverage, and cash assistance for her 5-year-old. A restrictive, time-limited welfare-to-work program did not lead to self-sufficiency but, instead, has left her unemployed and unable to meet her child's basic needs.

As researchers examined the impact of child and family services, they saw how settings remote from children's daily lives affect their well-being. As a result, investigators broadened their focus to include wider social contexts, such as workplace, community, mass media, and government. They also addressed the impact of societal changes on children, including high rates of poverty, divorce, family violence, teenage parenthood, maternal employment, and nonparental child care. All these efforts have helped to refine existing policies, inspire new initiatives, and expand our understanding of child development.

Over the past 50 years, the number of policy-relevant articles in *Child Development,* one of the field's leading scientific journals, has increased fivefold (Phillips & Styfco, 2007).

The field of child development now recognizes that sound public policy is among the most powerful tools for preventing developmental problems and enhancing children's quality of life.

Looking Toward the Future

Public policies aimed at fostering children's development can be justified on two grounds. The first is that children are the future—the parents, workers, and citizens of tomorrow. Investing in children yields valuable returns to a nation's economy and quality of life (Heckman & Masterov, 2004).

Second, child-oriented policies can be defended on humanitarian grounds—children's basic rights as human beings. In 1989, the U.N. General Assembly, with the assistance of experts from many child-related fields, drew up the *Convention on the Rights of the Child,* a legal agreement among nations that commits each cooperating country to work toward guaranteeing environments that foster children's development, protect them from harm, and enhance their community participation and self-determination. Examples of rights include the highest attainable standard of health; an adequate standard of living; free and compulsory education; a happy, understanding, and loving family life; protection from all forms of abuse and neglect; and freedom of thought, conscience, and religion, subject to appropriate parental guidance and national law.

Although the United States played a key role in drawing up the Convention, it is one of only two nations in the world whose legislature has not yet ratified it. (The other is war-torn Somalia, which does not have a centralized government in full control of the country.) American individualism has stood in the way. Opponents maintain that the Convention's provisions would shift the burden of child rearing from the family to the state (Melton, 2005).

Although the worrisome condition of many children and families persists, efforts are being made to improve their condition. Throughout this book, we will discuss many successful programs that could be expanded. Also, growing awareness of the gap between what we know and what we do to better children's lives has led experts in child development to join with concerned citizens as advocates for more effective policies. As a result, several influential interest groups devoted to the well-being of children have emerged.

In the United States, one of the most vigorous is the Children's Defense Fund—a nonprofit organization founded by Marian Wright Edelman in 1973—which engages in public education, legal action, drafting of legislation, congressional testimony, and community organizing. It also publishes many reports on U.S. children's condition, government-sponsored programs that serve children and families, and research-based proposals for improving those programs. To learn more about the Children's Defense Fund, visit its website at *www.childrensdefense.org*. Another energetic advocacy organization is the National Center for Children in Poverty, dedicated to advancing the economic security, health, and welfare of U.S. children in low-income families by informing policy makers of relevant research. To explore its activities, visit *www.nccp.org*.

Finally, more researchers are partnering with community and government agencies to enhance the social relevance of their investigations. They are also doing a better job of disseminating their findings in easily understandable, compelling ways, through reports to government officials, websites aimed at increasing public understanding, and collaborations with the media to ensure accurate and effective reporting in newspaper stories, magazine articles, and radio and television documentaries (Gruendel & Aber, 2007; Shonkoff & Bales, 2011). In these ways, researchers are helping to create the sense of immediacy about the condition of children and families that is necessary to spur a society into action.

AP IMAGES/GERALD HERBERT

First Lady Michelle Obama's "Let's Move!" campaign gives a high public profile to the issue of childhood obesity. Such advocacy efforts help create a sense of immediacy about improving conditions for children and families.

ASK YOURSELF

Review ■ Explain why both strong advocacy and policy-relevant research are vital for designing and implementing public policies that meet children's needs.

Connect ■ Give an example of how cultural values and economic decisions affect child-oriented public policies. What level of Bronfenbrenner's ecological systems theory contains these influences?

Apply ■ Check your local newspaper or one or two national news magazines to see how often articles on the condition of children and families appear. Why is it important for researchers to communicate with the general public about children's needs?

Reflect ■ Do you agree with the widespread American sentiment that government should not become involved in family life? Explain.

SUMMARY

The Field of Child Development (p. 4)

What is the field of child development, and what factors stimulated its expansion?

- **Child development** is an area of study devoted to understanding constancy and change from conception through adolescence. It is part of the larger, interdisciplinary field **developmental science,** which includes changes throughout the lifespan. Research on child development has been stimulated both by scientific curiosity and social pressures to better children's lives.

How is child development typically divided into domains and periods?

- Development is often divided into physical, cognitive, and emotional and social domains. These domains are not really distinct; they combine in an integrated, holistic fashion.
- Researchers generally divide child development into the following age periods: (1) the prenatal period (conception to birth), (2) infancy and toddlerhood (birth to 2 years), (3) early childhood (2 to 6 years), (4) middle childhood (6 to 11 years), and (5) adolescence (11 to 18 years). To describe the prolonged transition to adulthood typical of contemporary young people in industrialized nations, researchers have posited a new period of development, emerging adulthood, spanning ages 18 to 25 years.

Basic Issues (p. 6)

Identify three basic issues on which child development theories take a stand.

- Each **theory** of child development takes a stand on three fundamental issues: (1) Is development a **continuous** process, or is it **discontinuous,** following a series of distinct **stages?** (2) Does one general course of development characterize all children, or are there many possible courses, influenced by the **contexts** in which children grow up? (3) Are genetic or environmental factors more important in influencing development (the **nature–nurture controversy**), and are individual differences stable or characterized by substantial **plasticity?**
- Recent theories take a balanced stand on these issues. And contemporary researchers realize that answers may vary across domains of development and even, as research on **resilience** illustrates, across individuals.

Historical Foundations (p. 10)

Describe major historical influences on theories of child development.

- As early as medieval times, the sixth through the fifteenth centuries, childhood was regarded as a separate period of life.
- In the sixteenth and seventeenth centuries, the Puritan conception of original sin led to a harsh philosophy of child rearing. The seventeenth-century Enlightenment brought a new emphasis on human dignity and respect that led to more humane views of childhood. Locke's notion of the child as a tabula rasa ("blank slate") provided the basis for twentieth-century behaviorism, while Rousseau's view of children as noble savages foreshadowed the concepts of stage and **maturation**.
- Inspired by Darwin's theory of evolution, efforts to observe children directly began in the late nineteenth and early twentieth centuries. Soon after, Hall and Gesell introduced the **normative approach,** which produced a large body of descriptive facts about children. Binet and Simon constructed the first successful intelligence test, which sparked interest in individual differences in development and led to a heated controversy over nature versus nurture.
- Baldwin's theory was ahead of its time in granting nature and nurture equal importance and regarding children and their social surroundings as mutually influential.

Mid-Twentieth-Century Theories (p. 14)

What theories influenced child development research in the mid-twentieth century?

- In the 1930s and 1940s, psychiatrists and social workers turned to the **psychoanalytic perspective** for help in treating children's emotional and behavior problems. In Freud's **psychosexual theory,** children move through five stages, during which three parts of the personality—id, ego, and superego—become integrated.
- Erikson's **psychosocial theory** builds on Freud's theory, emphasizing the development of culturally relevant attitudes and skills, and—with the addition of three adult stages—the lifespan nature of development.

© DANITA DELMONT/ALAMY

- As the psychoanalytic perspective gained in prominence, **behaviorism** emerged, focusing on directly observable events (stimuli and responses) in an effort to create an objective science of psychology. Skinner's operant conditioning theory emphasizes the role of reinforcement and punishment in increasing or decreasing the frequency of a behavior. A related approach, Alfred Bandura's **social learning theory,** focuses on modeling as the major means through which children acquire new responses. Its most recent revision, a social-cognitive approach, stresses the role of thinking in children's imitation and learning.
- Behaviorism and social learning theory gave rise to **behavior modification** procedures to eliminate undesirable behaviors and increase desirable responses.

- Piaget's **cognitive-developmental theory** emphasizes that children actively construct knowledge as they move through four stages, beginning with the baby's sensorimotor action patterns and ending with the abstract, systematic reasoning system of the adolescent and adult. Piaget's theory has stimulated a wealth of research on children's thinking and has encouraged educational programs that emphasize discovery learning.

Recent Theoretical Perspectives (p. 21)

Describe recent theoretical perspectives on child development.

- **Information processing** views the mind as a complex, symbol-manipulating system, much like a computer. This approach helps investigators achieve a detailed understanding of what children of different ages do when faced with tasks and problems.
- Over the past three decades, researchers in **developmental cognitive neuroscience** have begun to study the relationship between changes in the brain and the developing child's cognitive processing and behavior patterns. They have made progress in identifying the types of experiences to which the brain is sensitive at various ages and in clarifying the brain bases of many learning and behavior disorders.
- Four contemporary perspectives emphasize contexts for development. **Ethology** stresses the adaptive value of behavior and inspired the **sensitive period** concept. In a new area of research called **evolutionary developmental psychology,** researchers have extended this emphasis, seeking to understand the adaptiveness of species-wide competencies as they change over time.
- Vygotsky's **sociocultural theory**, which views cognitive development as a socially mediated process, has enhanced our understanding of cultural variation. Through cooperative dialogues with more expert members of society, children use language to guide their own thought and actions and acquire culturally relevant knowledge and skills.
- Bronfenbrenner's **ecological systems theory** views the child as developing within a complex system of relationships affected by multiple, nested layers of the environment—**microsystem, mesosystem, exosystem,** and **macrosystem.** The **chronosystem** represents the dynamic, ever-changing nature of children and their experiences.
- A new wave of theorists has adopted a **dynamic systems perspective** to better understand how children alter their behavior to attain more advanced functioning. According to this view, the mind, body, and physical and social worlds form an integrated system that guides mastery of new skills. A change in any part of the system prompts the child to reorganize her behavior so the various components work together again, but in a more complex, effective way.

Comparing Child Development Theories (p. 31)

Identify the stand taken by each major theory on the basic issues of child development.

- Theories that are major forces in child development research vary in their focus on different domains of development, in their view of how development occurs, and in their strengths and limitations. (For a full summary, see Table 1.3 on page 32.)

Applied Directions: Child Development and Social Policy (p. 32)

Explain the importance of social policies for safeguarding children's well-being, and cite factors that affect the policy-making process, noting the role of child development research.

- The field of child development has become increasingly concerned with applying its vast knowledge base to solving pressing social problems. When widespread problems arise, nations attempt to solve them through a special type of **social policy** called **public policy**. Favorable laws and government programs are essential for safeguarding children's positive experiences in family, school, and community contexts.

AP IMAGES/GERALD HERBERT

- One important factor influencing public policies is the extent to which a society's values are **individualistic** (emphasizing individual well-being) or **collectivist** (emphasizing group needs and goals). Other factors are a nation's economic resources and the role of organizations and individuals that advocate for children's needs. Largely because of strongly individualistic American values, U.S. public policies favoring children and youths have lagged behind policies in other developed nations.
- Policy-relevant research helps refine existing policies, forge new policy directions, and expand our understanding of child development.

CULTURAL INFLUENCES: *Immigrant Youths: Adapting to a New Land*

Reliability and Validity: Keys to Scientifically Sound Research
Reliability • Validity

General Research Designs
Correlational Design • Experimental Design • Modified Experimental Designs

SOCIAL ISSUES: EDUCATION: *Can Musical Experiences Enhance Intelligence?*

Designs for Studying Development
The Longitudinal Design • The Cross-Sectional Design • Improving Developmental Designs

Ethics in Research on Children

SOCIAL ISSUES: HEALTH: *Children's Research Risks: Developmental and Individual Differences*

As my colleague Ron crossed the street between his academic department and our laboratory school, his face reflected apprehension. After weeks of planning, Ron was ready to launch his study on the development of children's peer relations. From his own school years, he recalled the anguish of several classmates who were taunted and shunned by peers. Ron thought his research could help rejected children, many of whom go on to lead troubled lives. So he was puzzled by a request to appear before the school's research committee.

The meeting included teachers and administrators charged with evaluating research proposals for their ethical integrity. A third-grade teacher spoke up: "Ron, I see the value of your work, but frankly, I'm concerned about your asking my students to indicate which classmates they like most and which they like least. I've got a couple of kids who are strongly disliked, and I'm doing my best to keep a lid on the situation. There's also an immigrant West Indian child who's new to my classroom, and she's being ostracized because of the way she dresses and speaks. If you come in and start sensitizing my class to whom they like and dislike, the children are going to share these opinions. Unfortunately, I think your study could promote conflict and negative interaction!"

Imagine Ron's dismay at the prospect of abandoning his research. This chapter looks at the research process—the many challenges investigators face as they plan and implement studies of children. By the time Ron arrived at the laboratory school, prepared to collect his data, he had already traveled a long and arduous path. First, he had spent many weeks developing a researchable idea, based on theory and prior knowledge of children's peer relations. Next, he had chosen an appropriate research strategy, a step that involves two main tasks: First, he selected from a variety of *research methods*—participants' specific activities, such as taking tests, answering questionnaires, responding to interviews, or being observed. Second, he decided on a *research design*—an overall plan for his study that would permit the best test of his research idea. Finally, Ron had scrutinized his procedures for any possible harm they might cause to participants.

Still, as Ron approached a committee charged with protecting the welfare of research participants, he faced an ethical dilemma. Research, whether on animals or humans, must meet certain standards that protect participants from stressful treatment. Because of children's immaturity and vulnerability, extra precautions must be taken to ensure that their rights are not violated. In the final section of this chapter, you will learn how Ron resolved the committee's challenge to the ethical integrity of his research.

From Theory to Hypothesis

In Chapter 1, we saw how theories structure the research process by identifying important research concerns and, occasionally, preferred methods for collecting data. We also discussed how theories guide the application of findings to real-life circumstances and practices with children. In fact, research usually begins with a prediction drawn from a theory, called a **hypothesis.** Think back to the various child development

© DAVID L. MOORE—LIFESTYLE/ALAMY

What factors influence teenagers' use of online social networking? Researchers interested in this topic may start with a research question, or they may form a hypothesis, or prediction, to test.

theories presented in Chapter 1. Many hypotheses can be drawn from any one of them that, once tested, would reflect on the accuracy of the theory.

Sometimes research pits a hypothesis taken from one theory against a hypothesis taken from another. For example, a theorist who emphasizes the role of maturation in development would predict that adult encouragement will have little effect on the age at which children utter their first words, learn to count, or tie their shoes. A sociocultural theorist, in contrast, would speculate that these skills can be promoted through adult teaching.

At other times, research tests predictions drawn from a single theory. For example, ecological systems theory suggests that providing isolated, divorced mothers with social supports will lead them to be more patient with their children. An ethologist might hypothesize that an infant's cry will stimulate strong physiological arousal in adults who hear it, motivating them to soothe and protect a suffering baby.

Occasionally, little or no theory exists on a topic of interest. In these instances, the investigator may start with a *research question,* such as, Have recent world events—for example, the U.S wars in Iraq and Afghanistan and a global rise in terrorism—heightened children's fears and anxieties? Which teenagers are the heaviest users of Internet communication—text messaging, social networking sites such as MySpace and Facebook, and chat rooms? What functions does Internet communication serve in the lives of teenagers? Hypotheses and research questions offer investigators vital guidance as they settle on research methods and research designs.

At this point, you may be wondering, Why learn about research strategies? Why not leave these matters to research specialists and concentrate on what we already know about children and how this knowledge can be applied? There are two reasons. First, each of us must be a wise and critical consumer of knowledge. Knowing the strengths and limitations of various research strategies is important in separating dependable information from misleading results. Second, individuals who work directly with children may be in a unique position to build bridges between research and practice by conducting studies, either on their own or in partnership with experienced investigators. Community agencies such as schools, mental health facilities, and parks and recreation programs are increasingly collaborating with researchers in identifying key research issues and designing, implementing, and evaluating interventions aimed at enhancing children's development (Guerra, Graham, & Tolan, 2011). To broaden these efforts, an understanding of the research process is essential.

▶ Describe the role of theories, hypotheses, and research questions in the research process.

▶ Describe research methods commonly used to study children, noting strengths and limitations of each.

Common Research Methods

How does a researcher choose a basic approach to gathering information about children? Common methods include systematic observation, self-reports (such as questionnaires and interviews), clinical or case studies of a single child, and ethnographies of the life circumstances of a specific group of children. Table 2.1 summarizes the strengths and limitations of each of these methods.

Systematic Observation

Observations of the behavior of children, and of adults who are important in their lives, can be made in different ways. One approach is to go into the field, or natural environment, and record the behavior of interest—a method called **naturalistic observation.**

TABLE 2.1 | **Strengths and Limitations of Common Information-Gathering Methods**

METHOD	DESCRIPTION	STRENGTHS	LIMITATIONS
Systematic Observation			
Naturalistic observation	Observation of behavior in natural contexts	Reflects participants' everyday behaviors.	Cannot control conditions under which participants are observed. Accuracy of observations may be reduced by observer influence and observer bias.
Structured observation	Observation of behavior in a laboratory, where conditions are the same for all participants	Grants each participant an equal opportunity to display the behavior of interest. Permits study of behaviors rarely seen in everyday life.	May not yield observations typical of participants' behavior in everyday life. Accuracy of observations may be reduced by observer influence and observer bias.
Self-Reports			
Clinical interview	Flexible interviewing procedure in which the investigator obtains a complete account of the participant's thoughts	Comes as close as possible to the way participants think in everyday life. Great breadth and depth of information can be obtained in a short time.	May not result in accurate reporting of information. Flexible procedure makes comparing individuals' responses difficult.
Structured interview, questionnaires, and tests	Self-report instruments in which each participant is asked the same questions in the same way	Permits comparisons of participants' responses and efficient data collection. Researchers can specify answer alternatives that participants might not think of in an open-ended interview.	Does not yield the same depth of information as a clinical interview. Responses are still subject to inaccurate reporting.
Neurobiological Methods	Methods that measure the relationship between nervous system processes and behavior	Reveals which central nervous system structures contribute to development and individual differences in certain competencies. Helps researchers infer the perceptions, thoughts, and emotions of infants and young children, who cannot report them clearly.	Cannot reveal with certainty the meaning of autonomic or brain activity. Many factors besides those of interest to the researcher can influence a physiological response.
Clinical, or Case Study, Method	A full picture of one individual's psychological functioning, obtained by combining interviews, observations, test scores, and sometimes neurobiological assessments	Provides rich, descriptive insights into the many factors affecting development.	May be biased by researchers' theoretical preferences. Findings cannot be applied to individuals other than the participant.
Ethnography	Participant observation of a culture or distinct social group. By making extensive field notes, the researcher tries to capture the culture's unique values and social processes.	Provides a more complete description than can be derived from a single observational visit, interview, or questionnaire.	May be biased by researchers' values and theoretical preferences. Findings cannot be applied to individuals and settings other than the ones studied.

A study of preschoolers' responses to their peers' distress provides a good example of this technique (Farver & Branstetter, 1994). Observing 3- and 4-year-olds in child-care centers, the researchers recorded each instance of crying and the reactions of nearby children—whether they ignored, watched, or commented on the child's unhappiness; scolded or teased; or shared, helped, or expressed sympathy. Caregiver behaviors—explaining why a child was crying, mediating conflict, or offering comfort—were noted to see if adult sensitivity was related to children's caring responses. A strong relationship emerged. The great strength of naturalistic observation is that investigators can see directly the everyday behaviors they hope to explain.

Naturalistic observation also has a major limitation: Not all children have the same opportunity to display a particular behavior in everyday life. In the study just mentioned,

© BOB DAEMMRICH/THE IMAGE WORKS

In naturalistic observation, the researcher goes into the field and records the behavior of interest. This researcher, who is observing children at a summer camp, may be noting their playmate choices, cooperation, helpfulness, or conflicts.

some children might have witnessed a child crying more often than others or been exposed to more cues for positive social responses from caregivers. For this reason, they might have displayed more compassion.

Researchers commonly deal with this difficulty by making **structured observations,** in which the investigator sets up a laboratory situation that evokes the behavior of interest so that every participant has an equal opportunity to display the response. In one study, 2-year-olds' emotional reactions to harm that they thought they had caused were observed by asking them to take care of a rag doll that had been modified so its leg would fall off when the child picked it up. To make the child feel at fault, once the leg detached, an adult, "talking for" the doll, said, "Ow!" Researchers recorded children's facial expressions of sadness and concern for the injured doll, efforts to help the doll, and body tension—responses that indicated remorse and a desire to make amends. In addition, mothers were asked to engage in brief conversations about emotions with their children (Garner, 2003). Toddlers whose mothers more often explained the causes and consequences of emotion were more likely to express concern for the injured doll.

Structured observation permits greater control over the research situation than does naturalistic observation. In addition, the method is especially useful for studying behaviors—such as parent–child or friendship interactions—that investigators rarely have an opportunity to see in everyday life. When aggressive and nonaggressive 10-year-old boys were observed playing games with their best friend in a laboratory, the aggressive boys and their friends more often violated game rules, cheated, and encouraged each other to engage in these dishonest acts. In addition, observers rated these boys' interactions as angrier and less cooperative than the interactions of nonaggressive boys and their friends (Bagwell & Coie, 2004). The researchers concluded that rather than being warm and supportive, aggressive boys' close peer ties provide a context in which they practice hostility and other negative acts, which may contribute to their antisocial behavior.

In this study, antisocial boys' laboratory interactions were probably similar to their natural behaviors. The boys acted negatively even though they knew they were being observed. But the great disadvantage of structured observations is that most of the time, we cannot be certain that participants behave in the laboratory as they do in their natural environments.

Collecting Systematic Observations

The procedures used to collect systematic observations vary, depending on the research problem posed. Some investigators choose to describe the entire behavior stream—everything said and done over a certain time period. In one study, researchers wanted to find out whether maternal sensitivity in infancy and early childhood contributes to readiness for formal schooling at ages 5 to 6 years (Hirsh-Pasek & Burchinal, 2006). Between age 6 months and 4½ years, the investigators periodically videotaped 15-minute mother–child play sessions. Then they rated each session for maternal positive emotion, support, stimulating play, and respect for the child's autonomy—ingredients of sensitivity that did predict better language and academic progress when the children reached kindergarten.

When researchers need information on only one or a few kinds of behavior, they can use more efficient procedures. In one approach, **event sampling,** the observer records all instances of a particular behavior during a specified time period. In the study of preschoolers' responses to their peers' distress reported earlier, the researchers used event sampling by recording each instance in which a child cried, followed by other children's reactions.

Another way to observe efficiently is **time sampling.** In this procedure, the researcher records whether certain behaviors occur during a sample of short intervals. First, a checklist of the target behaviors is prepared. Then the observation period is divided into a series of brief time segments. For example, a half-hour observation period might be divided into 120 fifteen-second intervals. The observer watches the target person and checks off behaviors during each interval, repeating this process until the observation period is complete. Recently, my collaborators and I used time sampling to find out how parents and children spent time while visiting a community children's museum. Our observers followed more than one hundred parent–child pairs for 10 minutes each, checking off parent and child behaviors during 20 thirty-second intervals. Findings revealed that, on average, parents and children were jointly engaged in the museum's exhibits during 45 percent of the intervals. During an additional 30 percent, parents remained nearby, closely observing their children's activities (Mann, Braswell, & Berk, 2005). Clearly, the museum afforded parents many opportunities to interact with and learn about their children.

Researchers have devised ingenious ways of observing children's difficult-to-capture behaviors. For example, to record instances of bullying, a group of investigators set up video cameras overlooking a classroom and a playground and had fourth to sixth graders wear small remote microphones and pocket-sized transmitters (Craig, Pepler, & Atlas, 2000). Results revealed that bullying occurred often—at rates of 2.4 episodes per hour in the classroom and 4.5 episodes per hour on the playground. Yet only 15 to 18 percent of the time did teachers take steps to stop the harassment. We will return to the topic of bullying in Chapter 15.

LOOK and LISTEN

Find a parent and young child to observe by visiting a home, a grocery store, a mall, or a public park. Choose an easily identifiable behavior, and ask the parent for permission to jot down each instance of its occurrence during a 15-minute period. What did you learn about the challenges of making systematic observations?

Limitations of Systematic Observation

A major problem with systematic observation is **observer influence**—the effects of the observer on the behavior studied. The presence of a watchful, unfamiliar individual may cause both children and adults to react in unnatural ways. For children under age 7 or 8, observer influence is generally limited to the first session or two. Young children cannot stop "being themselves" for long, and they quickly get used to the observer's presence. But older children and adults often engage in more socially desirable behavior when they know that they are being observed. In these instances, researchers can take participants' responses as an indication of the best behavior they can display under the circumstances.

To minimize observer influence, an adaptation period, in which observers visit the research setting so participants can get used to their presence, can be helpful. Another approach is to ask individuals who are part of the child's natural environment to do the observing. For example, in some studies, parents have been trained to record their children's behavior and, occasionally, their own. Besides reducing the impact of an unfamiliar observer, this method limits the amount of time needed to gather observations, as some information can take a long time to obtain.

In one such study, researchers wanted to know how 8- to 16-year-olds reacted to their parents' marital conflicts and whether children's responses affected the course of those conflicts. For a two-week period, parents recorded each conflict episode soon after it occurred, along with their own emotions, the tactics they used, their child's behavior, and whether the conflict was resolved (Schermerhorn, Chow, & Cummings, 2010). Findings revealed that children's negativity (expressing anger, sadness, or fear; misbehaving, yelling at the parents, or engaging in aggression) predicted increasing parental negativity and the likelihood that a conflict would remain unresolved. In contrast, when children acted assertively, in ways aimed at reducing conflict (helping out, comforting parents, taking sides, or trying to make peace), parents' emotions became more positive, and they more often worked out their differences.

Another serious danger in observational research is **observer bias.** When observers are aware of the purposes of a study, they may see and record what they expect to see rather than what participants actually do. Therefore, people who have no knowledge of the investigator's hypotheses—or, at least, have little personal investment in them—are best suited to collect the observations.

Finally, although systematic observation provides invaluable information on how children and adults behave, it tells us little about the reasoning behind their responses. For this kind of information, researchers must turn to self-report techniques.

Self-Reports: Interviews and Questionnaires

Self-reports ask research participants to provide information on their perceptions, thoughts, abilities, feelings, attitudes, beliefs, and past experiences. They range from relatively unstructured clinical interviews, the method used by Piaget to study children's thinking, to highly structured interviews, questionnaires, and tests.

Clinical Interviews

In a **clinical interview,** researchers use a flexible, conversational style to probe for the participant's point of view. In the following example, Piaget questioned a 3-year-old child about his understanding of dreams:

> *Where does the dream come from?*—I think you sleep so well that you dream.—*Does it come from us or from outside?*—From outside.—*When you are in bed and you dream, where is the dream?*—In my bed, under the blanket. I don't really know. If it was in my stomach, the bones would be in the way and I shouldn't see it.—*Is the dream there when you sleep?*—Yes, it is in the bed beside me. (Piaget, 1926/1930, pp. 97–98)

Although a researcher conducting clinical interviews with more than one child would typically ask the same first question to establish a common task, individualized prompts are used to provide a fuller picture of each child's reasoning (Ginsburg, 1997).

The clinical interview has two major strengths. First, it permits people to display their thoughts in terms that are as close as possible to the way they think in everyday life. Second, the clinical interview can provide a large amount of information in a fairly brief period. For example, in an hour-long session, we can obtain a wide range of child-rearing information from a parent—far more than we could capture by observing for the same amount of time.

© BILL ARON/PHOTOEDIT

The conversational style of the clinical interview allows children to express their thoughts as they do in everyday life. But unless questions are carefully designed, responses may not accurately reflect participants' views and experiences.

Limitations of Clinical Interviews

A major limitation of the clinical interview has to do with the accuracy with which people report their thoughts, feelings, and experiences. Some participants, wanting to please the interviewer, may make up answers that do not represent their actual thinking. When asked about past events, some may have trouble recalling exactly what happened. And because the clinical interview depends on verbal ability and expressiveness, it may underestimate the capacities of individuals who have difficulty putting their thoughts into words. To minimize these problems, skillful interviewers word questions carefully. They also watch for cues indicating that the participant may not have clearly understood a question or may need extra time to feel comfortable in the interview situation.

Interviews on certain topics are particularly vulnerable to distortion. In a few instances, researchers have been able to compare parents' and children's descriptions of past events with information gathered years earlier, at the time the events occurred. Reports of psychological states and family processes obtained on the two occasions showed little or no agreement (Henry et al., 1994). Parents often recall their child's development in glowing terms, reporting faster progress, fewer childhood problems, and child-rearing practices more in line with current expert advice than with records of behavior (Yarrow, Campbell, & Burton, 1970). Interviews that focus on current rather than past information and on specific characteristics rather than global judgments show a better match with observations and other sources of information. Even so, parents are far from perfect in describing their practices and their children's personalities, preferences, and cognitive abilities (Rothbart & Bates, 2006; Saudino, 2003; Waschbusch, Daleiden, & Drabman, 2000).

Finally, the clinical interview has been criticized because of its flexibility. When questions are phrased differently for each participant, variations in responses may reflect the manner of interviewing rather than real differences in the way individuals think about a topic. To reduce this problem, researchers can use a second self-report method, the structured interview.

Structured Interviews, Tests, and Questionnaires

In a **structured interview,** each individual is asked the same set of questions in the same way. This approach eliminates the possibility that an interviewer might press and prompt some participants more than others. Structured interviews are also much more efficient than clinical interviews. Answers are briefer, and researchers can obtain written responses from an entire group at the same time. Furthermore, by listing answer alternatives, researchers can specify the activities and behaviors of interest—ones that participants might not think of in an open-ended clinical interview. For example, when parents were asked what they considered "the most important thing for children to prepare them for life," 62 percent checked "to think for themselves" when this alternative appeared on a list. Yet only 5 percent thought of it during a clinical interview (Schwarz, 1999).

Nevertheless, structured interviews can still be affected by inaccurate reporting. And they do not yield the same depth of information as a clinical interview. Currently, more researchers are combining the two approaches to see if they yield consistent findings and a clearer picture than either method can alone (Yoshikawa et al., 2008). In a study of adolescent mothers, questionnaire responses revealed that those reporting the least emotional support from their own mothers at the time of the baby's birth managed to attain higher levels of education six years later (Way & Leadbeater, 1999). Clinical interviews with the teenagers helped explain this puzzling finding: Low maternal emotional support was partly due to anger and disappointment over the early birth, more likely to be expressed by mothers who also held high educational aspirations for their daughters.

Neurobiological Methods

Researchers' desire to uncover the biological bases of perceptual, cognitive, and emotional responses has led to the use of **neurobiological methods,** which measure the relationship between nervous system processes and behavior. Investigators use these methods to find out which nervous system structures contribute to development and individual differences. Neurobiological methods also help researchers infer the perceptions, thoughts, and emotions of infants and young children, who cannot report their psychological experiences clearly.

Involuntary activities of the autonomic nervous system[1]—changes in heart rate, blood pressure, respiration, pupil dilation, electrical conductance of the skin, and stress hormone levels—are highly sensitive to psychological state. For example, heart rate can be used to infer whether an infant is staring blankly at a stimulus (heart rate is stable), processing information (heart rate slows during concentration), or experiencing distress (heart rate rises). Heart rate variations are also linked to certain emotions, such as interest, fear, anger, and sadness (Fox & Card, 1998; Hastings, Zahn-Waxler, & Usher, 2007).

Saliva concentrations of the hormone *cortisol* provide information about children's stress reactivity. Known as the "fight or flight" hormone, cortisol increases respiration rate, blood pressure, and blood sugar; suppresses immune system functioning; and heightens memory for emotionally charged events so they will be avoided in the future. Chronically abnormal cortisol levels, either too high or too low—evident in children exposed to severe deprivation (such as early orphanage rearing), parental neglect, or abuse—signal a disrupted stress-response system. As we will see in later chapters, negative outcomes include impaired growth, illness, and learning and behavior problems (Loman & Gunnar, 2010; Lupien et al., 2009). And as Chapter 10 will reveal, distinct patterns of autonomic activity—indicated by heart rate, cortisol level, and other physiological measures—are related to aspects of temperament, such as shyness and sociability (Kagan & Fox, 2006).

---

[1] The autonomic nervous system, which regulates involuntary actions, is divided into two parts: (1) the *sympathetic nervous system,* which mobilizes energy to deal with threatening situations (as when your heart rate rises in response to a fear-arousing event); and (2) the *parasympathetic nervous system*, which acts to conserve energy (as when your heart rate slows as you focus on an interesting stimulus).

Autonomic indicators have been enriched by diverse measures of brain functioning, described in Table 2.2. Among these methods, the two most frequently used detect changes in *electrical activity* in the cerebral cortex—the brain's outer layers, which play a central role in complex mental functions, including attention, perception, memory, language, reasoning, planning, and problem solving. In an *electroencephalogram (EEG),* researchers examine brain-wave patterns for stability and organization—signs of mature functioning of the cortex. And as a child processes a particular stimulus, *event-related potentials* (*ERPs)* detect the general location of brain-wave activity—a technique often used to study preverbal infants' responsiveness to various stimuli, the impact of experience on development of regions of the cerebral cortex, and atypical brain functioning in children at risk for learning and emotional problems (DeBoer, Scott, & Nelson, 2007; deRegnier, 2005). For example, different wave patterns appear when 3-month-olds from English-speaking homes hear passages in English, Italian, and Dutch, suggesting that the infants can discriminate the intonation patterns of the three languages and indicating the brain regions involved (Shafer, Shucard, & Jaeger, 1999). And as the Biology and Environment box on the following page illustrates, ERP findings are clarifying the impact of deficient prenatal nutrition on early brain development and cognitive functioning.

TABLE 2.2 | **Methods for Measuring Brain Functioning**

METHOD	DESCRIPTION
Electroencephalogram (EEG)	Electrodes embedded in a head cap record electrical activity in the brain's outer layers—the cerebral cortex. Today, researchers use an advanced tool called a geodesic sensor net (GSN) to hold interconnected electrodes (up to 128 for infants and 256 for children and adults) in place through a cap that adjusts to each person's head shape, yielding improved brain-wave detection (see page 49).
Event-related potentials (ERPs)	Using the EEG, the frequency and amplitude of brain waves in response to particular stimuli (such as a picture, music, or speech) are recorded in multiple areas of the cerebral cortex. Enables identification of general regions of stimulus-induced activity.
Functional magnetic resonance imaging (fMRI)	While the person lies inside a tunnel-shaped apparatus that creates a magnetic field, a scanner magnetically detects increased blood flow and oxygen metabolism in precise areas of the brain as the individual processes particular stimuli. The scanner typically records images every 1 to 4 seconds; these are combined into a computerized moving picture of activity anywhere in the brain (not just its outer layers). Not appropriate for children younger than age 5 to 6, who cannot remain still during testing. Cost of equipment and testing is much higher than that of EEG and ERPs.
Positron emission tomography (PET)	After injection or inhalation of a radioactive substance, the person lies on an apparatus with a scanner that emits fine streams of X-rays, which detect increased blood flow and oxygen metabolism in areas of the brain as the person processes particular stimuli. As with fMRI, the result is a computerized moving picture of "online" activity anywhere in the brain, but not appropriate for children younger than age 5 to 6 and high in cost.
Near-infrared spectroscopy (NIRS)	Using thin, flexible optical fibers attached to the scalp, infrared (invisible) light is beamed at the brain; its absorption by areas of the cerebral cortex varies with changes in blood flow and oxygen metabolism as the individual processes particular stimuli. The result is a computerized moving picture of active areas in the cerebral cortex. Unlike fMRI and PET, NIRS is appropriate for infants and young children, who can move within limited range.

BIOLOGY and ENVIRONMENT

Prenatal Iron Deficiency and Memory Impairments in Infants of Diabetic Mothers: Findings of ERP Research

Diabetes affects nearly 11 percent of Americans age 20 and older—a rate that has risen sharply over the past quarter century as a result of widespread overweight and obesity. Although it is increasing among all sectors of the population, diabetes is at least twice as likely to affect low-income ethnic minority as white adults. Today, about 5 percent of pregnant mothers are diabetic—a rate that has more than doubled over the past decade. Most had the disease before becoming pregnant; others developed it during pregnancy (American Diabetes Association, 2011). In either case, their newborn babies are at risk for long-term problems.

In the early weeks of pregnancy, when organs are forming, a diabetic mother's out-of-control blood glucose increases the risk of birth defects. Later in pregnancy, excess blood glucose causes the fetus to be "overfed" and to grow unusually large, often causing birth complications. Furthermore, to metabolize this flood of maternal glucose, the fetus secretes abnormally high levels of insulin—a circumstance that greatly increases demand for oxygen. To extract extra oxygen from the mother's system, the fetus increases production of oxygen-carrying red blood cells. This expanding red blood-cell mass requires extra iron, which the fetus can obtain only by taxing its own iron stores in the liver, muscles, heart, and brain.

In animal research on maternal diabetes, by late pregnancy iron stores decline sharply in the brain's temporal lobes (located on each side of the brain, just above the ears), which house structures centrally involved in memory development—specifically, the *hippocampus,* which plays a crucial role in the formation of new memories. Prenatal iron depletion interferes with growth of brain cells and their connections, permanently reducing the size and altering the structure of the hippocampus and impairing memory in laboratory rats (Jorgenson et al., 2005; Schmidt et al., 2007).

In human research, diabetic mothers bear children who, at school age, tend to score lower than their agemates on intelligence tests (Rizzo et al., 1997). Is prenatal iron deficiency and resulting early damage to the brain's memory areas responsible? In a series of studies, Charles Nelson (2007) and his collaborators used ERPs to assess young infants' memory performance, focusing on a particular slow brain wave in the temporal lobes believed to reflect memory processing.

Typically developing newborns come to recognize their mother's voice through repeated exposure during pregnancy; they suck more on a nipple to hear a recording of it than the voice of an unfamiliar woman (DeCasper & Spence, 1988). In a comparison of newborns of diabetic mothers likely to have a brain iron deficiency (based on a measure of body iron stores) with normal-iron controls, ERPs were recorded as the babies listened to sound clips of their mother's or a stranger's voice (Sidappa et al., 2004). The controls showed a distinctive ERP slow wave to each stimulus, indicating recognition of the mother's voice. The brain iron-deficient babies showed no difference in brain waves to the two stimuli, suggesting memory impairment of prenatal origin.

Do these memory deficits persist beyond the newborn period—evidence that diabetes-linked prenatal brain damage has lasting consequences? The researchers recorded ERPs while 6-month-old infants alternately viewed a videotaped image of their mother's face and that of an unfamiliar woman. Consistent with the newborn findings, control infants responded with distinct ERP slow waves in the temporal lobes to the two faces, while infants of diabetic mothers displayed no difference. Even after months of experience, they could not recognize their mother's facial image (Nelson et al., 2000).

At an 8-month follow-up, babies were given a more challenging memory task. After feeling a novel object (an unusually shaped wooden block) held beneath an apron so they could not see it, the infants were tested visually: They viewed photos of the novel object interspersed with photos of familiar objects (Nelson et al., 2003). Again, infants of diabetic mothers showed no ERP evidence of distinguishing the novel object from other stimuli. The control babies, in contrast, responded to the novel object with a stronger temporal-lobe slow wave, suggesting a ready ability to recognize the novel stimulus, even when presented in a different sensory modality.

COURTESY OF DR. CHARLES A. NELSON, HARVARD UNIVERSITY

To study the impact of prenatal diabetes on early memory development, researchers use a geodesic sensor net, consisting of optical fibers attached to a head cap, to obtain this 8-month-old's electrical brain waves during a challenging memory task.

Nelson and his colleagues followed their research participants through the preschool years, amassing additional ERP and behavioral evidence for poorer memory (especially more rapid forgetting) in children born to diabetic mothers than in controls (Riggins et al., 2009). The ERP findings highlight a previously hidden pregnancy complication: As a result of iron depletion in critical brain areas, a diabetic pregnancy places the fetus at risk for lasting memory deficits and, thus, for long-term learning and academic problems. The researchers believe that damage to the hippocampus, located deep inside the temporal lobes, is responsible—a hypothesis they hope to pursue as new methods making possible fMRIs on babies become available.

Nelson's research underscores the need for more effective ways of intervening with iron supplementation in diabetic pregnancies, as well as the importance of sufficient dietary iron for every expectant mother and her developing fetus. Diabetes prevention is also vital, through weight control, increased exercise, and improved diet beginning in childhood—topics we take up in Chapter 5.

(b) The fMRI image shows which areas of the boy's brain are active while he views changing visual stimuli. (c) Here, NIRS is used to investigate a 2-month-old's response to a visual stimulus. During testing, the baby can move freely within a limited range. (Photo © From G. Taga, K. Asakawa, A. Maki, Y. Konishi, & H. Koisumi, 2003, "Brain Imaging in Awake Infants by Near-Infrared Optical Topography," *Proceedings of the National Academy of Sciences, 100,* p. 10723. Reprinted by permission.)

Neuroimaging techniques, which yield detailed, three-dimensional computerized pictures of the entire brain and its active areas, provide the most precise information about which brain regions are specialized for certain capacities and about abnormalities in brain functioning. In *positron emission tomography (PET),* the child must lie quietly on a scanner bed, and in *functional magnetic resonance imaging (fMRI),* inside a tunnel-like apparatus. But unlike PET, fMRI does not depend on X-ray photography, which requires injection of a radioactive substance. Rather, when a child is exposed to a stimulus, fMRI detects changes in blood flow and oxygen metabolism throughout the brain magnetically; a computer combines frequently recorded images into a colorful, moving picture of parts of the brain used to perform a given activity (see Figures 2.1a and b).

Because PET and fMRI require that the participant lie as motionless as possible for an extended time, they are not suitable for infants and young children (Nelson, Thomas, & de Haan, 2006). A neuroimaging technique that works well in infancy and early childhood is *near-infrared spectroscopy (NIRS),* in which infrared (invisible) light is beamed at regions of the cerebral cortex to measure blood flow and oxygen metabolism while the child attends to a stimulus (refer again to Table 2.2). Because the apparatus consists only of thin, flexible optical fibers attached to the scalp using a head cap, a baby can sit on the parent's lap and move during testing—as Figure 2.1c illustrates (Hespos et al., 2010). But unlike PET and fMRI, which map activity changes throughout the brain, NIRS examines only the functioning of the cerebral cortex.

Neurobiological methods are powerful tools for uncovering relationships between the brain and psychological development. But like all research methods, they have limitations. Even though a stimulus produces a consistent pattern of autonomic or brain activity, investigators cannot be certain that an individual has processed it in a certain way. And a researcher who takes a change in heart rate, respiration, or brain activity as an indicator of information processing or emotional state must make sure that the change was not due instead to hunger, boredom, fatigue, or body movements (Nicholson, 2006). Consequently, other methods—both observations and self-reports—must be combined with brain-wave and -imaging findings to clarify their meaning.

The Clinical, or Case Study, Method

An outgrowth of psychoanalytic theory, the **clinical,** or **case study, method** brings together a wide range of information on one child, including interviews, observations, test scores, and sometimes neurobiological measures. The aim is to obtain as complete a picture as possible of that child's psychological functioning and the experiences that led up to it.

The clinical method is well-suited to studying the development of certain types of individuals who are few in number but vary widely in characteristics. For example, the method has been used to find out what contributes to the accomplishments of *prodigies*—extremely gifted children who attain adult competence in a field before age 10 (Moran & Gardner, 2006). Consider Adam, a boy who read, wrote, and composed musical pieces before he was out of diapers. By age 4, Adam was deeply involved in mastering human symbol systems—French, German, Russian, Sanskrit, Greek, the computer programming language BASIC, ancient hieroglyphs, music, and mathematics. Adam's parents provided a home rich in stimulation and reared him with affection, firmness, and humor. They searched for schools in which he could both develop his abilities and form rewarding social relationships. He graduated from college at age 18 and continued to pursue musical composition. Would Adam have realized his potential without the chance combination of his special gift and nurturing, committed parents? Probably not, researchers concluded (Feldman, 2004).

The clinical method yields richly detailed case narratives that offer valuable insights into the many factors affecting development. Nevertheless, like all other methods, it has drawbacks. Because information often is collected unsystematically and subjectively, researchers' theoretical preferences may bias their observations and interpretations. In addition, investigators cannot assume that their conclusions apply, or generalize, to anyone other than the child studied (Stanovich, 2007). Even when patterns emerge across several cases, it is wise to confirm them with other research strategies.

Using the clinical, or case study, method, this researcher combines interviews with the mother and observations and testing of the child to construct an in-depth picture of the child's psychological functioning.

Methods for Studying Culture

To study the impact of culture, researchers adjust the methods just considered or tap procedures specially devised for cross-cultural and multicultural research (Triandis, 2007). Which approach investigators choose depends on their research goals.

Sometimes researchers are interested in characteristics that are believed to be universal but that vary in degree from one culture to the next: Are parents warmer or more directive in some cultures than in others? How strong are gender stereotypes in different nations? In each instance, several cultural groups will be compared, and all participants must be questioned or observed in the same way. Therefore, researchers draw on the observational and self-report procedures we have already considered, adapting them through translation so they can be understood in each cultural context. For example, to study cultural variation in parenting practices, the same questionnaire, asking for ratings on such items as "I often hug and kiss my child" or "I scold my child when his/her behavior does not meet my expectations," is given to all participants (Wu et al., 2002). Still, investigators must be mindful of cultural differences in familiarity with responding to self-report instruments, which may bias their findings (Van de Vijver, Hofer, & Chasiotis, 2010).

At other times, researchers want to uncover the *cultural meanings* of children's and adults' behaviors by becoming as familiar as possible with their way of life. To achieve this goal,

This Western ethnographer spent months living among the Efe people of the Republic of Congo. Here he observes young children sharing food. The Efe value and encourage cooperation and generosity at an early age.

investigators rely on a method borrowed from the field of anthropology—**ethnography.** Like the clinical method, ethnographic research is a descriptive, qualitative technique. But instead of aiming to understand a single individual, it is directed at understanding a culture or a distinct social group through *participant observation.* Typically, the researcher spends months and sometimes years in the cultural community, participating in its daily life. Extensive field notes are gathered, consisting of a mix of observations, self-reports from members of the culture, and careful interpretations by the investigator (Miller, Hengst, & Wang, 2003; Shweder et al., 2006). Later, these notes are put together into a description of the community that tries to capture its unique values and social processes.

The ethnographic method assumes that by entering into close contact with a social group, researchers can understand the beliefs and behaviors of its members in a way that is not possible with an observational visit, interview, or questionnaire. Some ethnographies take in many aspects of children's experience, as one researcher did in describing what it is like to grow up in a small American town. Others focus on one or a few settings, such as home, school, or neighborhood life (Higginbottom, 2006; Peshkin, 1997; Valdés, 1998). And still others are limited to a particular practice, such as uncovering cultural and religious influences on children's make-believe play. For example, ethnographic findings reveal that East Indian Hindu parents encourage preschoolers to communicate with "invisible" characters. They regard this activity as linked to *karma* (the cycle of birth and death) and believe that the child may be remembering a past life. In contrast, Christian fundamentalist parents often discourage children from pretending to be unreal characters, believing that such play promotes dangerous spiritual ideas and deceitful behavior (Taylor & Carlson, 2000). Researchers may supplement traditional self-report and observational methods with ethnography if they suspect that unique meanings underlie cultural differences, as the Cultural Influences box on the following page reveals.

Ethnographers strive to minimize their influence on the culture they are studying by becoming part of it. Nevertheless, as with clinical studies, investigators' cultural values and theoretical commitments sometimes lead them to observe selectively or misinterpret what they see. Finally, the findings of ethnographic studies cannot be assumed to generalize beyond the people and settings in which the research was conducted.

ASK YOURSELF

Review ■ Why might a researcher choose structured observation over naturalistic observation? How about the reverse? What might lead the researcher to opt for clinical interviewing over systematic observation?

Connect ■ What strengths and limitations do the clinical, or case study, method and ethnography have in common?

Apply ■ A researcher wants to study the thoughts and feelings of children who have a parent on active duty in the military. Which method should she use? Why?

CULTURAL INFLUENCES

Immigrant Youths: Adapting to a New Land

During the past quarter century, a rising tide of immigrants has come to North America, fleeing war and persecution in their homelands or seeking better life opportunities. Today, nearly one-fourth of U.S. children and adolescents have foreign-born parents, making them the fastest-growing segment of the U.S. youth population. About 20 percent of these young people are foreign-born themselves, mostly from Latin America, the Caribbean, and Asia (Hernandez, Denton, & Macartney, 2008; Suarez-Orozco, Todorova, & Qin, 2006).

How well are immigrant youths adapting to their new country? To find out, researchers use multiple research methods—academic testing, questionnaires assessing psychological adjustment, and in-depth ethnographies.

Academic Achievement and Adjustment

Although educators and laypeople often assume that the transition to a new country has a negative impact on psychological well-being, evidence reveals that many children of immigrant parents from diverse countries adapt amazingly well. Students who are first-generation (foreign-born) and second-generation (American-born, with immigrant parents) often achieve in school as well as or better than students of native-born parents (Fuligni, 2004; Hernandez, Denton, & Macartney, 2008; Saucier et al., 2002). Findings on psychological adjustment are similar. Compared with their agemates, adolescents from immigrant families are less likely to commit delinquent and violent acts, to use drugs and alcohol, or to have early sex. They are also less likely to be obese or to have missed school because of illness. And they tend to report just as high, and at times higher, self-esteem as young people with native-born parents (Fuligni, 1998; Saucier et al., 2002; Supple & Small, 2006).

These outcomes are strongest for Chinese, Filipino, Japanese, Korean, and East Indian youths (Fuligni, 2004; Louie, 2001; Portes & Rumbaut, 2005). Variation in adjustment is greater among Mexican, Central American, and Southeast Asian (Hmong, Cambodian, Laotian, Thai, and Vietnamese) young people, who show elevated rates of school failure and dropout, delinquency, teenage parenthood, and drug use. Disparities in parental economic resources, education, English-language proficiency, and support of children contribute to these trends (García Coll & Marks, 2009; Supple & Small, 2006).

Still, many first- and second-generation youths whose parents face considerable financial hardship and who speak little English are successful (Fuligni & Yoshikawa, 2003; Hernandez, Denton, & Macartney, 2008). Factors other than income are responsible—notably, family values and strong ethnic-community ties.

Family and Ethnic-Community Influences

Ethnographies reveal that immigrant parents view education as the surest way to improve life chances (García Coll & Marks, 2009; Goldenberg et al., 2001). Aware of the challenges their children face, they typically emphasize trying hard. They remind their children that, because educational opportunities were not available in their native countries, they themselves are often limited to menial jobs. And while preserving their culture's values, these parents also make certain adaptations—for example, supporting education for daughters even though their culture of origin approves of it only for sons.

© MICHAEL SILUK/THE IMAGE WORKS

These Hmong boys perform in an ethnic festival in St. Paul, Minnesota, where many Hmong immigrants have settled. Cultural values that engender allegiance to family and community promote high achievement and protect many immigrant youths from involvement in risky behaviors.

Adolescents from these families internalize their parents' valuing of academic achievement, endorsing it more strongly than agemates with native-born parents (Fuligni, 2004; Su & Costigan, 2009). Because minority ethnicities usually stress allegiance to family and community over individual goals, first- and second-generation young people often feel a strong sense of obligation to their parents. They view school success as an important way of repaying their parents for the hardships they have endured (Bacallao & Smokowski, 2007; Fuligni, Yip, & Tseng, 2002). Both family relationships and school achievement protect these youths from risky behaviors (see the Biology and Environment box on resilient children on pages 10–11 in Chapter 1).

Immigrant parents of successful youths typically develop close ties to an ethnic community, which exerts additional control through a high consensus on values and constant monitoring of young people's activities. The following comments capture the power of these family and community forces:

- *Elizabeth, age 16, from Vietnam, straight-A student, like her two older sisters:* My parents know pretty much all the kids in the neighborhood. Everybody here knows everybody else. It's hard to get away with much. (Zhou & Bankston, 1998, pp. 93, 130)
- *Juan, teenager from Mexico:* A really big part of the Hispanic population [is] being close to family, and the family being a priority all the time. I hate people who say, "Why do you want to go to a party where your family's at? Don't you want to get away from them?" You know, I don't really get tired of them. I've always been really close to them. That connection to my parents, that trust that you can talk to them, that makes me Mexican. (Bacallao & Smokowski, 2007, p. 62)

The experiences of well-adjusted immigrant youths are not problem-free. Chinese adolescents who had arrived in the United States within the previous year described their adjustment as very difficult because they were not proficient in English and, as a result, found many everyday tasks challenging and felt socially isolated (Yeh et al., 2008). Young immigrants also encounter racial and ethnic prejudices and experience tensions between family values and the new culture—challenges we will take up in Chapter 11. In the long term, however, family and community cohesion, supervision, and high expectations promote favorable outcomes.

- Explain how reliability and validity apply to research methods and to the overall accuracy of research findings and conclusions.

Reliability and Validity: Keys to Scientifically Sound Research

Once investigators choose their research methods, they must ensure that their procedures provide trustworthy information. To be acceptable to the scientific community, self-reports, observations, and physiological measures must be both *reliable* and *valid*—two keys to scientifically sound research.

Reliability

Suppose you and a research partner go into an elementary school classroom and record how attentive and cooperative each child is. But although you are simultaneously rating the same children, you and your partner come up with very different judgments. Or perhaps you question a group of children about their interests, but a week later, when you ask them again, they give you very different answers. **Reliability** refers to the consistency, or repeatability, of measures of behavior. To be reliable, observations and evaluations of peoples' actions cannot be unique to a single observer. Instead, observers must agree on what they see. And an interview, test, or questionnaire, when given again within a short time (before participants could reasonably be expected to change their opinions or develop new responses), must yield similar results on both occasions.

Researchers determine the reliability of data in various ways. In observational research, observers are asked to evaluate the same behaviors, and agreement between them—called *inter-rater reliability*—is obtained. Reliability of self-report and neurobiological data can be demonstrated by comparing children's responses to the same measures on separate occasions, an approach called *test–retest reliability.* In the case of self-reports, researchers can also compare children's answers on different forms of the same test or questionnaire. And if necessary, reliability can be estimated from a single testing session by comparing children's answers on different halves of the test.

Because clinical and ethnographic studies do not yield quantitative scores that can be matched with those of another observer or test form, other procedures must be used to determine the reliability of these methods. After examining the qualitative records, one or more judges can see if they agree with the researcher that the patterns and themes identified are grounded in evidence and are plausible (Silverman, 2006).

© GERRIT DE HEUS/ALAMY IMAGES

This boy may excel on math tests, but how well does he do on real-world tasks such as counting money or making change? If a test is valid, it should predict related behaviors in everyday life.

Validity

For research methods to have high **validity,** they must accurately measure characteristics that the researcher set out to measure. **TAKE A MOMENT...** After thinking about this idea, can you come up with an example that shows why reliability is essential for valid research? Methods that are implemented carelessly, unevenly, or inconsistently cannot possibly represent what an investigator originally intended to study.

But to guarantee validity, researchers must go further. They often examine the content of observations and self-reports to make sure all behaviors of interest are included. For example, a test intended to measure fifth-grade children's knowledge of mathematics would not be valid if it contained only addition problems but no subtraction, multiplication, or division problems (Miller, 2007). Another approach is to see how effective a method is in predicting behavior we would reasonably expect it to predict. If scores on a math test are valid, they should be related to how well children do on their math assignments in school or even to how quickly and accurately they can make change in a game of Monopoly.

As we turn now to research designs, you will discover that the concept of validity can also be applied more broadly: to the overall accuracy of research findings and conclusions. In setting up an investigation, researchers must safeguard two types of validity. The first, **internal validity,** is the degree to which *conditions internal to the design of the study* permit an accurate test of the researcher's hypothesis or question. If, during any phase of the investigation—selecting participants, choosing research settings and tasks, and implementing procedures—participants' behavior is influenced by factors unrelated to the hypothesis, then the accuracy of the results is in doubt. Second, researchers must consider **external validity,** the degree to which their *findings generalize to settings and participants outside the original study.* Ensuring that samples, tasks, and contexts for conducting research represent the real-world people and situations that the investigator aims to understand is key to this type of accuracy.

LOOK and LISTEN

Ask a teacher, counselor, social worker, or nurse to describe a question about development he or she would like researchers to address. After reading this chapter, recommend research strategies best suited to answering the question.

ASK YOURSELF

Review ■ Explain why, although a research method must be reliable to be valid, reliability *does not guarantee* validity.

Connect ■ Why is it better for a researcher to use multiple methods rather than just one method to test a hypothesis or answer a research question?

Apply ■ In studying the development of attention in school-age children, a researcher wonders whether to make naturalistic observations or structured observations. Which approach is best for ensuring internal validity? How about external validity? Why?

General Research Designs

- Distinguish correlational and experimental research designs, noting strengths and limitations of each.

In deciding on a research design, investigators choose a way of setting up a study that permits them to test their hypotheses with the greatest certainty possible. Two main designs are used in all research on human behavior: *correlational* and *experimental.*

Correlational Design

In a **correlational design,** researchers gather information on individuals, generally in natural life circumstances, and make no effort to alter their experiences. Then they look at relationships between participants' characteristics and their behavior or development. Suppose we want to answer such questions as, Do parents' styles of interacting with their children have any bearing on children's intelligence? Does attending a child-care center promote children's friendliness with peers? How do child abuse and neglect affect children's self-esteem and relationships with peers? In these and many other instances, the conditions of interest are difficult or impossible to arrange and control and must be studied as they currently exist.

Correlational studies have one major limitation: We cannot infer cause and effect. For example, if we find that parental interaction is related to children's intelligence, we would not know whether parents' behavior actually *causes* intellectual differences among children. In fact, the opposite is possible: The behaviors of highly intelligent children may be so attractive that they cause parents to interact more favorably. Or a third variable that we did not even consider, such as the amount of noise and distraction in the home, may cause changes in both parental interaction and children's intelligence.

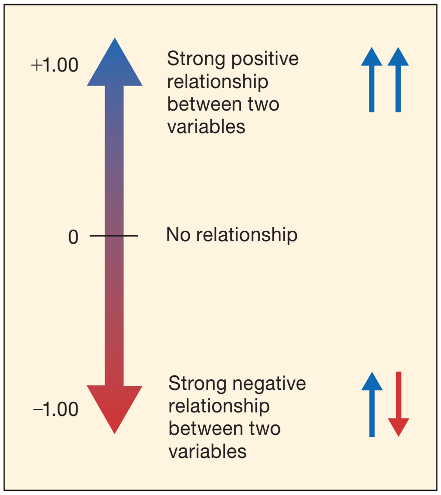
© IMAGE SOURCE/GLOW IMAGES

Do parents who speak more to their toddlers have children who are advanced in language development? A correlational design is well-suited to answering this question, but it does not permit inferences about cause and effect.

In correlational studies, and in other types of research designs, investigators often examine relationships by using a **correlation coefficient**—a number that describes how two measures, or variables, are associated with each other. Although other statistical approaches to examining relationships also exist, we will encounter the correlation coefficient in discussing research findings throughout this book. So let's look at what it is and how it is interpreted. A correlation coefficient can range in value from +1.00 to –1.00. The *magnitude,* or *size, of the number* shows the *strength of the relationship.* A zero correlation indicates no relationship; the closer the value is to either +1.00 or –1.00, the stronger the relationship (see Figure 2.2). For instance, a correlation of –.78 is high, –.52 is moderate, and –.18 is low. Note, however, that correlations of +.52 and –.52 are equally strong. The *sign of the number* refers to the *direction of the relationship.* A positive sign (+) means that as one variable *increases,* the other also *increases.* A negative sign (–) indicates that as one variable *increases,* the other *decreases.*

Let's look at some examples of how a correlation coefficient works. One researcher reported a +.55 correlation between a measure of maternal language stimulation and the size of children's vocabularies at age 2 years (Hoff, 2003). This is a moderate correlation, which indicates that mothers who spoke more to their toddlers had children who were more advanced in language development. In two other studies, child-rearing practices were related to children's compliance in consistent ways. First, maternal warmth and sensitivity during play correlated positively (+.34) with 2-year-olds' willingness to comply with their mother's directive to clean up toys (Feldman & Klein, 2003). Second, the extent to which mothers spoke harshly, interrupted, and controlled their 4-year-olds' play correlated negatively (–.31 for boys and –.42 for girls) with children's compliance (Smith et al., 2004). The more mothers expressed affection and support, the more their children cooperated. And the more mothers restricted and coerced, the less the children cooperated (see Figure 2.3 for visual portrayals of these relationships).

All these investigations found correlations between parenting and young children's behavior. **TAKE A MOMENT...** Are you tempted to conclude that maternal behaviors influenced children's responses? Although the researchers suspected this was so, they could not be sure of cause and effect. Can you think of other possible explanations? Finding a relationship in a correlational study does suggest that tracking down its cause—with a more powerful experimental strategy, if possible—would be worthwhile.



+1.00
Strong positive relationship between two variables
0
No relationship
–1.00
Strong negative relationship between two variables

FIGURE 2.2 **The meaning of correlation coefficients.** The magnitude of the number indicates the *strength* of the relationship. The sign of the number (+ or –) indicates the *direction* of the relationship.

Experimental Design

An **experimental design** permits inferences about cause and effect because researchers use an evenhanded procedure to assign people to two or more treatment conditions. In an experiment, the events and behaviors of interest are divided into two types: independent and dependent variables. The **independent variable** is the one the investigator expects to cause changes in another variable. The **dependent variable** is the one the investigator expects to be influenced by the independent variable. Cause-and-effect relationships can be detected because the researcher directly *controls* or *manipulates* changes in the independent variable by exposing participants to the treatment conditions. Then the researcher compares their performance on measures of the dependent variable.

In one **laboratory experiment,** researchers explored the impact of adults' angry interactions on children's adjustment (El-Sheikh, Cummings, & Reiter, 1996).

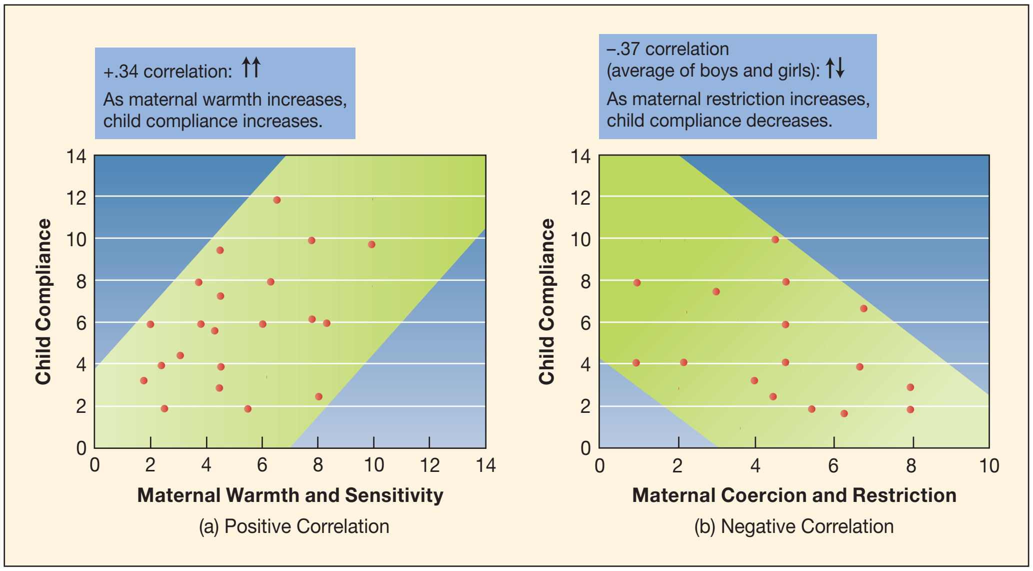


FIGURE 2.3 **A positive and a negative correlation.** A researcher reported that maternal warmth and sensitivity were positively correlated with children's willingness to comply with their mother's directive to clean up toys (a). A second researcher reported that maternal restriction and coercion were negatively correlated with children's compliance (b). Each dot represents a participant's score on the two variables—maternal behavior and child compliance. Both correlations are moderate in strength because the pattern of dots deviates from a straight line, which would be a perfect correlation. Notice how in the positive correlation, as maternal warmth *increases,* child compliance tends to *increase.* In the negative correlation, as maternal restriction *increases,* child compliance tends to *decrease.* If a pattern of dots shows no upward or downward trend, then the correlation is near zero, indicating little or no relationship between the two variables.

They hypothesized that the way angry encounters end (independent variable) affects children's emotional reactions (dependent variable). Four- and 5-year-olds were brought one at a time to a laboratory, accompanied by their mothers. One group was exposed to an *unresolved-anger treatment,* in which two adult actors entered the room and argued but did not work out their disagreements. The other group witnessed a *resolved-anger treatment,* in which the adults ended their disputes by apologizing and compromising. As Figure 2.4 shows, when they witnessed a follow-up adult conflict, more children in the resolved-anger treatment showed a decline in distress, as measured by fewer anxious facial expressions, less freezing in place, and less seeking of closeness to their mothers. The experiment revealed that anger resolution can reduce the stressful impact of adult conflict on children.

In experimental studies, investigators must take special precautions to control for participants' characteristics that could reduce the internal validity of their findings. For example, in the study just described, if more children from homes high in parental conflict ended up in the unresolved-anger treatment, we could not tell what produced the results—the independent variable or the children's backgrounds. Parental conflict and the treatment conditions would be **confounding variables**—so closely associated that their effects on an outcome cannot be distinguished. To protect against this problem, researchers engage in **random assignment** of participants to treatment

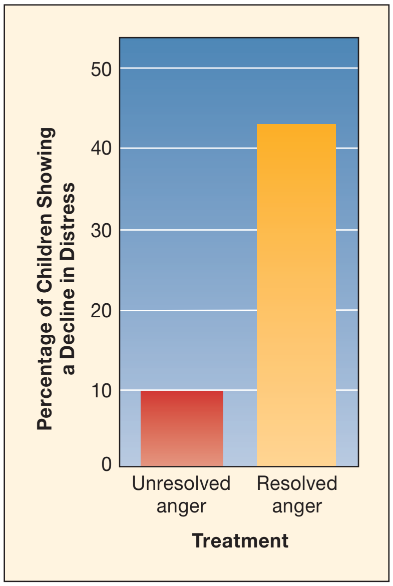

FIGURE 2.4 **Does the way adults end their angry encounters affect children's emotional reactions?** A laboratory experiment revealed that children who had previously witnessed adults resolving their disputes by apologizing and compromising were more likely to decline in distress when witnessing subsequent adult conflicts than were children who witnessed adults leaving their arguments unresolved. Notice in this graph that only 10 percent of children in the unresolved-anger treatment declined in distress (see bar on left), whereas 42 percent of children in the resolved-anger treatment did so (see bar on right). (Adapted from El-Sheikh, Cummings, & Reiter, 1996.)

conditions. By using an unbiased procedure, such as drawing numbers out of a hat or flipping a coin, investigators increase the chances that participants' characteristics will be equally distributed across treatment groups.

Sometimes researchers combine random assignment with another technique called **matching.** In this procedure, participants are measured ahead of time on the factor in question—in our example, exposure to parental conflict. Then children high and low on that factor are assigned in equal numbers to each treatment condition. In this way, the experimental groups are deliberately matched, or made equivalent, on characteristics that are likely to distort the results.

Modified Experimental Designs

Most experiments are conducted in laboratories, where researchers can achieve the maximum possible control over treatment conditions. But, as we have seen, findings obtained in laboratories often have limited external validity: They may not apply to everyday situations. In **field experiments,** researchers capitalize on opportunities to randomly assign participants to treatment conditions in natural settings. In the experiment we just considered, we can conclude that the emotional climate established by adults affects children's behavior in the laboratory. But does it have the same effect in daily life?

Another study helps answer this question. Ethnically diverse, poverty-stricken families with a 2-year-old child were scheduled for a home visit, during which researchers assessed family functioning and child problem behaviors by asking parents to respond to questionnaires and videotaping parent–child interaction. The families were then randomly assigned to either an intervention condition, called the Family Check-Up, or a no-intervention control group. The intervention consisted of three home-based sessions in which a consultant gave parents feedback about their child-rearing practices and their child's adjustment, explored parents' willingness to improve, and identified community services appropriate to each family's needs (Dishion et al., 2008). Findings showed that families assigned to the Family Check-Up (but not controls) gained in positive parenting, which predicted a reduction in child problem behaviors—sometimes still evident a year later, when participating children were reassessed at age 3. In other field experiments, adaptations of the Family Check-up were effective in improving parenting of adolescents and reducing rates of antisocial behavior and substance use (Stormshak & Dishion, 2009; Stormshak et al., 2011). See the Social Issues: Education box on the following page for another example of field research—this time with implications for how best to foster children's intelligence.

Often researchers cannot randomly assign participants and manipulate conditions in the real world, as these investigators were able to do. Sometimes they can compromise by conducting **natural,** or **quasi-, experiments.** Treatments that already exist, such as different family environments, child-care centers, or schools, are compared. These studies differ from correlational research only in that groups of participants are carefully chosen to ensure that their characteristics are as much alike as possible. Occasionally, the same participants experience both treatments. In this way, investigators do their best to avoid confounding variables and to rule out alternative explanations for treatment effects.

Natural experiments permit researchers to examine the impact of conditions that cannot be experimentally manipulated for ethical reasons—for example, the influence of premature birth, grade retention, or child maltreatment on development (Sameroff & MacKenzie, 2003). In one such study, maltreated and nonmaltreated 8- to 12-year-olds were enrolled in the same summer camp and, therefore, were observed and questioned under similar social conditions. When asked to complete stories about parenting that tapped themes of conflict, discipline, autonomy, and affection, maltreated children gave responses that were less elaborate and more negative than those of their nonmaltreated counterparts. Furthermore, peers rated maltreated children as more disruptive, more aggressive, and less cooperative (see Figure 2.6 on page 60). Not surprisingly, peers strongly disliked these youngsters. Finally, children who represented their parents negatively in stories were especially likely to display maladaptive

SOCIAL ISSUES: EDUCATION

Can Musical Experiences Enhance Intelligence?

In a 1993 experiment, researchers reported that college students who listened to a Mozart sonata for a few minutes just before taking a test of spatial reasoning abilities did better on the test than students who took the test after listening to relaxation instructions or sitting in silence (Rauscher, Shaw, & Ky, 1993). Strains of Mozart, the investigators concluded, seem to induce changes in the brain that "warm up" neural connections, thereby improving thinking. But the gain in performance, widely publicized as the "Mozart effect," was small, lasted briefly, and proved difficult to replicate (Pietschnig, Voracek, & Formann, 2010). Rather than involving a real change in ability, listening to Mozart seemed to improve arousal and mood, yielding better concentration on the test (Schellenberg et al., 2007).

Despite mounting evidence that the Mozart effect was uncertain at best, the media and politicians were enthralled with the idea that a brief exposure of the brain to classical music in infancy, when neural connections are forming rapidly, might yield lifelong intellectual benefits. For a time, the states of Georgia, Tennessee, and South Dakota provided free classical music CDs for every newborn baby leaving the hospital. Yet no studies of the Mozart effect have ever been conducted on infants! And an experiment with school-age children failed to demonstrate any intellectual gains as a result of simply listening to music (McKelvie & Low, 2002).

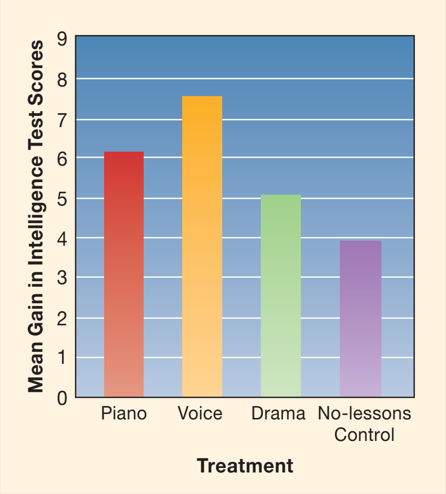

FIGURE 2.5 Music lessons promote gains in intelligence. In a field experiment comparing 36 weeks of piano and voice lessons with drama lessons and a no-lessons control, children in the two groups receiving music lessons showed slightly greater gains in intelligence test performance. (Adapted from Schellenberg, 2004.)

Research suggests that to produce lasting gains in mental-test scores, interventions must be long-lasting and involve children's active participation. Consequently, Glenn Schellenberg (2004) wondered, Can music lessons enhance intelligence? Children who take music lessons must practice regularly, exhibit extended focused attention, read music, memorize lengthy musical passages, understand diverse musical structures, and master technical skills. These experiences might foster cognitive processing, particularly during childhood, when regions of the brain are taking on specialized functions and are highly sensitive to environmental influences.

Schellenberg recruited 132 six-year-olds—children just old enough for formal lessons. First, the children took an intelligence test and were rated on social maturity, permitting the researchers to see whether music lessons would affect some aspects of development but not others. Next, the children were randomly assigned to one of four experimental conditions. Two were music groups; one received piano lessons and the other voice lessons. The third group took drama lessons—a condition that shed light on whether intellectual gains were unique to musical experiences. The fourth group—a no-lessons control—was offered music lessons the following year. All music and drama instruction took place at the prestigious Royal Conservatory of Music in Toronto, where experienced teachers taught the children in small groups. After 36 weeks of lessons, a longitudinal follow-up was conducted: The children's intelligence and social maturity were assessed again.

All four groups gained in mental-test performance, probably because the participants had just entered grade school, which usually leads to an increase in intelligence test scores (see Chapter 8). But the two music groups consistently gained more than the drama and no-lessons control groups (see Figure 2.5). Their advantage, though just a few points, extended across many mental abilities, including verbal and spatial skills and speed of thinking. At the same time, only the drama group improved in social maturity.

© TOM GRILL/CORBIS/GLOW IMAGES

Children taking music lessons make greater gains in mental test performance than children taking drama lessons or no lessons at all. Music making involves diverse, intellectually challenging activities: reading notation, memorizing lengthy passages, analyzing musical structures, and mastering technical skills.

In sum, active, sustained musical experiences can lead to small increases in intelligence among 6-year-olds that do not arise from comparable drama lessons. But other enrichment activities with similar properties, such as reading, science, math, and chess programs, may confer similar benefits. All demand that children invest far more time and effort than they would in listening to a Mozart sonata. Nevertheless—despite absence of evidence to support their claims—music companies persist in selling CDs with such titles as "Music for Accelerated Learning" and "The Mozart Effect: Music for Newborns—A Bright Beginning."

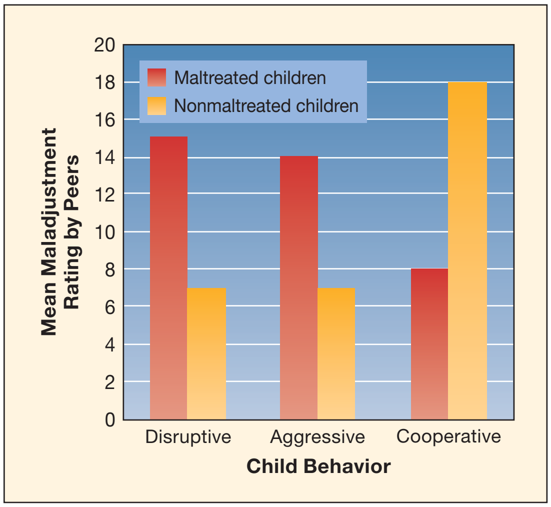

FIGURE 2.6 **A natural, or quasi-, experiment on the relationship of child maltreatment to children's social adjustment.** Researchers brought maltreated and nonmaltreated children together at a summer camp so they could be observed under similar conditions. After only a short time together, peers consistently rated maltreated children as less well-adjusted—more disruptive, more aggressive, and less cooperative. (Adapted from Shields, Ryan, & Cicchetti, 2001.)

social behaviors (Shields, Ryan, & Cicchetti, 2001). The investigators concluded that maltreated children's internalized, unfavorable parenting images probably contribute to their poor social adjustment. And their poor adjustment reduces their access to the healing effects of warm, enjoyable relationships with peers. Despite intriguing findings like these, natural experiments cannot achieve the precision and rigor of true experimental research.

To help you compare correlational and experimental designs, Table 2.3 summarizes their strengths and limitations. Now let's take a close look at designs for studying development.

ASK YOURSELF

Review ■ Why are natural experiments less precise than laboratory and field experiments?

Connect ■ Reread the description of the study of aggressive boys and their friendships on page 44. What type of design did the researchers use, and why?

Apply ■ A researcher compares children who went to summer leadership camps with children who attended athletic camps. She finds that those who attended leadership camps are friendlier. Should the investigator tell parents that sending children to leadership camps will cause them to be more sociable? Why or why not?

Reflect ■ Design a study to investigate whether time devoted to adult–child picture-book reading in the preschool years contributes to reading readiness at school entry. List steps you will take to protect the internal and external validity of your investigation.

- Describe designs for studying development, noting strengths and limitations of each.

Designs for Studying Development

Scientists interested in child development require information about the way research participants change over time. To answer questions about development, they must extend correlational and experimental approaches to include measurements at different ages. Longitudinal and cross-sectional designs are special *developmental research* strategies. In each, age comparisons form the basis of the research plan.

The Longitudinal Design

In a **longitudinal design,** participants are studied repeatedly at different ages, and changes are noted as they get older. The time spanned may be relatively short (a few months to several years) or very long (a decade or even a lifetime).

Advantages of the Longitudinal Design

The longitudinal approach has two major strengths. First, because it tracks the performance of each person over time, researchers can identify common patterns as well as individual differences in development. Second, longitudinal studies permit investigators to examine relationships between early and later events and behaviors. Let's illustrate these ideas.

A group of researchers wondered whether children who display extreme personality styles—either angry and explosive or shy and withdrawn—retain the same dispositions

TABLE 2.3 Strengths and Limitations of General Research Designs

DESIGN	DESCRIPTION	STRENGTHS	LIMITATIONS
Correlational design	The investigator obtains information on participants without altering their experiences.	Permits study of relationships between variables.	Does not permit inferences about cause-and-effect relationships.
Laboratory experiment	Under controlled laboratory conditions, the investigator manipulates an independent variable and looks at its effect on a dependent variable; requires random assignment of participants to treatment conditions.	Permits inferences about cause-and-effect relationships.	Findings may not generalize to the real world.
Field experiment	The investigator randomly assigns participants to treatment conditions in natural settings.	Permits generalization of experimental findings to the real world.	Control over the treatment is generally weaker than in a laboratory experiment.
Natural, or quasi-, experiment	The investigator compares already existing treatments in the real world, carefully selecting groups of participants to ensure that their characteristics are as much alike as possible.	Permits study of many real-world conditions that cannot be experimentally manipulated.	Findings may be due to variables other than the treatment.

when they become adults. In addition, the researchers wanted to know what kinds of experiences promote stability or change in personality and what consequences explosiveness and shyness have for long-term adjustment. To answer these questions, the researchers delved into the archives of the Guidance Study, a well-known longitudinal investigation that was initiated in 1928 at the University of California, Berkeley, and continued for several decades (Caspi, Elder, & Bem, 1987, 1988).

Results revealed that the two personality styles were moderately stable. Between ages 8 and 30, a good number of individuals remained the same, whereas others changed substantially. When stability did occur, it appeared to be due to a "snowballing effect," in which children evoked responses from adults and peers that acted to maintain their dispositions. Explosive youngsters were likely to be treated with anger, whereas shy children were apt to be ignored. As a result, the two types of children came to view their social worlds differently. Explosive children regarded others as hostile; shy children regarded them as unfriendly (Caspi & Roberts, 2001). Together, these factors led explosive children to sustain or increase their unruliness and shy children to continue to withdraw.

Persistence of extreme personality styles affected many areas of adult adjustment. For men, the results of early explosiveness were most apparent in their work lives, in the form of conflicts with supervisors, frequent job changes, and unemployment. Because few women in this sample of an earlier generation worked after marriage, their family lives were most affected. Explosive girls grew up to be hotheaded wives and mothers who were especially prone to divorce. Sex differences in the long-term consequences of shyness were even greater. Men who had been withdrawn in childhood were delayed in marrying, becoming fathers, and developing careers. However, because a withdrawn, unassertive style was socially acceptable for females in the mid-twentieth century, women who had shy personalities showed no special adjustment problems.

Problems in Conducting Longitudinal Research Despite their strengths, longitudinal investigations pose a number of problems that can compromise both internal and external validity. A common difficulty is **biased sampling**—the failure to enlist participants who represent the population of interest. People who willingly participate in research that requires them to be observed and tested over many years are likely to have distinctive characteristics—perhaps a special appreciation for the scientific value of research, or a unique need or desire for medical, mental health, or educational services provided by the investigators.

As a result, we cannot easily generalize from them to the rest of the population. Furthermore, longitudinal samples generally become more biased as the investigation proceeds because of **selective attrition.** Participants may move away or drop out for other reasons, and those who continue are likely to differ in important ways from those who drop out.

The very experience of being repeatedly observed, interviewed, and tested can also interfere with a study's validity. As children and adults are alerted to their own thoughts, feelings, and actions, they may consciously revise them in ways that have little to do with age-related change. In addition, with repeated testing, participants may become "test-wise." Their performance may improve as a result of **practice effects**—better test-taking skills and increased familiarity with the test—not because of factors commonly associated with development.

The most widely discussed threat to the validity of longitudinal findings is cultural–historical change, commonly called **cohort effects.** Longitudinal studies examine the development of *cohorts*—children developing in the same time period who are influenced by particular cultural and historical conditions. Results based on one cohort may not apply to children developing at other times. For example, look back at the findings on female shyness described in the previous section, which were gathered in the 1950s. Today's shy young women tend to be poorly adjusted—a difference that may be due to changes in gender roles in Western societies. Shy adults, whether male or female, feel more depressed, have fewer social supports, and may do less well in educational and career attainment than their agemates (Caspi, 2000; Caspi et al., 2003; Mounts et al., 2006). Similarly, a longitudinal study of social development would probably result in quite different findings if it were carried out in the first decade of the twenty-first century, around the time of World War II, or during the Great Depression of the 1930s.

© JENSEN WALKER/SAVE THE CHILDREN

This 6-year-old and his father, who lost their home in the March 2011 tsunami in northern Japan, receive aid from Save the Children, an international organization serving vulnerable children and families. This destructive historical event will likely induce a cohort effect for many Japanese children.

Cohort effects don't just operate broadly on an entire generation. They also occur when specific experiences influence some children but not others in the same generation. For example, children who witnessed the terrorist attacks of September 11, 2001 (either because they were near Ground Zero or because they saw injury and death on TV) or who had a parent, other relative, or family member directly exposed were far more likely than other children to display persistent emotional problems, including intense fear, anxiety, and depression (Mullett-Hume et al., 2008; Pfeffer et al., 2007; Rosen & Cohen, 2010). A study of one New York City sample suggested that as many as one-fourth of the city's children were affected (Hoven et al., 2005).

Finally, changes occurring within the field of child development may create problems for longitudinal research covering an extended time period. Theories and methods that first inspired a longitudinal study may become outdated. For this reason, as well as the others just mentioned, many recent longitudinal studies span only a few months or years. Although short-term longitudinal research does not yield the same breadth of information as long-term studies, it does spare researchers some formidable obstacles.

The Cross-Sectional Design

The length of time it takes for many behaviors to change, even in limited longitudinal studies, has led researchers to turn to a more convenient strategy for studying development. In the **cross-sectional design,** groups of people differing in age are studied at the same point in time.

Advantages of the Cross-Sectional Design The cross-sectional design is an efficient strategy for describing age-related trends. And because participants are measured only once, researchers need not be concerned about such difficulties as selective attrition, practice effects, or changes in the field that might make the findings obsolete by the time the study is complete.

An investigation in which students in grades 3, 6, 9, and 12 filled out a questionnaire asking about their sibling relationships provides a good illustration (Buhrmester & Furman, 1990). Findings revealed that sibling interaction was characterized by greater equality and less power assertion with age. Also, feelings of sibling companionship declined during adolescence. The researchers thought that several factors contributed to these age differences. As later-born children become more competent and independent, they no longer need, and are probably less willing to accept, direction from older siblings. And as adolescents move from psychological dependence on the family to greater involvement with peers, they may have less time and emotional need to invest in siblings. As you will see in Chapter 14, subsequent research has confirmed these intriguing ideas about the development of sibling relationships.

Problems in Conducting Cross-Sectional Research Despite its convenience, cross-sectional research does not provide evidence about development at the level at which it actually occurs: the individual. For example, in the cross-sectional study of sibling relationships just discussed, comparisons are limited to age-group averages. We cannot tell if important individual differences exist. Indeed, longitudinal findings reveal that adolescents vary considerably in the changing quality of their sibling relationships. Although many become more distant, others become more supportive and intimate, still others more rivalrous and antagonistic (Branje et al., 2004; Kim et al., 2006; Whiteman & Loken, 2006).

Cross-sectional studies—especially those that cover a wide age span—have another problem. Like longitudinal research, they can be threatened by cohort effects. For example, comparisons of 5-year-old cohorts and 15-year-old cohorts—groups born and reared in different years—may not really represent age-related changes. Instead, they may reflect unique experiences associated with the time period in which the age groups were growing up.

Improving Developmental Designs

Researchers have devised ways of building on the strengths and minimizing the weaknesses of longitudinal and cross-sectional approaches. Several modified developmental designs have resulted.

Sequential Designs To overcome some of the limitations of traditional developmental designs, investigators sometimes use **sequential designs,** in which they conduct several cross-sectional or longitudinal investigations (called *sequences*). The sequences might study participants over the same ages but in different years, or they might study participants over different ages but during the same years. Figure 2.7 illustrates the second of these options. As it also reveals,

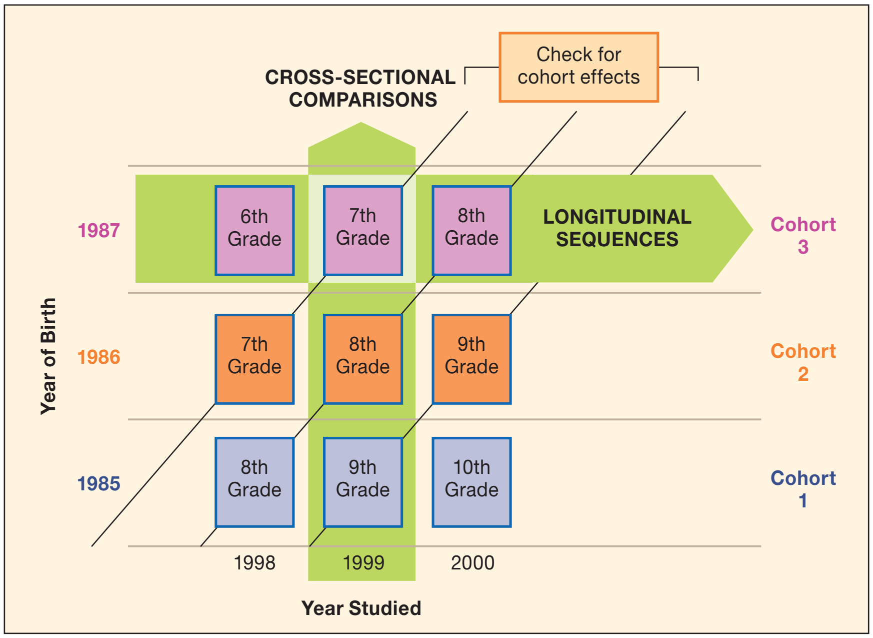

FIGURE 2.7 **Example of a sequential design.** Three cohorts, born in 1985 (blue), 1986 (orange), and 1987 (pink), respectively, are followed longitudinally for three years. Testing the cohorts in overlapping grades enables researchers to check for cohort effects by comparing participants born in different years when they reach the same grade (see diagonals). In a study using this design, same-grade adolescents who were members of different cohorts scored similarly on a questionnaire assessing family harmony, indicating no cohort effects. By following each cohort for just three years, the investigator could infer a developmental trend across five years, from sixth to tenth grade.

some sequential designs combine longitudinal and cross-sectional strategies, an approach that has three advantages:

- We can find out whether cohort effects are operating by comparing participants of the same age who were born in different years. In Figure 2.7, for example, we can compare the longitudinal samples at seventh, eighth, and ninth grades. If they do not differ, we can rule out cohort effects.
- We can make both longitudinal and cross-sectional comparisons. If outcomes are similar, we can be especially confident about the findings.
- The design is efficient. In our example, we can find out about change over a five-year period by following each cohort for three years.

In a study that used the design in Figure 2.7, researchers wanted to find out if family harmony changed as young people experienced the dramatic physical and psychological changes of adolescence (Baer, 2002). A questionnaire assessing emotional bonding among family members was given to three adolescent cohorts, each born a year apart. In longitudinal follow-ups, each cohort again responded to the questionnaire during the following two years.

Findings for the three cohorts converged: All reported (1) a slight decline in family harmony with grade and (2) similar levels of family harmony as they reached the same grade, confirming that there were no cohort effects. Therefore, the researchers concluded that family closeness diminishes steadily from sixth to tenth grade, noting, however, that the change is mild—not enough to threaten supportive family ties. **TAKE A MOMENT...** Turn back to our discussion of parent–adolescent communication as a dynamic system on page 31 in Chapter 1 and our consideration of adolescent sibling relationships on page 63. How are those results helpful in interpreting the outcomes of the sequential study just described?

Examining Microcosms of Development In the examples of developmental research we have discussed, observations of children are fairly widely spaced. When we observe once a year or every few years, we can describe change, but we cannot easily capture the processes that produce it. The **microgenetic design,** an adaptation of the longitudinal approach, presents children with a novel task and follows their mastery over a series of closely spaced sessions. Within this "microcosm" of development, researchers observe how change occurs (Flynn & Siegler, 2007; Kuhn, 1995; Siegler & Crowley, 1991). The microgenetic design is especially useful for studying cognitive development—for example, the strategies children use to acquire knowledge in reading, mathematics, and science, along with teaching interventions that facilitate their progress (Siegler, 2002, 2006). As you will see in Chapter 4, the microgenetic design has also been used to trace infants' mastery of motor skills.

In one microgenetic study, researchers had sixth graders engage in frequent debate of controversial issues (such as capital punishment) over a school year (Kuhn et al., 2008). The children worked in pairs, collaborating against a series of opposing pairs, who took the opposite side. Only when both pair members agreed on an argument could they communicate it—a rule aimed at promoting more thoughtful contributions along with critical reflection. To further these goals, children conducted dialogues using instant messaging, which preserved a record that enabled them to reflect on their arguments and discuss possible improvements. Findings revealed that over time, most children made an increasing number of statements indicating awareness of argument quality, especially to the opposition ("Give us some reasons." "You haven't answered."). The more such

© ELLEN B. SENISI PHOTOGRAPHY

How do these first graders make use of manipulatives to master place value in arithmetic? A microgenetic design, which permits researchers to follow children's mastery of a challenging task, is uniquely suited to answering this question.

statements children made, the more they improved in debate skill, especially in counterargument and rebuttal—the most challenging debate activities.

Microgenetic studies, however, are difficult to carry out. Researchers must pore over hours of recorded information, analyzing each participant's behavior many times. In addition, the time required for children to change is hard to anticipate. It depends on a careful match between the child's capabilities and the demands of the task. Finally, as in other longitudinal research, practice effects can distort microgenetic findings. As a check, researchers can compare microgenetic with cross-sectional observations. If new behaviors that emerge microgenetically reflect typical development, they should match the behaviors displayed by more advanced participants in cross-sectional studies, who are observed only once (Kuhn, 1995). When researchers overcome the challenges of microgenetic research, they reap the benefits of seeing development as it takes place.

Combining Experimental and Developmental Designs Perhaps you noticed that all the examples of longitudinal and cross-sectional research we have considered permit only correlational, not causal, inferences. Yet causal information is also desirable, both for testing theories and for finding ways to enhance development. Sometimes researchers can explore the causal link between experiences and development by experimentally manipulating the experiences. If, as a result, development is enhanced, then we have strong evidence for a causal association. Today, research that combines an experimental strategy with either a longitudinal or a cross-sectional approach is becoming increasingly common. For a summary of the strengths and limitations of developmental research designs, refer to Table 2.4.

LOOK and LISTEN

Find a recent news article reporting a research study on children. Obtain the original research report from its scientific journal, and identify the research method(s) and design(s) used, listing strengths and limitations. Did the news article describe the findings accurately?

TABLE 2.4 Strengths and Limitations of Developmental Research Designs

DESIGN	DESCRIPTION	STRENGTHS	LIMITATIONS
Longitudinal	The investigator studies the same group of participants repeatedly at different ages.	Permits study of common patterns and individual differences in development and relationships between early and later events and behaviors.	Age-related changes may be distorted because of biased sampling, selective attrition, practice effects, and cohort effects. Theoretical and methodological changes in the field can make findings obsolete.
Cross-sectional	The investigator studies groups of participants differing in age at the same time.	More efficient than the longitudinal design. Avoids problems of selective attrition, practice effects, and theoretical and methodological changes in the field.	Does not permit study of individual developmental trends. Age differences may be distorted because of cohort effects.
Sequential	The investigator conducts several cross-sectional or longitudinal investigations (called sequences). These might study participants over the same ages but in different years, or they might study participants over different ages but during the same years.	When the design includes longitudinal sequences, permits both longitudinal and cross-sectional comparisons. Also reveals cohort effects. Enables tracking of age-related changes more efficiently than the longitudinal design.	May have the same problems as longitudinal and cross-sectional strategies, but the design itself helps identify difficulties.
Microgenetic	The investigator presents children with a novel task and follows their mastery over a series of closely spaced sessions.	Offers insights into how change occurs.	Requires intensive study of participants' moment-by-moment behaviors; the time required for participants to change is difficult to anticipate. Practice effects may distort developmental trends.

ASK YOURSELF

Review ■ Explain how cohort effects can distort the findings of both longitudinal and cross-sectional studies. How does the sequential design reveal cohort effects?

Connect ■ Review the study on music lessons and intelligence reported in the Social Issues: Education box on page 59. Explain how it combines an experimental with a developmental design. What advantage does this approach offer?

Apply ■ A researcher wants to know whether children enrolled in child-care centers in the first few years of life do as well in school as those who are not in child care. Which developmental design is appropriate for answering this question? Explain.

Reflect ■ Suppose a researcher asks you to enroll your baby in a 10-year longitudinal study. What factors would lead you to agree and to stay involved? Do your answers shed light on why longitudinal studies often have biased samples? Explain.

▶ What special ethical issues arise in doing research on children?

Ethics in Research on Children

Research into human behavior creates ethical issues because, unfortunately, the quest for scientific knowledge can sometimes exploit people. When children take part in research, the ethical concerns are especially complex. Children are more vulnerable than adults to physical and psychological harm. In addition, immaturity makes it difficult or impossible for children to evaluate for themselves what participation in research will mean. For these reasons, special ethical guidelines for research on children have been developed by the federal government, by funding agencies, and by research-oriented associations such as the American Psychological Association (2002) and the Society for Research in Child Development (2007).

Table 2.5 presents a summary of children's basic research rights. **TAKE A MOMENT...** After examining them, think back to the ethical controversy faced by my colleague Ron, described at the beginning of this chapter. Then read about the following research situations,

TABLE 2.5 Children's Research Rights

RESEARCH RIGHT	DESCRIPTION
Protection from harm	Children have the right to be protected from physical or psychological harm in research. If in doubt about the harmful effects of research, investigators should seek the opinion of others. When harm seems possible, investigators should find other means for obtaining the desired information or abandon the research.
Informed consent	All research participants, including children, have the right to have explained to them, in language appropriate to their level of understanding, all aspects of the research that may affect their willingness to participate. When children are participants, informed consent of parents as well as others who act on the child's behalf (such as school officials) should be obtained, preferably in writing. Children, and the adults responsible for them, have the right to discontinue participation in the research at any time.
Privacy	Children have the right to concealment of their identity on all information collected in the course of research. They also have this right with respect to written reports and any informal discussions about the research.
Knowledge of results	Children have the right to be informed of the results of research in language that is appropriate to their level of understanding.
Beneficial treatments	If experimental treatments believed to be beneficial are under investigation, children in control groups have the right to alternative beneficial treatments if they are available.

Sources: American Psychological Association, 2002; Society for Research in Child Development, 2007.

each of which also poses a serious ethical dilemma. What precautions do you think should be taken in each instance? Is either so threatening to children's well-being that it should not be carried out?

- In a study of moral development, a researcher wants to assess children's ability to resist temptation by videotaping their behavior without their knowledge. She promises 7-year-olds a prize for solving difficult puzzles but tells them not to look at a classmate's correct solutions, which are deliberately placed at the back of the room. Informing children ahead of time that cheating is being studied or that their behavior is being monitored will destroy the purpose of the study.
- A researcher is interviewing fifth graders about their experiences with bullying. A girl describes frequent name-calling and derogatory comments by her older sister. Although the girl is unhappy, she wants to handle the problem on her own. If the researcher alerts the girl's parents to provide protection and help, he will violate his promise to keep participants' responses private.

Did you find it difficult to evaluate these examples? Virtually every organization that has devised ethical principles for research has concluded that conflicts arising in research situations do not have simple right or wrong answers. The ultimate responsibility for the ethical integrity of research lies with the investigator. But researchers are advised—and often required—to seek advice from others. Committees for this purpose (like the one that evaluated Ron's research) exist in colleges, universities, and other institutions. These *institutional review boards (IRBs)* assess proposed studies on the basis of a **risks-versus-benefits ratio,** which involves weighing the costs to participants in terms of inconvenience and possible psychological or physical injury against the study's value for advancing knowledge and improving conditions of life.

Ron's procedures, the school's research committee claimed, might not offer children sufficient **protection from harm.** If there are any risks to the safety and welfare of participants that the research does not justify, then preference is always given to the research participants. Vulnerability to harm, as the Social Issues: Health box on page 68 reveals, varies with children's age and characteristics. Occasionally, further inquiry can help resolve perplexing ethical dilemmas. In Ron's case, he provided the research committee with findings showing that asking elementary school children to identify disliked peers does not cause them to interact less frequently or more negatively with those children (Bell-Dolan, Foster, & Sikora, 1989). At the same time, Ron agreed to take special precautions when requesting such information. He promised to ask all the children to keep their comments confidential. He also arranged to conduct the study at a time when classmates have limited opportunity to interact with one another—just before a school vacation (Bell-Dolan & Wessler, 1994). With these safeguards in place, the committee approved Ron's research.

The ethical principle of **informed consent**—people's right to have all aspects of a study explained to them that might affect their willingness to participate—requires special interpretation when participants cannot fully appreciate the research goals and activities. Parental consent is meant to protect the safety of children whose ability to decide is not yet fully mature. In addition, researchers should obtain the agreement of other individuals who act on children's behalf, such as institutional officials when research is conducted in schools, child-care centers, or hospitals. This is especially important when studies include special groups, such as abused children, whose parents may not always represent their best interests (refer again to the Social Issues: Health box).

As soon as children are old enough to appreciate the purpose of the research, and certainly by 7 years of age, their own informed consent should be obtained in addition to parental consent. Around age 7, changes in children's thinking permit them to better understand basic scientific principles and the needs of others. Researchers should respect and enhance these new capacities by giving school-age children a full explanation of research activities in language they can understand (Fisher, 1993). Careful attention to informed consent helps resolve dilemmas about revealing children's responses to parents, teachers, or other authorities when those responses suggest that the child's welfare is in

SOCIAL ISSUES: HEALTH

Children's Research Risks: Developmental and Individual Differences

Researchers interested in children face formidable challenges in defining their ethical responsibilities. Compared with adults, children are less capable of benefiting from research experiences. Furthermore, most risks children encounter are psychological rather than physical (as in medical research) and therefore difficult to anticipate or even detect (Thompson, 1992). Consider, for example, 7-year-old Henry, who did not want to answer a researcher's questions about how he feels about his younger brother, who has physical disabilities. Because Henry's parents told him they had given permission for his participation, he did not feel free to say no. Or take 11-year-old Isabelle, who tried to solve a problem but failed. Despite the researcher's assurances that the task was set up to be impossible, Isabelle ended up doubting her own competence.

How can we make sure that children are subjected to the least research risk possible? One valuable resource is our expanding knowledge of age-related capacities and individual differences. Research risks vary with development in complex ways. Some risks decrease with age, others increase, and still others occur at many or all ages (Thompson, 1990). And because of their personal characteristics and life circumstances, some children are more vulnerable to harm than others.

Age Differences

Research plans for younger children typically receive the most scrutiny because their limited cognitive competencies restrict their ability to make reasoned decisions and resist violations of their rights. In addition, as Henry's predicament illustrates, young children's limited social power can make it hard to refuse participation. In research that examined children's understanding of research procedures, 9-year-olds had great difficulty identifying their research rights and recognizing violations of those rights. Even 12-year-olds struggled to grasp their rights to decline participation, be protected from harm, and be given the study's results (Bruzzese & Fisher, 2003). And regardless of age, most children and adolescents thought that withdrawing from a study would have negative consequences and felt external pressure to continue. For example, they believed the researcher would be unhappy if they stopped (Ondrusek et al., 1998). But if researchers briefly name and explain each research right, comprehension improves, especially among adolescents.

Whereas young children often fail to comprehend the research process, older children are more susceptible to procedures that threaten the way they view themselves. As middle childhood brings greater sensitivity to others' evaluations, giving false negative feedback or inducing failure (as happened to Isabelle) becomes more stressful. In adolescence, when questioning of authority is common, young people may be better at sizing up and rejecting researchers' deceptive evaluations (Thompson, 1992).

Children's Unique Characteristics

At times, children's backgrounds and experiences introduce vulnerabilities. For example, in certain ethnic minority communities, where deference to authority, maintaining pleasant relationships, and meeting the needs of a guest (the researcher) are highly valued, children and parents may be likely to consent when they would rather not do so (Fisher et al., 2002). In other circumstances, such as child maltreatment, parents are not necessarily good advocates for their children's rights. The consent of an additional adult invested in the child's welfare—a relative, teacher, or therapist—may be necessary to protect the child. And in some cases, such as teenagers who are substance abusers or delinquents, parents may be so eager to get them into contact with professionals that they are willing to agree to almost any research, with little forethought (Drotar et al., 2000).

Finding ways to reconcile the risks-versus-benefits conflicts we have considered is vital because research on children is of great value to society. As institutional review boards evaluate each study, participants' age and unique characteristics should be central to the discussion. Children and adolescents need clear, age-appropriate explanations of their rights, reminders of those rights as the research proceeds, and invitations to ask questions about anything they do not understand (Kon & Klug, 2006). And their decision should be the final word in most investigations, even though this standard is not mandatory in current guidelines.

© LISA F. YOUNG/ALAMY

In consenting to participate in a study, this teenager may not fully understand that she has the right to withdraw without penalty. And adolescents are especially vulnerable to certain research risks, such as false negative feedback that threatens their self-concept.

danger. Children can be told in advance that if they report that someone is harming them, the researcher will tell an appropriate adult to take action to ensure the child's safety (Jennifer & Cowie, 2009).

Finally, all ethical guidelines advise that special precautions be taken in the use of deception and concealment, as occurs when researchers observe children from behind one-way mirrors, give them false feedback about their performance, or misrepresent the real purpose of the research. By their very nature, studies involving deception breach the research right to make a fully informed decision about participation. Furthermore, deception can be particularly disturbing to children, who rely on a basic faith in the honesty of adults to feel secure.

Nevertheless, when revealing the purpose of a study would compromise internal validity, deception may be necessary. Its appropriateness depends on whether a study's potential benefits to society are great enough to justify infringing on informed consent and risking other harm (Fisher, 2005). In one controversial investigation, researchers planned to study children's formation of stereotypes and prejudices against a visible minority group by having most students in summer school classes wear red T-shirts (the "majority") and several children in each class wear yellow T-shirts (the "minority"), without giving the children any reason for the groupings (Brown & Bigler, 2002). At the end of the summer session, the children would be asked to rate the likability of each of their classmates, and to rate each group on positive and negative traits ("friendly," "smart," "dirty," "mean").

At first, teachers refused to allow the study, arguing that students assigned to the "minority" group could be psychologically harmed. But the investigators countered that millions of racial and ethnic minority children and children with disabilities are placed in a similar position every day and that it would be of great value to the mostly white participants to better understand the consequences of being a minority group member (Bigler, 2007). As a result, the teachers allowed the research to go forward.

When deception is used with adults, **debriefing,** in which the researcher provides a full account and justification of the activities, occurs after the research session is over. Debriefing should also be done with children, and in the study just described it seemed to work well. Still, young children often lack the cognitive skills to understand the reasons for deceptive procedures, and despite explanations they may leave the research situation with their belief in the honesty of adults undermined. Ethical standards permit deception in research with children if investigators satisfy IRBs that nondeceptive alternatives do not offer sufficient scientific controls to test the hypothesis under investigation. Nevertheless, because deception may have serious emotional consequences for some youngsters, many child development specialists believe that researchers should use it only if the risk of harm is minimal.

ASK YOURSELF

Review ■ Explain why researchers must consider children's age-related capacities to ensure that they are protected from harm and have freely consented to research.

Connect ■ In the experiment on music lessons and intelligence reported in the Social Issues: Education box on page 59, why was it ethically important for the researchers to offer music lessons to the no-lessons control group during the year after completion of the study?

Apply ■ As a researcher was engaged in naturalistic observation of preschoolers' play, one child said, "Stop watching me!" Referring to the research rights listed in Table 2.5, indicate how the researcher should respond, and why.

Reflect ■ Would you approve the study on stereotyping and prejudice, in which summer-school students (without an explanation) were asked to wear colored T-shirts that identified them as members of "majority" and "minority" groups? Explain. What ethical safeguards do you believe are vital in research that requires deception of children to ensure internal validity?

SUMMARY

From Theory to Hypothesis (p. 41)

Describe the role of theories, hypotheses, and research questions in the research process.

- Research usually begins with a **hypothesis,** a prediction about behavior drawn from a theory, or—when little or no theory exists on a topic of interest—with a research question. On the basis of the hypothesis or question, the investigator selects research methods (specific activities of participants) and a research design (overall plan for the study).

© DAVID L. MOORE—LIFESTYLE/ALAMY

Common Research Methods (p. 42)

Describe research methods commonly used to study children, noting strengths and limitations of each.

- **Naturalistic observations**, gathered in children's everyday environments, permit researchers to see directly the everyday behaviors they hope to explain. In contrast, **structured observations** in laboratories give every participant an equal opportunity to display the behaviors of interest.
- Observations can preserve participants' entire stream of behavior, or they can be limited to one or a few behaviors, as in **event sampling** and **time sampling. Observer influence** and **observer bias** can reduce the accuracy of observational findings.
- Self-reports may be flexible and open-ended, like the **clinical interview**, which permits participants to express their thoughts in ways similar to their thinking in everyday life. Alternatively, **structured interviews**, tests, and questionnaires are more efficient, permitting researchers to specify activities and behaviors that participants might not think of in an open-ended interview. Both approaches depend on participants' ability and willingness to engage in accurate reporting. Currently, more researchers are combining the two approaches to see if they yield a clearer picture than either method can alone.
- **Neurobiological methods** measure the relationship between nervous system processes and behavior. Among autonomic nervous system indicators, saliva concentrations of the hormone cortisol provide information about stress reactivity. Electroencephalogram (EEG) and event-related potentials (ERPs) detect changes in electrical activity in the cerebral cortex.
- Neuroimaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), yield the most precise information about brain region specialization and abnormalities in brain functioning. Near-infrared spectroscopy (NIRS) is well-suited for use with infants and young children. However, investigators cannot be sure that a child demonstrating a particular pattern of autonomic or brain activity has actually processed a stimulus in a certain way.

© IMAGE SOURCE/GLOW IMAGES

- The **clinical,** or **case study, method** provides an in-depth understanding of a single child. But collection of information may be unsystematic and subjective, and researchers cannot generalize beyond the child studied.
- To uncover the cultural meanings of children's and adults' behaviors, researchers rely on **ethnography,** engaging in participant observation. But investigators' cultural values and theoretical commitments may lead them to observe selectively or misinterpret what they see.

Reliability and Validity: Keys to Scientifically Sound Research (p. 54)

Explain how reliability and validity apply to research methods and to the overall accuracy of research findings and conclusions.

- **Reliability** refers to the consistency, or repeatability, of measures of behavior. In observational research, inter-rater reliability is determined by having observers evaluate the same behaviors. For self-report and neurobiological measures, test–retest reliability is determined. In clinical and ethnographic research, reliability involves assessing whether the patterns and themes identified by the researcher are grounded in evidence and are plausible.
- A research method has high **validity** if, after examining its content and relationships with other measures of behavior, the researcher finds that it reflects what it was intended to measure. The concept of validity can also be applied to the overall accuracy of research findings and conclusions. In designing a study, investigators must ensure **internal validity**—that conditions internal to the design permit an accurate test of the hypothesis or question. They must also consider **external validity**—the degree to which findings generalize to settings and participants outside the original study.

General Research Designs (p. 55)

Distinguish correlational and experimental research designs, noting strengths and limitations of each.

- A **correlational design** examines relationships between variables without altering people's experiences. The **correlation coefficient** is often used to measure the association between variables. Correlational studies do not permit cause-and-effect inferences, but they can be helpful in identifying relationships that are worth exploring with a more powerful experimental strategy.

- An **experimental design** permits cause-and-effect inferences. Researchers manipulate an **independent variable** by exposing participants to two or more treatment conditions. Then they determine what effect this variable has on a **dependent variable**. **Random assignment** and **matching** ensure that characteristics of participants and treatment conditions do not operate as **confounding variables**, reducing the internal validity of experimental findings.

© TOM GRILL/CORBIS/GLOW IMAGES

- **Laboratory experiments** usually achieve a high degree of control, but their findings may not apply to everyday life. In **field experiments**, researchers randomly assign participants to treatment conditions in the real world. Some investigators conduct **natural**, or **quasi-, experiments**, comparing existing treatments. However, these approaches are less rigorous than true experimental designs.

Designs for Studying Development **(p. 60)**

Describe designs for studying development, noting strengths and limitations of each.

- In the **longitudinal design**, participants are studied repeatedly at different ages to identify common patterns as well as individual differences in development, and the relationship between early and later events and behaviors. Problems include **biased sampling**, **selective attrition**, **practice effects**, and long-term changes in accepted theories and methods. **Cohort effects** threaten the validity of longitudinal findings because of difficulty generalizing to children growing up during other time periods.
- The **cross-sectional design**, in which groups of children differing in age are studied at the same point in time, offers an efficient approach to investigating development. However, it is limited to comparisons of age-group averages and vulnerable to cohort effects.
- By comparing participants of the same age who were born in different years, investigators use **sequential designs** to test for cohort effects, make longitudinal and cross-sectional comparisons, and gather information about development efficiently. In the **microgenetic design**, researchers track change as it occurs to gain insights into processes of development. However, the time required for children to change is hard to anticipate, and practice effects can bias findings.

Ethics in Research on Children **(p. 66)**

What special ethical issues arise in doing research on children?

- Because of their immaturity, children are especially vulnerable to harm and often cannot evaluate the risks and benefits of research. Ethical principles and institutional review boards (IRBs) that weigh research in terms of a **risks-versus-benefits ratio** help ensure **protection from harm**. In addition to parental consent and agreement of others acting on children's behalf, researchers should seek the **informed consent** of children age 7 and older. The use of deception, though sometimes necessary, is especially risky with children because **debriefing** can undermine their faith in the trustworthiness of adults.

IMPORTANT TERMS AND CONCEPTS

biased sampling (p. 61)
clinical interview (p. 46)
clinical, or case study, method (p. 50)
cohort effects (p. 62)
confounding variables (p. 57)
correlation coefficient (p. 56)
correlational design (p. 55)
cross-sectional design (p. 62)
debriefing (p. 69)
dependent variable (p. 56)
ethnography (p. 52)
event sampling (p. 44)
experimental design (p. 56)

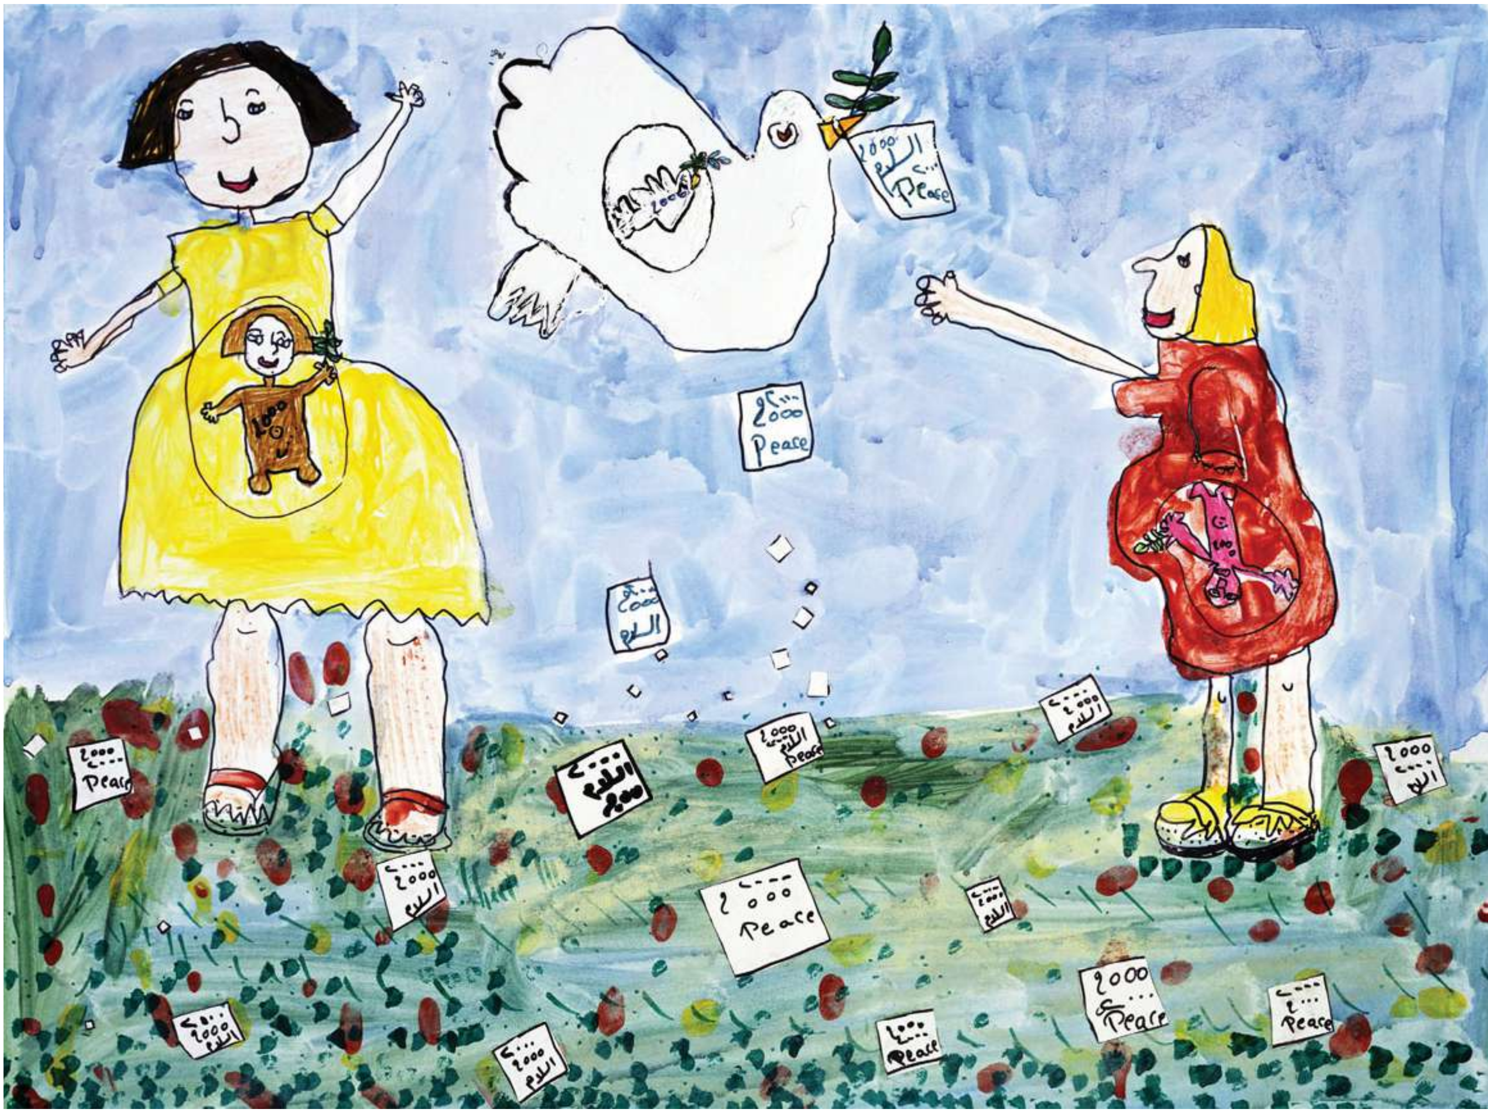
CHAPTER 3



“Giving Birth to Peace”

Lotfeh Mohamed El Masri, 11 years, Lebanon

This painting captures expectant parents’ hopes for a compassionate world in which to rear their children. How is the one-celled organism gradually transformed into a baby with the human capacity to play, dream, and create? What factors support or undermine this earliest period of development? Chapter 3 provides answers to these questions.

Heredity, Environment, and Behavior: A Look Ahead
The Question, "How Much?" • The Question, "How?"

■ **BIOLOGY AND ENVIRONMENT:** *A Case of Epigenesis: Smoking During Pregnancy Alters Gene Expression*

"It's a girl," announces the doctor, holding up the squalling newborn baby as her new parents gaze with amazement at their miraculous creation.

"A girl! We've named her Sarah!" exclaims the proud father to eager relatives waiting for news of their new family member.

As we join these parents in thinking about how this wondrous being came into existence and imagining her future, we are struck by many questions. How could this baby, equipped with everything necessary for life outside the womb, have developed from the union of two tiny cells? What ensures that Sarah will, in due time, roll over, reach for objects, walk, talk, make friends, learn, imagine, and create—just like other typical children born before her? Why is she a girl and not a boy, dark-haired rather than blond, calm and cuddly instead of wiry and energetic? What difference will it make that Sarah is given a name and place in one family, community, nation, and culture rather than another?

To answer these questions, we begin by considering genetic foundations. Because nature has prepared us for survival, all humans have features in common. Yet each of us is also unique. **TAKE A MOMENT...** Think about several children you know well, and jot down the most obvious physical and behavioral similarities between them and their parents. Did you find that one child shows combined features of both parents, another resembles just one parent, whereas a third is not like either parent? These directly observable characteristics are called **phenotypes.** They depend in part on the individual's **genotype**—the complex blend of genetic information that determines our species and influences all our unique characteristics. Yet phenotypes, as our discussion will show, are also affected by environmental influences—ones that begin even before conception.

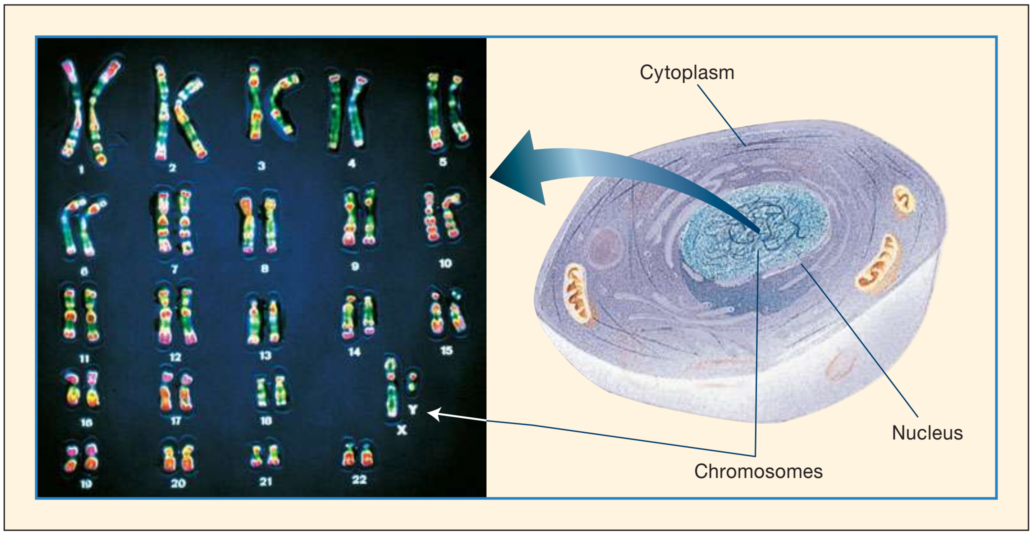
Next, we trace prenatal development, the most rapid period of growth, during which complex transactions between heredity and environment profoundly affect children's health and well-being. Then we turn to the drama of birth and to the problems of infants who are born underweight or too early.

As our discussion proceeds, some findings about the influence of nature and nurture may surprise you. For example, many people believe that when children inherit unfavorable characteristics, not much can be done to help them. Others are convinced that the damage done to a child by a harmful environment can easily be corrected. We will see that neither of these assumptions is true. In the final section of this chapter, we take up the question of how nature and nurture work together to shape the course of development.

Genetic Foundations

Each of us is made up of trillions of units called *cells*. Within every cell is a control center, or *nucleus*, that contains rodlike structures called **chromosomes,** which store and transmit genetic information. Human chromosomes come in 23 matching pairs (an exception is the XY pair in males, which we will discuss shortly). Each member of a pair corresponds to the other in size, shape, and genetic functions. One is inherited from the mother and one from the father (see Figure 3.1 on page 74).

FIGURE 3.1 **A karyotype, or photograph, of human chromosomes.** The 46 chromosomes shown here were isolated from a human cell, stained, greatly magnified, and arranged in pairs according to decreasing size of the upper "arm" of each chromosome. The twenty-third pair, XY, reveals that the cell donor is a male. In a female, this pair would be XX. (© CNRI/Science Photo Library/Photo Researchers, Inc.)



- What are genes, and how are they transmitted from one generation to the next?
- Describe various patterns of genetic inheritance.
- Describe major chromosomal abnormalities, and explain how they occur.

The Genetic Code

Chromosomes are made up of **deoxyribonucleic acid,** or **DNA.** As Figure 3.2 shows, DNA is a long double-stranded molecule that looks like a twisted ladder. Each rung of the ladder consists of a pair of chemical substances called *bases*. Although the bases always pair up in the same way across the ladder rungs—A with T, C with G—they can occur in any order along its sides. It is this sequence of base pairs that provides genetic instructions. A **gene** is a segment of DNA along the length of the chromosome. Genes can be of different lengths—perhaps 100 to several thousand ladder rungs long. An estimated 20,000 to 25,000 genes lie along the human chromosomes (Human Genome Program, 2008).

We share some of our genetic makeup with even the simplest organisms, such as bacteria and molds, and most of it with other mammals, especially primates. Between 98 and 99 percent of chimpanzee and human DNA is identical. This means that only a small portion of our heredity is responsible for the traits that make us human, from our upright gait to our extraordinary language and cognitive capacities. And the genetic variation from one human to the next is even less! Individuals around the world are about 99.1 percent genetically identical (Gibbons, 1998; Gibbons et al., 2004). But it takes a change in only a single base pair to influence human traits. And such tiny changes can combine in unique ways across multiple genes, thereby amplifying variability within the human species.

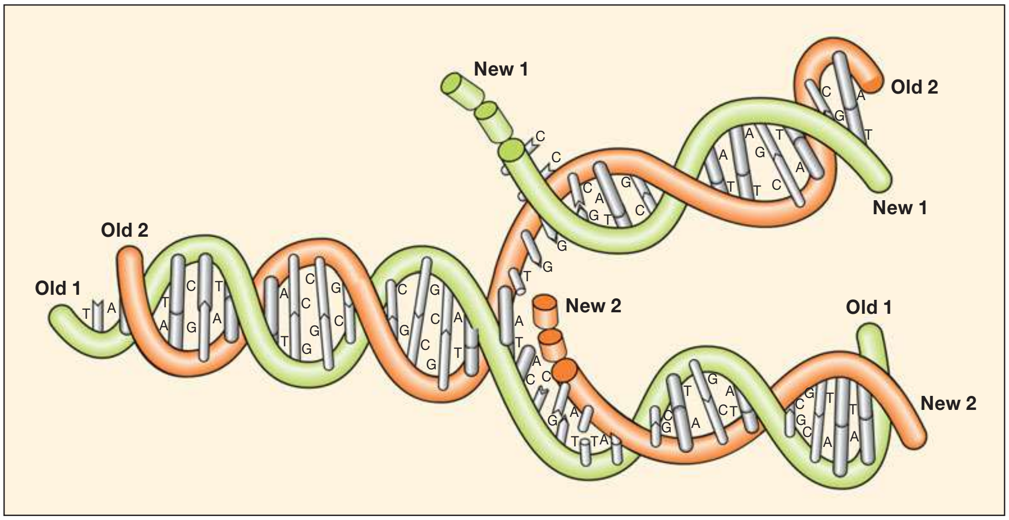


FIGURE 3.2 **DNA's ladderlike structure.** This figure shows that the pairings of bases across the rungs of the ladder are very specific: Adenine (A) always appears with thymine (T), and cytosine (C) always appears with guanine (G). Here, the DNA ladder duplicates by splitting down the middle of its ladder rungs. Each free base picks up a new complementary partner from the area surrounding the cell nucleus.

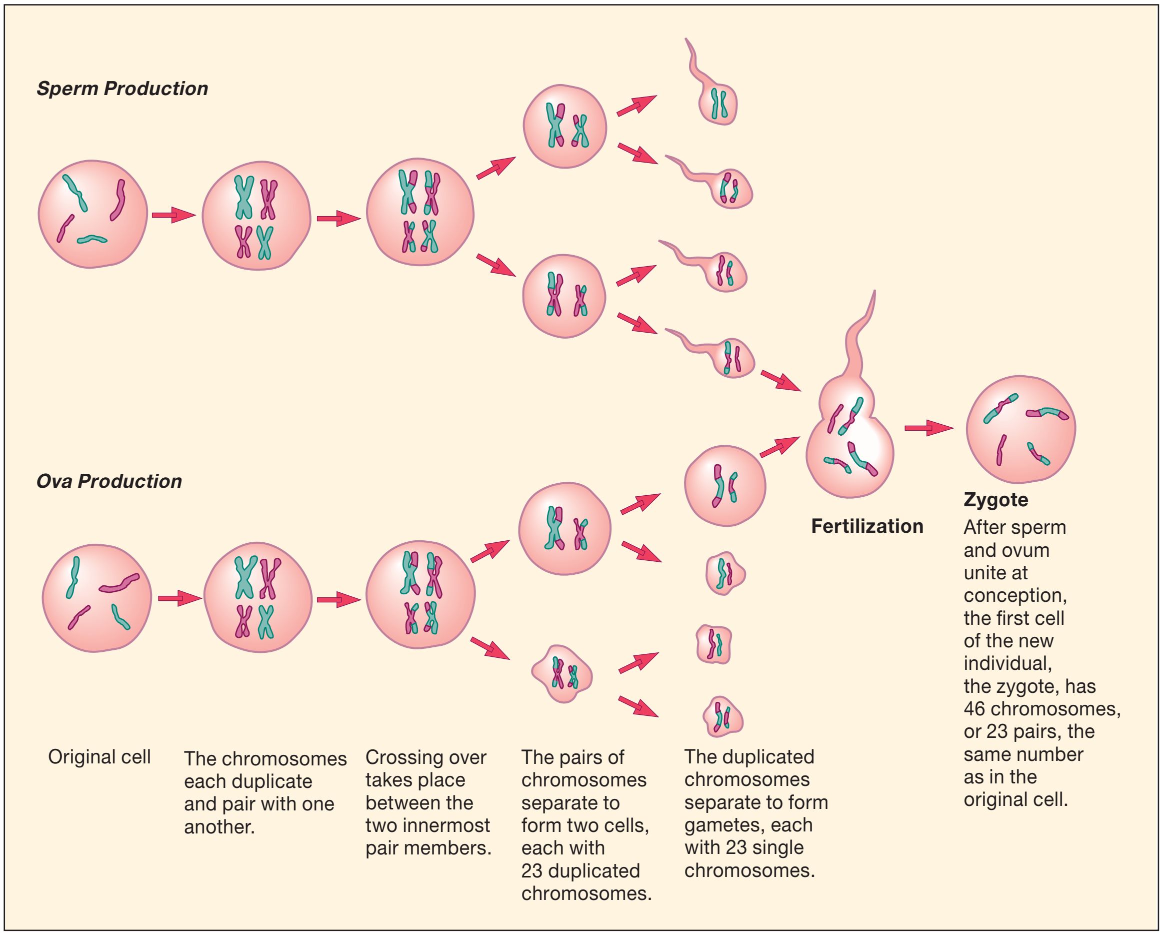
A unique feature of DNA is that it can duplicate itself through a process called **mitosis.** This special ability permits a single cell, formed at conception, to develop into a complex human being composed of a great many cells. Refer again to Figure 3.2, and you will see that during mitosis, the chromosomes copy themselves. As a result, each new body cell contains the same number of chromosomes and the identical genetic information.

Genes accomplish their task by sending instructions for making a rich assortment of proteins to the *cytoplasm*, the area surrounding the cell nucleus. Proteins, which trigger chemical reactions throughout the body, are the biological foundation on which our characteristics are built. How do humans, with far fewer genes than scientists once thought (only twice as many as the worm or fly), manage to develop into such complex beings? The answer lies in the proteins our genes make, which break up and reassemble in staggering variety—about 10 to 20 million altogether. Simpler species have far fewer proteins. Furthermore, the communication system between the cell nucleus and cytoplasm, which fine-tunes gene activity, is more intricate in humans than in simpler organisms. Within the cell, a wide range of environmental factors modify gene expression (Lashley, 2007). So even at this microscopic level, biological events are the result of *both* genetic and nongenetic forces.

The Sex Cells

New individuals are created when two special cells called **gametes,** or sex cells—the sperm and ovum—combine. A gamete contains only 23 chromosomes, half as many as a regular body cell. Gametes are formed through a cell division process called **meiosis,** which halves the number of chromosomes normally present in body cells. When sperm and ovum unite at fertilization, the resulting cell, called a **zygote,** will again have 46 chromosomes.

The steps involved in meiosis are shown in Figure 3.3. First, the chromosomes pair up, and each one copies itself. Then a special event called **crossing over** occurs, in which



Sperm Production
Ova Production
Fertilization
Zygote
After sperm and ovum unite at conception, the first cell of the new individual, the zygote, has 46 chromosomes, or 23 pairs, the same number as in the original cell.
Original cell
The chromosomes each duplicate and pair with one another.
Crossing over takes place between the two innermost pair members.
The pairs of chromosomes separate to form two cells, each with 23 duplicated chromosomes.
The duplicated chromosomes separate to form gametes, each with 23 single chromosomes.

FIGURE 3.3 **The cell division process of meiosis, leading to gamete formation.** (Here, original cells are depicted with 2 rather than the full complement of 23 pairs.) Meiosis creates gametes with only half the usual number of chromosomes. When sperm and ovum unite at conception, the first cell of the new individual (the zygote) has the correct, full number of chromosomes.

chromosomes next to each other break at one or more points along their length and exchange segments, so that genes from one are replaced by genes from another. This shuffling of genes creates new hereditary combinations. Next, the chromosome pairs separate into different cells, but chance determines which member of each pair will gather with others and end up in the same gamete. Finally, each chromosome leaves its partner and becomes part of a gamete containing only 23 chromosomes instead of the usual 46.

These events make the likelihood extremely low—about 1 in 700 trillion—that nontwin siblings will be genetically identical (Gould & Keeton, 1996). The genetic variability produced by meiosis is adaptive: Because it generates offspring that vary in phenotype, it increases the chances that at least some members of a species will cope with ever-changing environments and will survive.

In the male, four sperm are produced when meiosis is complete. Also, the cells from which sperm arise are produced continuously throughout life. For this reason, a healthy man can father a child at any age after sexual maturity. In the female, meiosis results in just one ovum; the remaining genetic material degenerates. In addition, the female is born with all her ova already present in her ovaries, and she can bear children for only three to four decades. Still, there are plenty of female sex cells. About 1 to 2 million are present at birth, 40,000 remain at adolescence, and approximately 350 to 450 will mature during a woman's childbearing years (Moore & Persaud, 2008).

Boy or Girl?

Return to Figure 3.1, and note the 22 matching pairs of chromosomes, which geneticists number from longest (1) to shortest (22). These are called **autosomes** (meaning *not* sex chromosomes). The twenty-third pair consists of **sex chromosomes.** In females, this pair is called XX; in males, it is called XY. The X is a relatively large chromosome, whereas the Y is short and carries little genetic material. When gametes form in males, the X and Y chromosomes separate into different sperm cells. The gametes that form in females all carry an X chromosome. Therefore, the sex of the new organism is determined by whether an X-bearing or a Y-bearing sperm fertilizes the ovum. In fact, scientists have isolated a gene on the Y chromosome that initiates the formation of male sex organs during the prenatal period (Sekido & Lovell-Badge, 2009). But they also know that other genes, some yet to be discovered, are involved in the development of sexual characteristics.

These identical, or monozygotic, twins were created when a duplicating zygote separated into two clusters of cells, which developed into two individuals with the same genetic makeup.

© F4FOTO/ALAMY

Multiple Offspring

Sometimes a zygote that has started to duplicate separates into two clusters of cells that develop into two individuals. These are called **identical,** or **monozygotic, twins** because they have the same genetic makeup. The frequency of identical twins is the same around the world—about 1 in every 330 births (Hall, 2003). Animal research has uncovered a variety of environmental influences that prompt this type of twinning, including temperature changes, variation in oxygen levels, and late fertilization of the ovum. In a minority of cases, the identical twinning runs in families, suggesting a genetic influence (Lashley, 2007).

Fraternal, or **dizygotic, twins,** the most common type of multiple birth, result from the release and fertilization of two ova. Genetically, they are no more alike than ordinary siblings. Table 3.1 summarizes genetic and environmental factors that increase the chances of giving birth to fraternal twins. Older maternal age, fertility drugs, and in vitro fertilization (to be discussed shortly) are major causes of the dramatic rise in fraternal twinning and other multiple births in industrialized

TABLE 3.1 Maternal Factors Linked to Fraternal Twinning

FACTOR	DESCRIPTION
Ethnicity	Occurs in 4 per 1,000 births among Asians, 8 per 1,000 births among whites, 12 to 16 per 1,000 births among blacks[a]
Family history of twinning	Occurs more often among women whose mothers and sisters gave birth to fraternal twins
Age	Rises with maternal age, peaking between 35 and 39 years, and then rapidly falls
Nutrition	Occurs less often among women with poor diets; occurs more often among women who are tall and overweight or of normal weight as opposed to slight body build
Number of births	Is more likely with each additional birth
Fertility drugs and in vitro fertilization	Is more likely with fertility hormones and in vitro fertilization (see page 86), which also increase the chances of bearing triplets, quadruplets, or quintuplets

[a] Worldwide rates, not including multiple births resulting from use of fertility drugs.

Sources: Hall, 2003; Hoekstra et al., 2008; Lashley, 2007.

nations over the past several decades (Machin, 2005; Russell et al., 2003). Currently, fraternal twins account for 1 in about every 60 births in the United States (U.S. Department of Health and Human Services, 2010a).

Patterns of Genetic Inheritance

Two forms of each gene occur at the same place on the chromosomes, one inherited from the mother and one from the father. Each form of a gene is called an **allele.** If the alleles from both parents are alike, the child is **homozygous** and will display the inherited trait. If the alleles differ, then the child is **heterozygous,** and relationships between the alleles determine the phenotype.

Dominant–Recessive Relationships

In many heterozygous pairings, **dominant–recessive inheritance** occurs: Only one allele affects the child's characteristics. It is called *dominant*; the second allele, which has no effect, is called *recessive*. Hair color is an example. The allele for dark hair is dominant (we can represent it with a capital *D*), whereas the one for blond hair is recessive (symbolized by a lowercase *b*). A child who inherits a homozygous pair of dominant alleles *(DD)* and a child who inherits a heterozygous pair *(Db)* will both be dark-haired, even though their genotypes differ. Blond hair can result only from having two recessive alleles *(bb)*. Still, heterozygous individuals with just one recessive allele *(Db)* can pass that trait to their children. Therefore, they are called **carriers** of the trait.

Some human characteristics and disorders that follow the rules of dominant–recessive inheritance are listed in Table 3.2 and Table 3.3 on page 78, respectively. As you can see, many disabilities and diseases are the product of recessive alleles. One of the most frequently occurring recessive disorders is *phenylketonuria*, or *PKU*, which affects the way the body breaks down proteins contained in many foods. Infants born with two recessive alleles lack an enzyme that converts one of the basic amino acids that make up proteins (phenylalanine) into a byproduct essential for body functioning

TABLE 3.2 Examples of Dominant and Recessive Characteristics

DOMINANT	RECESSIVE
Dark hair	Blond hair
Normal hair	Pattern baldness
Curly hair	Straight hair
Nonred hair	Red hair
Facial dimples	No dimples
Normal hearing	Some forms of deafness
Normal vision	Nearsightedness
Farsightedness	Normal vision
Normal vision	Congenital eye cataracts
Normally pigmented skin	Albinism
Double-jointedness	Normal joints
Type A blood	Type O blood
Type B blood	Type O blood
Rh-positive blood	Rh-negative blood

Note: Many normal characteristics that were previously thought to be due to dominant–recessive inheritance, such as eye color, are now regarded as due to multiple genes. For the characteristics listed here, there still seems to be general agreement that the simple dominant–recessive relationship holds.

DISEASE	DESCRIPTION	MODE OF INHERITANCE	INCIDENCE	TREATMENT
Autosomal Diseases				
Cooley's anemia	Pale appearance, retarded physical growth, and lethargic behavior begin in infancy.	Recessive	1 in 500 births to parents of Mediterranean descent	Frequent blood transfusion; death from complications usually occurs by adolescence.
Cystic fibrosis	Lungs, liver, and pancreas secrete large amounts of thick mucus, leading to breathing and digestive difficulties.	Recessive	1 in 2,000 to 2,500 Caucasian births; 1 in 16,000 births to North Americans of African descent	Bronchial drainage, prompt treatment of respiratory infection, dietary management. Advances in medical care allow survival with good life quality into adulthood.
Phenylketonuria (PKU)	Inability to metabolize the amino acid phenylalanine, contained in many proteins, causes severe central nervous system damage in the first year of life.	Recessive	1 in 8,000 births	Placing the child on a special diet results in average intelligence and normal lifespan. Subtle deficits in memory, planning, decision making, and problem solving are often present.
Sickle cell anemia	Abnormal sickling of red blood cells causes oxygen deprivation, pain, swelling, and tissue damage. Anemia and susceptibility to infections, especially pneumonia, occur.	Recessive	1 in 500 births to North Americans of African descent	Blood transfusions, painkillers, prompt treatment of infection. No known cure; 50 percent die by age 55.
Tay-Sachs disease	Central nervous system degeneration, with onset at about 6 months, leads to poor muscle tone, blindness, deafness, and convulsions.	Recessive	1 in 3,600 births to Jews of European descent and to French Canadians	None. Death occurs by 3 to 4 years of age.
Huntington disease	Central nervous system degeneration leads to muscular coordination difficulties, mental deterioration, and personality changes. Symptoms usually do not appear until age 35 or later.	Dominant	1 in 18,000 to 25,000 births to North Americans	None. Death occurs 10 to 20 years after symptom onset.
Marfan syndrome	Tall, slender build; thin, elongated arms and legs; and heart defects and eye abnormalities, especially of the lens. Excessive lengthening of the body results in a variety of skeletal defects.	Dominant	1 in 5,000 to 10,000 births	Correction of heart and eye defects is sometimes possible. Death from heart failure in early adulthood is common.
X-Linked Diseases				
Duchenne muscular dystrophy	Degenerative muscle disease. Abnormal gait, loss of ability to walk between 7 and 13 years of age.	Recessive	1 in 3,000 to 5,000 male births	None. Death from respiratory infection or weakening of the heart muscle usually occurs in adolescence.
Hemophilia	Blood fails to clot normally; can lead to severe internal bleeding and tissue damage.	Recessive	1 in 4,000 to 7,000 male births	Blood transfusions. Safety precautions to prevent injury.
Diabetes insipidus	Insufficient production of the hormone vasopressin results in excessive thirst and urination. Dehydration can cause central nervous system damage.	Recessive	1 in 2,500 male births	Hormone replacement.

Note: For recessive disorders, carrier status can be detected in prospective parents through a blood test or genetic analyses. For all disorders listed, prenatal diagnosis is available (see Table 3.5 on p. 85).

Sources: Kliegman et al., 2008; Lashley, 2007; McKusick, 2011.

(tyrosine). Without this enzyme, phenylalanine quickly builds to toxic levels that damage the central nervous system. By 1 year, infants with untreated PKU are permanently mentally retarded.

Despite its potentially damaging effects, PKU provides an excellent illustration of the fact that inheriting unfavorable genes does not always lead to an untreatable condition. All U.S. states require that each newborn be given a blood test for PKU. If the disease is found, doctors place the baby on a diet low in phenylalanine. Children who receive this treatment nevertheless show mild deficits in certain cognitive skills, such as memory, planning, decision making, and problem solving, because even small amounts of phenylalanine interfere with brain functioning (DeRoche & Welsh, 2008). But as long as dietary treatment begins early and continues, children with PKU usually attain an average level of intelligence and have a normal lifespan.

In dominant–recessive inheritance, if we know the genetic makeup of the parents, we can predict the percentage of children in a family who are likely to display or carry a trait. Figure 3.4 illustrates this for PKU. For a child to inherit the condition, each parent must have a recessive allele *(p)*. As the figure also illustrates, a single gene can affect more than one trait. Because of their inability to convert phenylalanine into tyrosine (which is responsible for pigmentation), children with PKU usually have light hair and blue eyes. Furthermore, children vary in the degree to which phenylalanine accumulates in their tissues and in the extent to which they respond to treatment. This is due to the action of **modifier genes,** which enhance or dilute the effects of other genes.

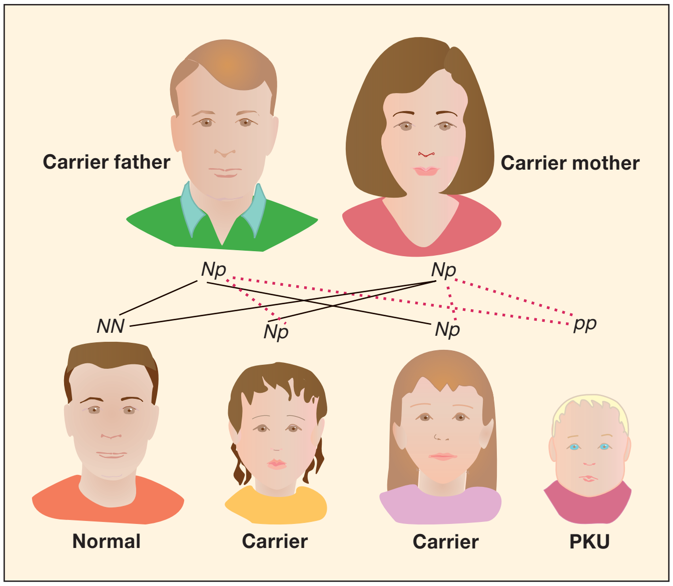

FIGURE 3.4 Dominant–recessive mode of inheritance, as illustrated by PKU. When both parents are heterozygous carriers of the recessive gene *(p)*, we can predict that 25 percent of their offspring are likely to be normal *(NN)*, 50 percent are likely to be carriers *(Np)*, and 25 percent are likely to inherit the disorder *(pp)*. Notice that the PKU-affected child, in contrast to his siblings, has light hair. The recessive gene for PKU affects more than one trait. It also leads to fair coloring.

Only rarely are serious diseases due to dominant alleles. Think about why this is so. Children who inherit the dominant allele always develop the disorder. They seldom live long enough to reproduce, so the harmful dominant allele is eliminated from the family's heredity in a single generation. Some dominant disorders, however, do persist. One is *Huntington disease*, a condition in which the central nervous system degenerates. Why has this disorder endured? Its symptoms usually do not appear until age 35 or later, after the person has passed the dominant allele to his or her children.

Incomplete Dominance

In some heterozygous circumstances, the dominant–recessive relationship does not hold completely. Instead, we see **incomplete dominance,** a pattern of inheritance in which both alleles are expressed in the phenotype, resulting in a combined trait, or one that is intermediate between the two.

The *sickle cell trait*, a heterozygous condition present in many black Africans, provides an example. *Sickle cell anemia* (see Table 3.3) occurs in full form when a child inherits two recessive alleles. They cause the usually round red blood cells to become sickle (crescent-moon) shaped, especially under low-oxygen conditions. The sickled cells clog the blood vessels and block the flow of blood, causing intense pain, swelling, and tissue damage. Despite medical advances that today allow 85 percent of affected children to survive to adulthood, North Americans with sickle cell anemia have an average life expectancy of only 55 years (Driscoll, 2007). Heterozygous individuals are protected from the disease under most circumstances. However, when they experience oxygen deprivation—for example, at high altitudes or after intense physical exercise—the single recessive allele asserts itself, and a temporary, mild form of the illness occurs.

The sickle cell allele is common among black Africans for a special reason. Carriers of it are more resistant to malaria than are individuals with two alleles for normal red blood cells. In Africa, where malaria is common, these carriers survived and reproduced more frequently than others, leading the gene to be maintained in the black population. But in regions of the world where the risk of malaria is low, the frequency of the gene is declining. For example, only 8 percent of African Americans are carriers, compared with 20 percent of black Africans (National Center for Biotechnology Information, 2007).

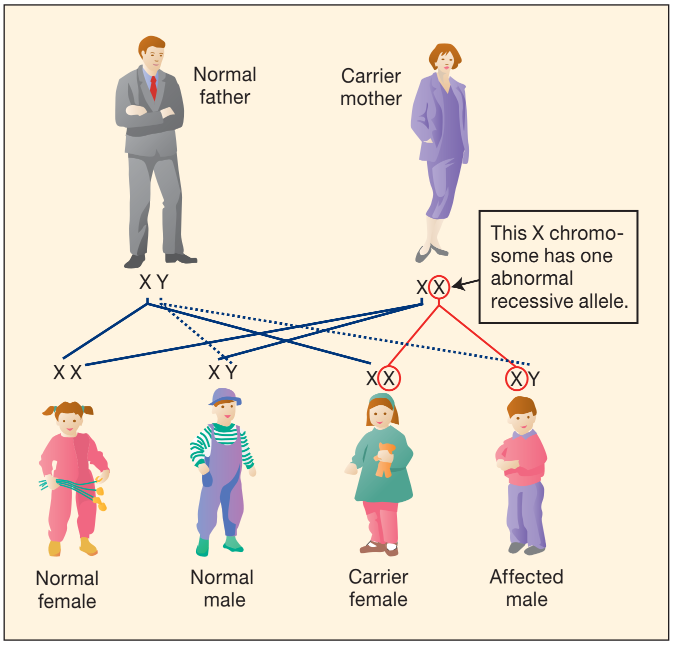

FIGURE 3.5 **X-linked inheritance.** In the example shown here, the allele on the father's X chromosome is normal. The mother has one normal and one abnormal recessive allele on her X chromosomes. By looking at the possible combinations of the parents' alleles, we can predict that 50 percent of these parents' male children are likely to have the disorder, and 50 percent of their female children are likely to be carriers of it.

X-Linked Inheritance

Males and females have an equal chance of inheriting recessive disorders carried on the autosomes, such as PKU and sickle cell anemia. But when a harmful allele is carried on the X chromosome, **X-linked inheritance** applies. Males are more likely to be affected because their sex chromosomes do not match. In females, any recessive allele on one X chromosome has a good chance of being suppressed by a dominant allele on the other X. But the Y chromosome is only about one-third as long and therefore lacks many corresponding alleles to override those on the X. A well-known example is *hemophilia*, a disorder in which the blood fails to clot normally. Figure 3.5 shows its greater likelihood of inheritance by male children whose mothers carry the abnormal allele.

Besides X-linked disorders, many other sex differences reveal the male to be at a disadvantage. Rates of miscarriage, infant and childhood deaths, birth defects, learning disabilities, behavior disorders, and mental retardation all are greater for boys (Butler & Meaney, 2005). It is possible that these sex differences can be traced to the genetic code. The female, with two X chromosomes, benefits from a greater variety of genes. Nature, however, seems to have adjusted for the male's disadvantage. Worldwide, about 107 boys are born for every 100 girls, and judging from miscarriage and abortion statistics, an even greater number of boys are conceived (United Nations, 2010).

Nevertheless, in recent decades, the proportion of male births has declined in many industrialized countries, including the United States, Canada, and European nations (Jongbloet et al., 2001). Some researchers attribute the trend to a rise in stressful living conditions, which heighten spontaneous abortions, especially of male fetuses (Catalano et al., 2010). In a test of this hypothesis, male-to-female birth ratios in East Germany were examined over the 54-year period between 1946 and 1999. The ratio was lowest in 1991, the year that the country's economy collapsed (Catalano, 2003). Similarly, in a California study spanning the decade of the 1990s, the percentage of male fetal deaths increased in months in which unemployment (a major stressor) also rose above its typical level (Catalano et al., 2009).

Genomic Imprinting

More than 1,000 human characteristics follow the rules of dominant–recessive and incomplete-dominance inheritance (McKusick, 2011). In these cases, whichever parent contributes a gene to the new individual, the gene responds in the same way. Geneticists, however, have identified some exceptions. In **genomic imprinting,** alleles are *imprinted*, or chemically marked, so that one pair member (either the mother's or the father's) is activated, regardless of its makeup (Hirasawa & Feil, 2010). The imprint is often temporary; it may be erased in the next generation, and it may not occur in all individuals.

Imprinting helps us understand certain puzzling genetic patterns. For example, children are more likely to develop diabetes if their father, rather than their mother, suffers from it. And people with asthma or hay fever tend to have mothers, not fathers, with the illness. Imprinting is involved in several childhood cancers and in *Prader-Willi syndrome*, a disorder with symptoms of mental retardation and severe obesity (Butler, 2009). It may also explain why Huntington disease, when inherited from the father, tends to emerge at an earlier age and to progress more rapidly (Gropman & Adams, 2007).

Genomic imprinting can also operate on the sex chromosomes, as *fragile X syndrome*—the most common inherited cause of mental retardation—reveals. In this disorder, which affects about 1 in 4,000 males and 1 in 6,000 females, an abnormal repetition of a sequence of DNA bases occurs in a special spot on the X chromosome, damaging a particular gene. The defective gene at the fragile site is expressed only when it is passed from mother to child. Because the disorder is X-linked, males are more severely affected (Hagerman et al., 2009).

Females usually have a normally functioning gene on their other X chromosome (inherited from the father) that partially compensates for the abnormal gene.

EEG and fMRI research on children with fragile X syndrome reveals reduced size, structural abnormalities, and atypical activity in many areas of the cerebral cortex (Schneider, Hagerman, & Hessl, 2009). Intellectual deficits range from mild learning disabilities to severe mental retardation. Certain physical features, such as enlarged ears, a long face with a prominent chin, and (in males) enlarged testicles are common. About 30 percent of individuals with fragile X syndrome also have symptoms of *autism*, a serious disorder usually diagnosed in early childhood that involves impaired social interaction, delayed or absent language and communication, and repetitive motor behavior (Schwarte, 2008).

© LAURA DWIGHT PHOTOGRAPHY

A 9-year-old who has fragile X syndrome participates in an art class with typical students. This X-linked disorder, which causes mental retardation, is expressed only when an abnormal gene is passed from mother to child.

Mutation

Although less than 3 percent of pregnancies result in the birth of a baby with a hereditary abnormality, these children account for about 20 percent of infant deaths and contribute substantially to lifelong impaired physical and mental functioning (U.S. Department of Health and Human Services, 2010f). How are harmful genes created in the first place? The answer is **mutation,** a sudden but permanent change in a segment of DNA. A mutation may affect only one or two genes, or it may involve many genes, as in the chromosomal disorders we will discuss shortly. Some mutations occur spontaneously, simply by chance. Others are caused by hazardous environmental agents.

Although nonionizing forms of radiation—electromagnetic waves and microwaves—have no demonstrated impact on DNA, ionizing (high-energy) radiation is an established cause of mutation. Women who receive repeated doses before conception are more likely to miscarry or give birth to children with hereditary defects. The incidence of genetic abnormalities, such as physical malformations and childhood cancer, is also higher in children whose fathers are exposed to radiation in their occupation. However, infrequent and mild exposure to radiation does not cause genetic damage (Jacquet, 2004). Rather, high doses over a long period impair DNA.

The examples just given illustrate *germline mutation*, which takes place in the cells that give rise to gametes. When the affected individual mates, the defective DNA is passed on to the next generation. In a second type, called *somatic mutation*, normal body cells mutate, an event that can occur at any time of life. The DNA defect appears in every cell derived from the affected body cell, eventually becoming widespread enough to cause disease (such as cancer) or disability.

It is easy to see how disorders that run in families can result from germline mutation. But somatic mutation may be involved in these disorders as well. Some people harbor a genetic susceptibility that causes certain body cells to mutate easily in the presence of triggering events (Weiss, 2005). This helps explain why some individuals develop serious illnesses (such as cancer) as a result of smoking, exposure to pollutants, or psychological stress, while others do not.

Polygenic Inheritance

So far, we have discussed patterns of inheritance in which people either display a particular trait or do not. These cut-and-dried individual differences are much easier to trace to their genetic origins than are characteristics that vary on a continuum among people, such as height, weight, intelligence, and personality. These traits are due to **polygenic inheritance,** in which many genes determine the characteristic in question. Polygenic inheritance is complex, and much about it is still unknown. In the final section of this chapter, we will discuss how researchers infer the influence of heredity on human attributes when they do not know the precise patterns of inheritance.

Chromosomal Abnormalities

Besides harmful recessive alleles, abnormalities of the chromosomes are a major cause of serious developmental problems. Most chromosomal defects result from mistakes occurring during meiosis, when the ovum and sperm are formed. A chromosome pair does not separate properly, or part of a chromosome breaks off. Because these errors involve far more DNA than problems due to single genes, they usually produce many physical and mental symptoms.

© ROBIN NELSON/PHOTOEDIT

Despite impaired development, this toddler with Down syndrome profits from growing up in a stimulating, caring environment. As his physical therapist engages him in water play, he benefits intellectually, physically, and emotionally.

Down Syndrome

The most common chromosomal disorder, occurring in 1 out of every 770 live births, is *Down syndrome.* In 95 percent of cases, it results from a failure of the twenty-first pair of chromosomes to separate during meiosis, so the new individual inherits three of these chromosomes rather than the normal two. For this reason, Down syndrome is sometimes called *trisomy 21.* In other, less frequent forms, an extra twenty-first chromosome is attached to part of another chromosome (called *translocation* pattern). Or an error occurs during the early stages of mitosis, causing some but not all body cells to have the defective chromosomal makeup (called *mosaic* pattern) (U.S. Department of Health and Human Services, 2011a). Because the mosaic type involves less genetic material, symptoms may be less extreme.

The consequences of Down syndrome include mental retardation, memory and speech problems, limited vocabulary, and slow motor development. Brain-imaging studies reveal a reduction in size of the brain, which is more pronounced in certain regions of the cerebral cortex (Pinter et al., 2001). Affected individuals also have distinct physical features—a short, stocky build, a flattened face, a protruding tongue, almond-shaped eyes, and (in 50 percent of cases) an unusual crease running across the palm of the hand. In addition, infants with Down syndrome are often born with eye cataracts, hearing loss, and heart and intestinal defects (U.S. Department of Health and Human Services 2011a). Because of medical advances, fewer individuals with Down syndrome die early than was the case in the past. Many survive into their fifties and a few into their sixties to eighties. However, more than half of affected individuals who live past age 40 show symptoms of *Alzheimer's disease,* the most common form of dementia (Wiseman et al., 2009). Genes on chromosome 21 are linked to this disorder.

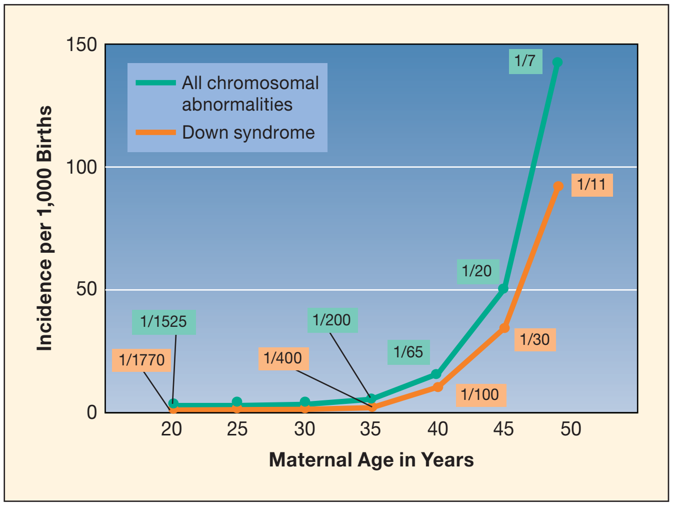

FIGURE 3.6 Risk of Down Syndrome and all chromosomal abnormalities by maternal age. Risk rises sharply after age 35. (From R. L. Schonberg & C. J. Tifft, 2007, "Birth Defects and Prenatal Diagnosis," from *Children with Disabilities*, 6/e, M. L. Matshaw, L. Pellegrino, & N. J. Roizen, editors, p. 85. Baltimore: Paul H. Brookes Publishing Co., Inc. Adapted by permission.)

Infants with Down syndrome smile less readily, show poor eye-to-eye contact, have weak muscle tone, and explore objects less persistently (Slonims & McConachie, 2006). But when parents encourage them to engage with their surroundings, children with Down syndrome develop more favorably. They also benefit from infant and preschool intervention programs, although emotional, social, and motor skills improve more than intellectual performance (Carr, 2002). Clearly, environmental factors affect how well children with Down syndrome fare.

As Figure 3.6 shows, the risk of bearing a baby with Down syndrome rises dramatically with maternal age. But exactly why older mothers are more likely to release ova with meiotic errors is not yet known (Martin, 2008). In about 5 to 10 percent of cases, the extra genetic material originates with the father. Some studies suggest a role for advanced paternal age, while others show no age effects (De Souza, Alberman, & Morris, 2009; Dzurova & Pikhart, 2005; Sherman et al., 2005).

TABLE 3.4 Sex Chromosomal Disorders

DISORDER	DESCRIPTION	INCIDENCE	TREATMENT
XYY syndrome	Extra Y chromosome. Above-average height, large teeth, and sometimes severe acne. Normal to mildly impaired intelligence. Male sexual development and fertility are normal.	1 in 1,000 male births	No special treatment necessary.
Triple X syndrome (XXX)	Extra X chromosome. Tallness and impaired verbal intelligence. Female sexual development and fertility are normal.	1 in 500 to 1,250 female births	Special education to treat verbal ability problems.
Klinefelter syndrome (XXY)	Extra X chromosome. Tallness, body fat distribution resembling that of females, incomplete development of sex characteristics at puberty, sterility, and impaired verbal intelligence.	1 in 900 male births	Hormone therapy at puberty to stimulate development of sex characteristics; special education to treat verbal ability problems.
Turner syndrome (XO)	Missing X chromosome. Short stature, webbed neck, incomplete development of sex characteristics at puberty, sterility, and impaired spatial intelligence.	1 in 2,500 to 8,000 female births	Hormone therapy in childhood to stimulate physical growth and at puberty to promote development of sex characteristics; special education to treat spatial ability problems.

Sources: Geerts, Steyaert, & Fryns, 2003; Kesler, 2007; Saitta & Zackai, 2005; Simpson et al., 2003.

Abnormalities of the Sex Chromosomes Disorders of the autosomes other than Down syndrome usually disrupt development so severely that miscarriage occurs. When such babies are born, they rarely survive beyond early childhood. In contrast, sex chromosome disorders often are not recognized until adolescence when, in some deviations, puberty is delayed. The most common problems involve the presence of an extra chromosome (either X or Y) or the absence of one X in females (see Table 3.4).

Research has discredited a variety of myths about individuals with sex chromosome disorders. For example, as Table 3.4 reveals, males with *XYY syndrome* are not necessarily more aggressive and antisocial than XY males. And most children with sex chromosome disorders do not suffer from mental retardation. Rather, their intellectual problems are usually very specific. Verbal difficulties—for example, with reading and vocabulary—are common among girls with *triple X syndrome* and boys with *Klinefelter syndrome*, both of whom inherit an extra X chromosome. In contrast, girls with *Turner syndrome*, who are missing an X, have trouble with spatial relationships—for example, drawing pictures, telling right from left, following travel directions, and noticing changes in facial expressions (Kesler, 2007; Lawrence et al., 2003; Simpson et al., 2003). Brain-imaging research confirms that adding to or subtracting from the usual number of X chromosomes alters development of certain brain structures, yielding particular intellectual deficits (Cutter et al., 2006; Itti et al., 2006).

ASK YOURSELF

Review ■ Cite evidence indicating that both heredity and environment contribute to the development of children with PKU and Down syndrome.

Review ■ Using your knowledge of X-linked inheritance, explain why males are more vulnerable than females to miscarriage, infant death, genetic disorders, and other problems.

Connect ■ Referring to ecological systems theory (Chapter 1, pages 26–28), explain why parents of children with genetic disorders often experience increased stress. What factors, within and beyond the family, can help these parents support their children's development?

Apply ■ Gilbert's genetic makeup is homozygous for dark hair. Jan's is homozygous for blond hair. What color is Gilbert's hair? How about Jan's? What proportion of their children are likely to be dark-haired? Explain.

▶ What procedures can assist prospective parents in having healthy children?

Reproductive Choices

In the past, many couples with genetic disorders in their families chose not to bear a child at all rather than risk the birth of a baby with abnormalities. Today, genetic counseling and prenatal diagnosis help people make informed decisions about conceiving, carrying a pregnancy to term, or adopting a child.

Genetic Counseling

Genetic counseling is a communication process designed to help couples assess their chances of giving birth to a baby with a hereditary disorder and choose the best course of action in view of risks and family goals (Resta et al., 2006). Individuals likely to seek counseling are those who have had difficulties bearing children—for example, repeated miscarriages—or who know that genetic problems exist in their families. In addition, women who delay childbearing past age 35 are often candidates for genetic counseling. After this time, the overall rate of chromosomal abnormalities rises sharply (refer again to Figure 3.6). But because younger mothers give birth in far greater numbers than older mothers, they still bear the majority of babies with genetic defects. Therefore, some experts argue that maternal needs, not age, should determine referral for genetic counseling (Berkowitz, Roberts, & Minkoff, 2006).

If a family history of mental retardation, psychological disorders, physical defects, or inherited diseases exists, the genetic counselor interviews the couple and prepares a *pedigree*, a picture of the family tree in which affected relatives are identified. The pedigree is used to estimate the likelihood that parents will have an abnormal child, using the genetic principles discussed earlier in this chapter. For many disorders, molecular genetic analyses (in which DNA is examined) can reveal whether the parent is a carrier of the harmful gene. Carrier detection is possible for all the recessive diseases listed in Table 3.3, as well as others, and for fragile X syndrome.

© MICHELLE DEL GUERCIO/PHOTO RESEARCHERS, INC.

Working with a genetic counselor, a couple assess their risk of bearing a child with inherited abnormalities. Using this information, they can decide whether to try to conceive, use reproductive technologies, or adopt.

When all the relevant information is in, the genetic counselor helps people consider appropriate options. These include taking a chance and conceiving, choosing from among a variety of reproductive technologies (see the Social Issues: Health box on pages 86–87), or adopting a child.

Prenatal Diagnosis and Fetal Medicine

If couples who might bear a child with abnormalities decide to conceive, several **prenatal diagnostic methods**—medical procedures that permit detection of developmental problems before birth—are available (see Table 3.5). Women of advanced maternal age are prime candidates for *amniocentesis* or *chorionic villus sampling*. Except for *maternal blood analysis*, however, prenatal diagnosis should not be used routinely because of injury risks to the developing organism.

Prenatal diagnosis has led to advances in fetal medicine. For example, by inserting a needle into the uterus, doctors can administer drugs to the fetus. Surgery has been performed to repair such problems as heart, lung, and diaphragm malformations, urinary tract

TABLE 3.5 Prenatal Diagnostic Methods

METHOD	DESCRIPTION
Amniocentesis	The most widely used technique. A hollow needle is inserted through the abdominal wall to obtain a sample of fluid in the uterus. Cells are examined for genetic defects. Can be performed by the 14th week after conception; 1 to 2 more weeks are required for test results. Small risk of miscarriage.
Chorionic villus sampling	A procedure that can be used if results are desired or needed very early in pregnancy. A thin tube is inserted into the uterus through the vagina, or a hollow needle is inserted through the abdominal wall. A small plug of tissue is removed from the end of one or more chorionic villi, the hairlike projections on the membrane surrounding the developing organism. Cells are examined for genetic defects. Can be performed at 9 weeks after conception; results are available within 24 hours. Entails a slightly greater risk of miscarriage than amniocentesis. Also associated with a small risk of limb deformities, which increases the earlier the procedure is performed.
Fetoscopy	A small tube with a light source at one end is inserted into the uterus to inspect the fetus for defects of the limbs and face. Also allows a sample of fetal blood to be obtained, permitting diagnosis of such disorders as hemophilia and sickle cell anemia, as well as neural defects (see below). Usually performed between 15 and 18 weeks after conception but can be done as early as 5 weeks. Entails some risk of miscarriage.
Ultrasound	High-frequency sound waves are beamed at the uterus; their reflection is translated into a picture on a video screen that reveals the size, shape, and placement of the fetus. Permits assessment of fetal age, detection of multiple pregnancies, and identification of gross physical defects; also used to guide amniocentesis, chorionic villus sampling, and fetoscopy. When used five or more times, may increase the chances of low birth weight.
Ultrafast MRI	Sometimes used as a supplement to ultrasound, where brain or other abnormalities are detected and MRI can provide greater diagnostic accuracy. The ultrafast technique overcomes image blurring due to fetal movements. No evidence of adverse effects.
Maternal blood analysis	By the second month of pregnancy, some of the developing organism's cells enter the maternal bloodstream. An elevated level of alpha-fetoprotein may indicate kidney disease, abnormal closure of the esophagus, or neural tube defects, such as anencephaly (absence of most of the brain) and spina bifida (bulging of the spinal cord from the spinal column). Isolated cells can be examined for genetic defects.
Preimplantation genetic diagnosis	After in vitro fertilization and duplication of the zygote into a cluster of about 8 to 10 cells, 1 or 2 cells are removed and examined for hereditary defects. Only if that sample is free of detectable genetic disorders is the fertilized ovum implanted in the woman's uterus.

Sources: Hahn & Chitty, 2008; Jokhi & Whitby, 2011; Kumar & O'Brien, 2004; Moore & Persaud, 2008; Sermon, Van Steirteghem, & Liebaers, 2004.

obstructions, and neural defects. Fetuses with blood disorders have been given blood transfusions. And those with immune deficiencies have received bone marrow transplants that succeeded in creating a normally functioning immune system (Deprest et al., 2010).

These techniques frequently result in complications, the most common being premature labor and miscarriage (Schonberg & Tifft, 2007). Yet parents may be willing to try almost any option, even one with only a slim chance of success. Currently, the medical profession is struggling with how to help parents make informed decisions about fetal surgery.

Advances in *genetic engineering* also offer new hope for correcting hereditary defects. As part of the Human Genome Project—an ambitious international research program aimed at deciphering the chemical makeup of human genetic material (genome)—researchers have mapped the sequence of all human DNA base pairs. Using that information, they are "annotating" the genome—identifying all its genes and their functions, including their protein products and what these products do. A major goal is to understand the estimated 4,000 human disorders, both those due to single genes and those resulting from a complex interplay of multiple genes and environmental factors.

Already, thousands of genes have been identified, including those involved in hundreds of diseases, such as cystic fibrosis; Duchenne muscular dystrophy; Huntington disease; Marfan syndrome; heart, digestive, blood, eye, and nervous system abnormalities; and many forms of cancer (National Institutes of Health, 2011). As a result, new treatments are being explored, such as *gene therapy*—correcting genetic abnormalities by delivering DNA carrying a functional gene to the cells. In recent experiments, gene therapy relieved symptoms

SOCIAL ISSUES: HEALTH

The Pros and Cons of Reproductive Technologies

Some couples decide not to risk pregnancy because of a family history of genetic disease. Many others—in fact, one-sixth of all couples who try to conceive—discover that they are sterile. And some never-married adults and gay and lesbian partners want to bear children. Today, increasing numbers of individuals are turning to alternative methods of conception to fulfill the wish of parenthood. These technologies have become the subject of heated debate.

Donor Insemination and In Vitro Fertilization

For several decades, *donor insemination*—injection of sperm from an anonymous man into a woman—has been used to overcome male reproductive difficulties. In recent years, it has also enabled women without a male partner to become pregnant. Donor insemination is 70 to 80 percent successful, resulting in about 40,000 deliveries and 52,000 newborn babies in the United States each year (Wright et al., 2008).

In vitro fertilization is another reproductive technology that has become increasingly common. Since the first "test tube" baby was born in England in 1978, 1 percent of all children in developed countries—about 40,000 babies in the United States—have been conceived through this technique annually (Jackson, Gibson, & Wu, 2004). With in vitro fertilization, a woman is given hormones that stimulate the ripening of several ova. These are removed surgically and placed in a dish of nutrients, to which sperm are added. Once an ovum is fertilized and begins to duplicate into several cells, it is injected into the mother's uterus.

By mixing and matching gametes, pregnancies can be brought about when either or both partners have a reproductive problem. Usually, in vitro fertilization is used to treat women whose fallopian tubes are permanently damaged. But a modified technique permits a single sperm to be injected directly into an ovum, thereby overcoming most male fertility problems. And a "sex sorter" method helps ensure that couples who carry X-linked diseases (which usually affect males) have a daughter. Fertilized ova and sperm can even be frozen and stored in embryo banks for future use, thereby guaranteeing healthy zygotes should age or illness lead to fertility problems.

The overall success rate of assisted reproductive techniques is about 35 percent. However, success declines steadily with age, from 40 percent in women younger than age 35 to 8 percent in women age 43 and older (Pauli et al., 2009).

Children conceived through these methods may be genetically unrelated to one or both of their parents. In addition, most parents who used in vitro fertilization do not tell their children about their origins. Does lack of genetic ties or secrecy surrounding these techniques interfere with parent–child relationships? Perhaps because of a strong desire for parenthood, caregiving is actually somewhat warmer for young children conceived through donor insemination or in vitro fertilization. Also, in vitro infants are as securely attached to their parents, and in vitro children and adolescents as well-adjusted, as their counterparts who were naturally conceived (Golombok et al., 2004; Punamaki, 2006; Wagenaar et al., 2008).

Although reproductive technologies have many benefits, serious questions have arisen about their use. In many countries, including the United States, doctors are not required to keep records of donor characteristics, though information about the child's genetic background might be critical in the case of serious disease (Adamson, 2005). Another concern is that the in vitro "sex sorter" method will lead to parental sex selection, thereby eroding the moral value that boys and girls are equally precious.

Furthermore, about 50 percent of in vitro procedures result in multiple births. Most are twins, but 9 percent are triplets and higher-order multiples. Consequently, among in vitro babies, the rate of low birth weight is 2.6 times as high as in the general population (Wright et al., 2008). Risk of major birth defects also doubles because of many factors, including drugs used to induce ripening of ova and delays in fertilizing ova outside the womb (Neri, Takeuchi, & Palermo, 2008). In sum, in vitro fertilization poses greater risks than natural conception to infant survival and healthy development.

Surrogate Motherhood

An even more controversial form of medically assisted conception is *surrogate motherhood*. In this procedure, in vitro fertilization may be used to impregnate a woman (called a surrogate) with a couple's fertilized ovum. Alternatively, sperm from a man whose partner is infertile may be used to inseminate the surrogate, who agrees to turn the baby over to the natural father. The child is then adopted by his partner. In both cases, the surrogate is paid a fee for her childbearing services.

Although most of these arrangements proceed smoothly, those that end up in court highlight serious risks for all concerned. In one case, both parties rejected the infant with severe disabilities that resulted from the pregnancy. In several others, the surrogate mother wanted to keep the baby, or the couple changed their

in hemophilia patients and in patients with severe immune system dysfunction. A few, however, experienced serious side effects (Gillet et al., 2009). In another approach, called *proteomics*, scientists modify gene-specified proteins involved in disease (Van Eyk & Dunn, 2008).

Genetic treatments seem some distance in the future for most single-gene defects, however, and even further off for diseases involving multiple genes that combine in complex ways with one another and the environment. Fortunately, 95 percent of fetuses examined through prenatal diagnosis are normal (Moore & Persaud, 2008). The availability of such tests allows many individuals whose family history would have caused them to avoid pregnancy to bear healthy children.

minds during the pregnancy. These children came into the world in the midst of conflict that threatened to last for years.

Because surrogacy usually involves the wealthy as contractors for infants and the less economically advantaged as surrogates, it may promote exploitation of financially needy women. In addition, most surrogates already have children of their own, and knowledge that their mother would give away a baby may cause these children to worry about the security of their own family circumstances.

New Reproductive Frontiers

Reproductive technologies are evolving faster than societies can weigh the ethics of these procedures. Doctors have used donor ova from younger women in combination with in vitro fertilization to help postmenopausal women become pregnant. Most recipients are in their forties, but some in their fifties and sixties, and a few at age 70, have given birth. These cases raise questions about bringing children into the world whose parents may not live to see them reach adulthood. Based on U.S. life expectancy data, 1 in 3 mothers and 1 in 2 fathers having a baby at age 55 will die before their child enters college (U.S. Census Bureau, 2011b).

Currently, experts are debating other reproductive options. At donor banks, customers can select ova or sperm on the basis of physical characteristics and even IQ. And scientists are devising ways to alter the DNA of human ova, sperm, and embryos to protect against hereditary disorders—techniques that could be used to engineer other desired characteristics. Many worry that these practices are dangerous steps toward selective breeding through "designer babies"—controlling offspring traits by manipulating genetic makeup.

Although new reproductive technologies permit many barren couples to rear healthy newborn babies, laws are needed to regulate such practices. In Australia, New Zealand, Sweden, and Switzerland, individuals conceived with donor gametes have a right to information about their genetic origins (Frith, 2001). Pressure from those working in the field of assisted reproduction may soon lead to similar policies in the United States. Australia, Canada, and the Netherlands prohibit any genetic alteration of human gametes, with other nations following suit (Isasi, Nguyen, & Knoppers, 2006). But some scientists argue that this total ban is too restrictive because it interferes with serving therapeutic needs.

In the case of surrogate motherhood, the ethical problems are so complex that 11 U.S. states and the District of Columbia have sharply restricted the practice (Human Rights Campaign, 2008). Australia, Canada, and many European nations have banned it, arguing that the status of a baby should not be a matter of commercial arrangement. Denmark, France, and Italy have prohibited in vitro fertilization for women past menopause. At present, nothing is known about the psychological consequences of being a product of these procedures. Research on how such children grow up, including what they know and how they feel about their origins, is important for weighing the pros and cons of these techniques.

Fertility drugs and in vitro fertilization often result in multiple fetuses. These quadruplets are healthy, but babies born with the aid of reproductive technologies are at high risk for low birth weight and major birth defects.

ASK YOURSELF

Review ■ Why is genetic counseling called a *communication process?* Who should seek it?

Review ■ Describe the ethical pros and cons of fetal surgery, surrogate motherhood, and postmenopausal-assisted childbearing.

Apply ■ Imagine that you must counsel a couple considering in vitro fertilization using donor ova to overcome infertility. What medical and ethical risks would you raise?

Reflect ■ Imagine you are a carrier of fragile X syndrome and want to have children. Would you choose pregnancy, adoption, or surrogacy? If you became pregnant, would you opt for prenatal diagnosis? Explain.

- List the three periods of prenatal development, and describe the major milestones of each.

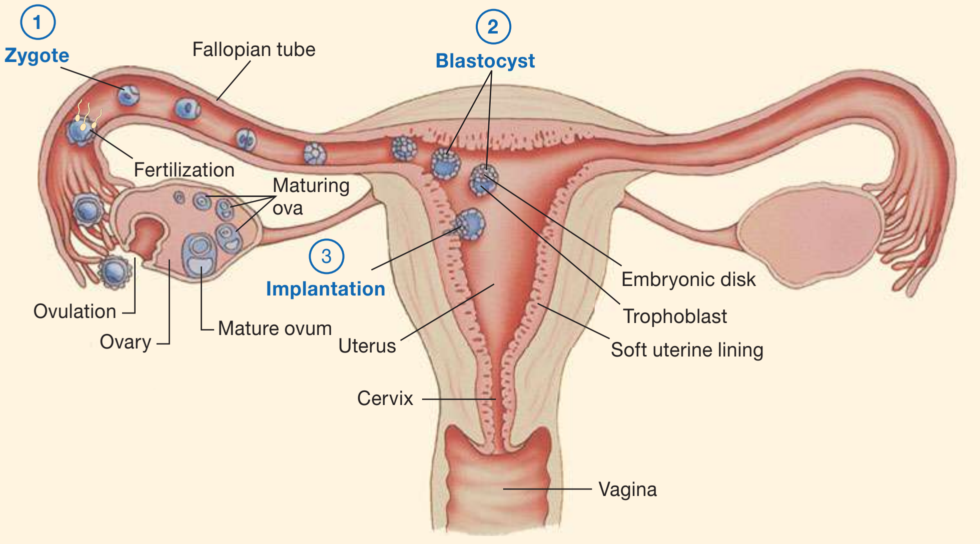
Prenatal Development

The sperm and ovum that unite to form the new individual are uniquely suited for the task of reproduction. The ovum is a tiny sphere, measuring 1/175 inch in diameter, that is barely visible to the naked eye as a dot the size of the period at the end of this sentence. But in its microscopic world, it is a giant—the largest cell in the human body. The ovum's size makes it a perfect target for the much smaller sperm, which measure only 1/500 inch.

Conception

About once every 28 days, in the middle of a woman's menstrual cycle, an ovum bursts from one of her *ovaries*, two walnut-sized organs located deep inside her abdomen, and is drawn into one of two *fallopian tubes*—long, thin structures that lead to the hollow, soft-lined uterus (see Figure 3.7). While the ovum is traveling, the spot on the ovary from which it was released, now called the *corpus luteum*, secretes hormones that prepare the lining of the uterus to receive a fertilized ovum. If pregnancy does not occur, the corpus luteum shrinks, and the lining of the uterus is discarded two weeks later with menstruation.

The male produces sperm in vast numbers—an average of 300 million a day. In the final process of maturation, each sperm develops a tail that permits it to swim long distances, upstream in the female reproductive tract, through the *cervix* (opening of the uterus), and into the fallopian tube, where fertilization usually takes place. The journey is difficult, and many sperm die. Only 300 to 500 reach the ovum, if one happens to be present. Sperm



① **Zygote**
As the zygote moves down the fallopian tube, it duplicates, at first slowly and then more rapidly.

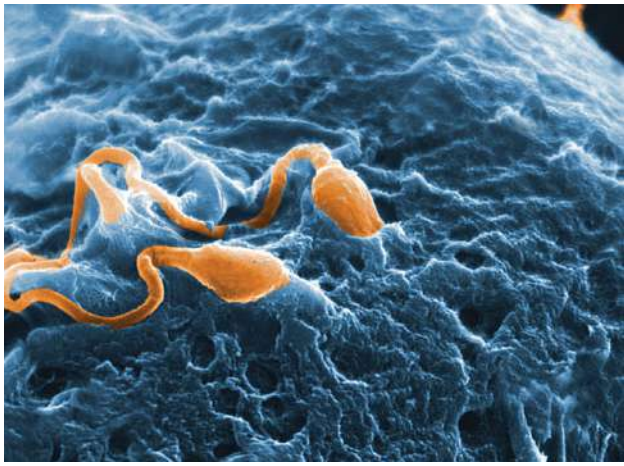
② **Blastocyst**
By the fourth day it forms a hollow, fluid-filled ball, called a blastocyst. The inner cells, called the embryonic disk, will become the new organism. The outer cells, or trophoblast, will provide protective covering.

③ **Implantation**
At the end of the first week, the blastocyst begins to implant in the uterine lining.

FIGURE 3.7 **Female reproductive organs, showing fertilization, early cell duplication, and implantation.** (From *Before We Are Born*, 6th ed., by K. L. Moore & T. V. N. Persaud, p. 87. Copyright © 2003, reprinted with permission from Elsevier, Inc.)

live for up to 6 days and can lie in wait for the ovum, which survives for only 1 day after being released into the fallopian tube. However, most conceptions result from intercourse during a 3-day period—on the day of ovulation or during the 2 days preceding it (Wilcox, Weinberg, & Baird, 1995).

With conception, the story of prenatal development begins to unfold. The vast changes that take place during the 38 weeks of pregnancy are usually divided into three periods: (1) the period of the zygote, (2) the period of the embryo, and (3) the period of the fetus. As we look at what happens in each, you may find it useful to refer to the Milestones table on page 90.



© PASCAL GOETGHELUCK/PHOTO RESEARCHERS, INC.

Conception. In this photo taken with the aid of a powerful microscope, two sperm penetrate the surface of the ovum, the largest cell in the human body. When one sperm succeeds in fertilizing the ovum, the resulting zygote begins to duplicate.

Period of the Zygote

The period of the zygote lasts about two weeks, from fertilization until the tiny mass of cells drifts down and out of the fallopian tube and attaches itself to the wall of the uterus. The zygote's first cell duplication is long and drawn out; it is not complete until about 30 hours after conception. Gradually, new cells are added at a faster rate. By the fourth day, 60 to 70 cells exist that form a hollow, fluid-filled ball called a *blastocyst* (refer again to Figure 3.7). The cells on the inside of the blastocyst, called the *embryonic disk*, will become the new organism; the thin outer ring of cells, termed the *trophoblast*, will become the structures that provide protective covering and nourishment.

Implantation

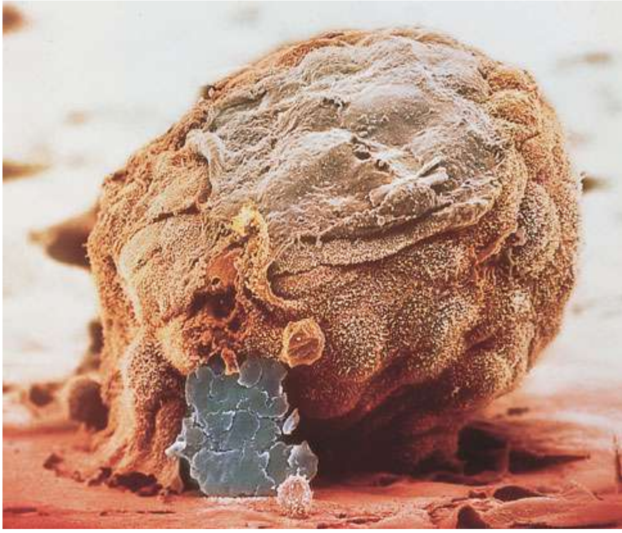
Between the seventh and ninth days, implantation occurs: The blastocyst burrows deep into the uterine lining where, surrounded by the woman's nourishing blood, it starts to grow in earnest. At first, the trophoblast (protective outer layer) multiplies fastest. It forms a membrane, called the **amnion,** that encloses the developing organism in *amniotic fluid*, which helps keep the temperature of the prenatal world constant and provides a cushion against any jolts caused by the woman's movement. A *yolk sac* emerges that produces blood cells until the developing liver, spleen, and bone marrow are mature enough to take over this function (Moore & Persaud, 2008).

The events of these first two weeks are delicate and uncertain. As many as 30 percent of zygotes do not survive this period. In some, the sperm and ovum do not join properly. In others, for some unknown reason, cell duplication never begins. By preventing implantation in these cases, nature eliminates most prenatal abnormalities (Sadler, 2009).

The Placenta and Umbilical Cord

By the end of the second week, cells of the trophoblast form another protective membrane—the **chorion,** which surrounds the amnion. From the chorion, tiny fingerlike *villi,* or blood vessels, emerge.[1] As these villi burrow into the uterine wall, a special organ called the *placenta* starts to develop. By bringing the mother's and the embryo's blood close together, the **placenta** permits food and oxygen to reach the developing organism and waste products to be carried away. A membrane forms that allows these substances to be exchanged but prevents the mother's and the embryo's blood from mixing directly.

The placenta is connected to the developing organism by the **umbilical cord,** which first appears as a primitive body stalk and, during the course of pregnancy, grows to a length of 1 to 3 feet. The umbilical cord contains



© LENNART NILSSON, *A CHILD IS BORN*/SCANPIX

Period of the zygote: seventh to ninth day. The fertilized ovum duplicates at an increasingly rapid rate, forming a hollow ball of cells, or blastocyst, by the fourth day after fertilization. Between the seventh and ninth day, as shown here, the blastocyst burrows into the uterine lining.

---

[1] Recall from Table 3.5 on page 85 that *chorionic villus sampling* is a prenatal diagnostic method that can be performed very early, at nine weeks after conception. In this procedure, tissues from the ends of the villi are removed and examined for genetic abnormalities.

Milestones

Prenatal Development

TRIMESTER	PERIOD	WEEKS	LENGTH AND WEIGHT	MAJOR EVENTS
First	Zygote 	1		The one-celled zygote multiplies and forms a blastocyst.
		2		The blastocyst burrows into the uterine lining. Structures that feed and protect the developing organism begin to form—*amnion, chorion, yolk sac, placenta*, and *umbilical cord*.
	Embryo 	3–4	¼ inch (6 mm)	A primitive brain and spinal cord appear. Heart, muscles, ribs, backbone, and digestive tract begin to develop.
		5–8	1 inch (2.5 cm); ⅐ ounce (4 g)	Many external body structures (face, arms, legs, toes, fingers) and internal organs form. Production of neurons begins, occurring at an astounding pace. The sense of touch emerges, and the embryo can move.
	Fetus 	9–12	3 inches (7.6 cm); less than 1 ounce (28 g)	Rapid increase in size begins. Nervous system, organs, and muscles become organized and connected, and new behavioral capacities (kicking, thumb sucking, mouth opening, and rehearsal of breathing) appear. External genitals are well-formed, and the fetus's sex is evident.
Second		13–24	12 inches (30 cm); 1.8 pounds (820 g)	The fetus continues to enlarge rapidly. In the middle of this period, the mother can feel fetal movements. Vernix and lanugo keep the fetus's skin from chapping in the amniotic fluid. Most of the brain's neurons are in place by 24 weeks. Eyes are sensitive to light, and the fetus reacts to sound.
Third		25–38	20 inches (50 cm); 7.5 pounds (3,400 g)	The fetus has a good chance of survival if born during this time. Size increases. Lungs mature. Rapid brain development causes sensory and behavioral capacities to expand. In the middle of this period, a layer of fat is added under the skin. Antibodies are transmitted from mother to fetus to protect against disease. Most fetuses rotate into an upside-down position in preparation for birth.

one large vein that delivers blood loaded with nutrients and two arteries that remove waste products. The force of blood flowing through the cord keeps it firm, much like a garden hose, so it seldom tangles while the embryo, like a space-walking astronaut, floats freely in its fluid-filled chamber (Moore & Persaud, 2008).

By the end of the period of the zygote, the developing organism has found food and shelter in the uterus. Already, it is a very complex being. These dramatic beginnings take place before most mothers know they are pregnant.

Period of the Embryo

The period of the **embryo** lasts from implantation through the eighth week of pregnancy. During these brief six weeks, the most rapid prenatal changes take place, as the groundwork is laid for all body structures and internal organs. Because all parts of the body are forming, the embryo is especially vulnerable to interference with healthy development. But the short time span of embryonic growth helps limit opportunities for serious harm.

Last Half of the First Month

In the first week of this period, the embryonic disk forms three layers of cells: (1) the *ectoderm*, which will become the nervous system and skin; (2) the *mesoderm*, from which will develop the muscles, skeleton, circulatory system, and other internal organs; and (3) the *endoderm*, which will become the digestive system, lungs, urinary tract, and glands. These three layers give rise to all parts of the body.

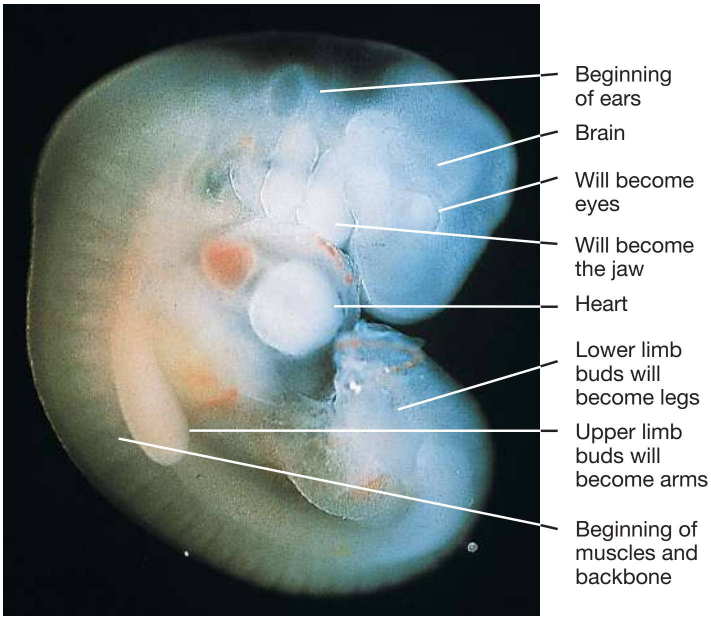
At first, the nervous system develops fastest. The ectoderm folds over to form the *neural tube*, or primitive spinal cord. At 3½ weeks, the top swells to form the brain. While the nervous system is developing, the heart begins to pump blood, and muscles, backbone, ribs, and digestive tract appear. At the end of the first month, the curled embryo—only ¼ inch long—consists of millions of organized groups of cells with specific functions.

The Second Month

In the second month, growth continues rapidly. The eyes, ears, nose, jaw, and neck form. Tiny buds become arms, legs, fingers, and toes. Internal organs are more distinct: The intestines grow, the heart develops separate chambers, and the liver and spleen take over production of blood cells so that the yolk sac is no longer needed. Changing body proportions cause the embryo's posture to become more upright.

At 7 weeks, production of *neurons* (nerve cells that store and transmit information) begins deep inside the neural tube at the astounding pace of more than 250,000 per minute (Nelson, 2011). Once formed, neurons begin traveling along tiny threads to their permanent locations, where they will form the major parts of the brain.

At the end of this period, the embryo—about 1 inch long and ⅐ ounce in weight—can already sense its world. It responds to touch, particularly in the mouth area and on the soles of the feet. And it can move, although its tiny flutters are still too light to be felt by the mother (Moore & Persaud, 2008).



Beginning of ears
Brain
Will become eyes
Will become the jaw
Heart
Lower limb buds will become legs
Upper limb buds will become arms
Beginning of muscles and backbone

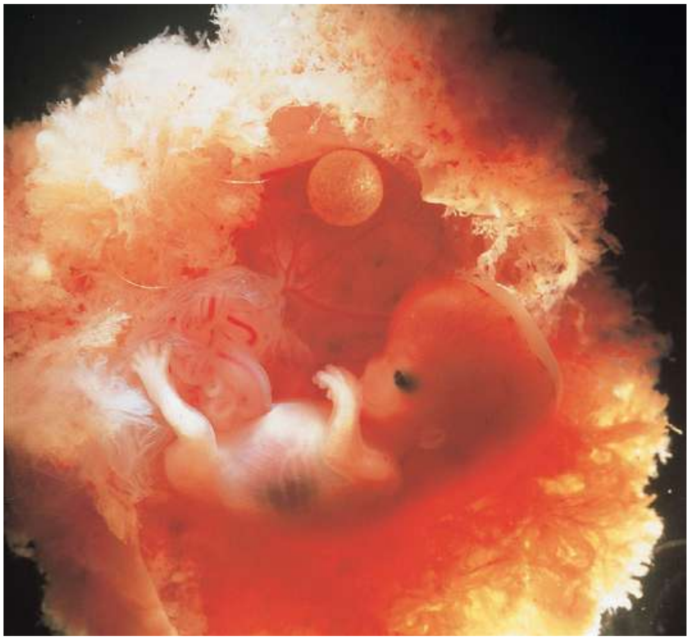
Period of the embryo: fourth week. This 4-week-old embryo is only ¼ inch long, but many body structures have begun to form.

© LENNART NILSSON, *A CHILD IS BORN*/SCANPIX

Period of the embryo: seventh week. The embryo's posture is more upright. Body structures—eyes, nose, arms, legs, and internal organs—are more distinct. The embryo responds to touch but is still too tiny to be felt by the mother.

Period of the Fetus

The period of the **fetus,** from the ninth week to the end of pregnancy, is the longest prenatal period. During this "growth and finishing" phase, the organism increases rapidly in size, especially from the ninth to the twentieth week.



© LENNART NILSSON, *A CHILD IS BORN*/SCANPIX

Period of the fetus: eleventh week. The brain and muscles are better connected. The fetus can kick, bend its arms, and open and close its hands and mouth. The yolk sac shrinks as the internal organs assume blood cell production.

The Third Month

In the third month, the organs, muscles, and nervous system start to become organized and connected. When the brain signals, the fetus kicks, bends its arms, forms a fist, curls its toes, turns its head, opens its mouth, and even sucks its thumb, stretches, and yawns. Body position changes occur as often as 25 times per hour (Einspieler, Marschik, & Prechtl, 2008). The tiny lungs begin to expand and contract in an early rehearsal of breathing movements. By the twelfth week, the external genitals are well-formed, and the sex of the fetus can be detected with ultrasound (Sadler, 2009). Other finishing touches appear, such as fingernails, toenails, tooth buds, and eyelids. The heartbeat can now be heard through a stethoscope.

Prenatal development is sometimes divided into *trimesters*, or three equal time periods. At the end of the third month, the first trimester is complete.

The Second Trimester

By the middle of the second trimester, between 17 and 20 weeks, the new being has grown large enough that the mother can feel its movements. A white, cheeselike substance called **vernix** covers the skin, protecting it from chapping during the long months spent in the amniotic fluid. White, downy hair called **lanugo** also covers the entire body, helping the vernix stick to the skin.

At the end of the second trimester, many organs are well-developed. Also, most of the brain's billions of neurons are in place; few will be produced after this time. However, *glial cells*, which support and feed the neurons, continue to increase rapidly throughout the remaining months of pregnancy, as well as after birth. Consequently, brain weight increases tenfold from the twentieth week until birth (Roelfsema et al., 2004). At the same time, neurons begin forming *synapses*, or connections, at a rapid pace.

Brain growth means new behavioral capacities. The 20-week-old fetus can be stimulated as well as irritated by sounds. Slow eye movements appear, with rapid eye movements following at 22 weeks. And if a doctor looks inside the uterus using fetoscopy (refer again to Table 3.5), fetuses try to shield their eyes from the light with their hands, indicating that sight has begun to emerge (Moore & Persaud, 2008). Still, a fetus born at this time cannot survive. Its lungs are too immature, and the brain cannot yet control breathing movements or body temperature.

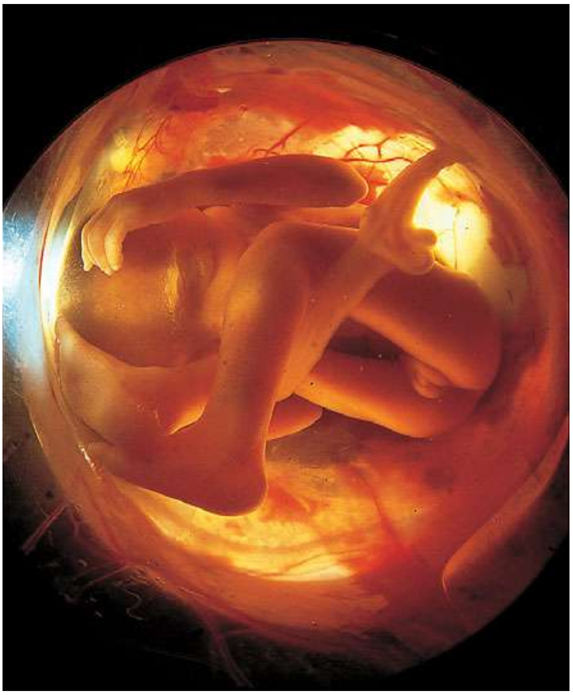
The Third Trimester

During the final trimester, a fetus born early has a chance of survival. The point at which the baby can first survive, called the **age of viability,** occurs sometime between 22 and 26 weeks (Moore & Persaud, 2008). A baby born between the seventh and eighth months, however, usually needs oxygen assistance to breathe. Although the brain's respiratory center is now mature, tiny air sacs in the lungs are not yet ready to inflate and exchange carbon dioxide for oxygen.

The brain continues to make great strides. The *cerebral cortex*, the seat of human intelligence, enlarges. Convolutions and grooves in its surface appear, permitting a dramatic increase in surface area that allows for maximum prenatal brain growth without the full-term baby's head becoming too large to pass through the birth canal. As neural connectivity and organization improve, the fetus spends more time awake. At 20 weeks, fetal heart rate reveals no periods of alertness. But by 28 weeks, fetuses are awake about 11 percent of the time, a figure that rises to 16 percent just before birth (DiPietro et al., 1996). Between 30 and 34 weeks, fetuses show rhythmic alternations between sleep and wakefulness that gradually increase in organization (Rivkees, 2003). Around this time, synchrony between fetal heart rate and motor activity peaks: A rise in heart rate is usually followed within 5 seconds by a burst of motor activity (DiPietro et al., 2006). These are clear signs that coordinated neural networks are beginning to form in the brain.

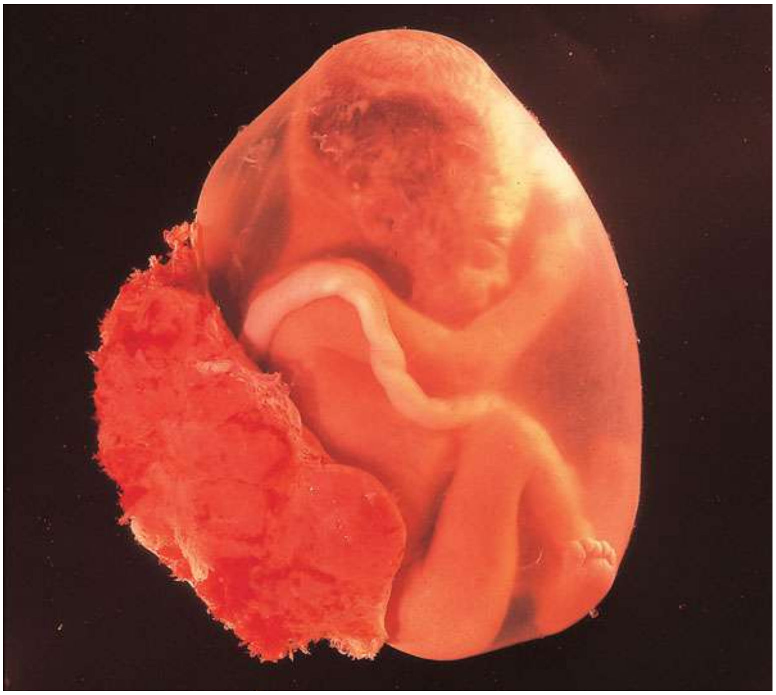
By the end of pregnancy, the fetus takes on the beginnings of a personality. Higher fetal activity in the last weeks of pregnancy predicts a more active infant in the first month of life—a relationship that, for boys, persists into early childhood (Groome et al., 1999). Fetal activity is linked in other ways to infant temperament. In one study, more active fetuses during the third trimester became 1-year-olds who could better handle frustration and 2-year-olds who were less fearful, in that they more readily interacted with toys and with an unfamiliar adult in a laboratory (DiPietro et al., 2002). Perhaps fetal activity level is an indicator of healthy neurological development, which fosters adaptability in childhood. The relationships just described, however, are only modest. As we will see in Chapter 10, sensitive caregiving can modify the temperaments of children who have difficulty adapting to new experiences.

The third trimester also brings greater responsiveness to external stimulation. Between 23 and 30 weeks, connections form between the cerebral cortex and brain regions involved in pain sensitivity. By this time, painkillers should be used in any surgical procedures (Lee et al., 2005). Around 28 weeks, fetuses blink their eyes in reaction to nearby sounds (Kisilevsky & Low, 1998; Saffran, Werker, & Werner, 2006). And at 30 weeks, fetuses presented with a repeated auditory stimulus against the mother's abdomen initially react with a rise in heart rate and body movements. But over the next 5 to 6 minutes, responsiveness gradually



© LENNART NILSSON, *A CHILD IS BORN*/SCANPIX

Period of the fetus: twenty-second week. This fetus is almost 1 foot long and weighs around 1 pound. Its movements can be felt by touching the mother's abdomen. If born now, the fetus has a slim chance of surviving.



© LENNART NILSSON, *A CHILD IS BORN*/SCANPIX

Period of the fetus: thirty-sixth week. This fetus fills the uterus. To nourish it, the umbilical cord and placenta have grown large. Vernix (cheeselike substance) protects the skin from chapping. The fetus has accumulated fat to aid temperature regulation after birth. In two more weeks, it will be full term.

declines, indicating *habituation* (adaptation) to the sound. If the stimulus is reintroduced after a 10-minute delay, heart rate falls off far more quickly (Dirix et al., 2009). This suggests that fetuses can remember for at least a brief period.

Within the next six weeks, fetuses distinguish the tone and rhythm of different voices and sounds: They show systematic heart rate changes in response to a male versus a female speaker, to the mother's voice versus a stranger's, to a stranger speaking their native language (English) versus a foreign language (Mandarin Chinese), and to a simple familiar melody (descending tones) versus an unfamiliar melody (ascending tones) (Granier-Deferre et al., 2003; Huotilainen et al., 2005; Kisilevsky et al., 2003, 2009; Lecanuet et al., 1993). And in one clever study, mothers read aloud Dr. Seuss's lively book *The Cat in the Hat* each day during the last six weeks of pregnancy. After birth, their infants learned to turn on recordings of the mother's voice by sucking on nipples. They sucked hardest to hear *The Cat in the Hat*—the sound they had come to know while still in the womb (DeCasper & Spence, 1988).

TAKE A MOMENT... On the basis of these findings, would you recommend that expectant mothers provide fetuses with stimulation specially designed to enhance later mental development? Notice how risky it is to draw such conclusions. First, specific forms of fetal stimulation, such as reading aloud or playing classical music, are unlikely to have a long-lasting impact on cognitive development because of the developing child's constantly changing capacities and experiences, which can override the impact of fetal stimulation (Lecanuet, Granier-Deferre, & DeCasper, 2005). Second, although ordinary stimulation contributes to the functioning of sensory systems, excessive input can be dangerous. For example, animal studies indicate that a sensitive period (see page 24 in Chapter 1) exists in which the fetal ear is highly susceptible to injury. During that time, prolonged exposure to sounds that are harmless to the mature ear can permanently damage fetal inner-ear structures (Pierson, 1996).

In the final three months, the fetus gains more than 5 pounds and grows 7 inches. As it fills the uterus, it gradually moves less often. In addition, brain development, which enables the organism to inhibit behavior, contributes to this decline in physical activity (DiPietro et al., 1996). In the eighth month, a layer of fat is added to assist with temperature regulation. The fetus also receives antibodies from the mother's blood to protect against illnesses, since the newborn's own immune system will not work well until several months after birth. In the last weeks, most fetuses assume an upside-down position, partly because of the shape of the uterus and also because the head is heavier than the feet. Growth slows, and birth is about to take place.

ASK YOURSELF

Review ■ Why is the period of the embryo regarded as the most dramatic prenatal period? Why is the period of the fetus called the "growth and finishing" phase?

Connect ■ How is brain development related to fetal capacities and behavior? What implications do individual differences in fetal behavior have for the baby's temperament after birth?

Apply ■ Amy, two months pregnant, wonders how the developing organism is being fed and what parts of the body have formed. "I don't look pregnant yet, so does that mean not much development has taken place?" she asks. How would you respond to Amy?

- Cite factors that influence the impact of teratogens, noting agents that are known teratogens.
- Describe the impact of additional maternal factors on prenatal development.

Prenatal Environmental Influences

Although the prenatal environment is far more constant than the world outside the womb, many factors can affect the embryo and fetus. In the following sections, you will see that there is much that parents—and society as a whole—can do to create a safe environment for development before birth.

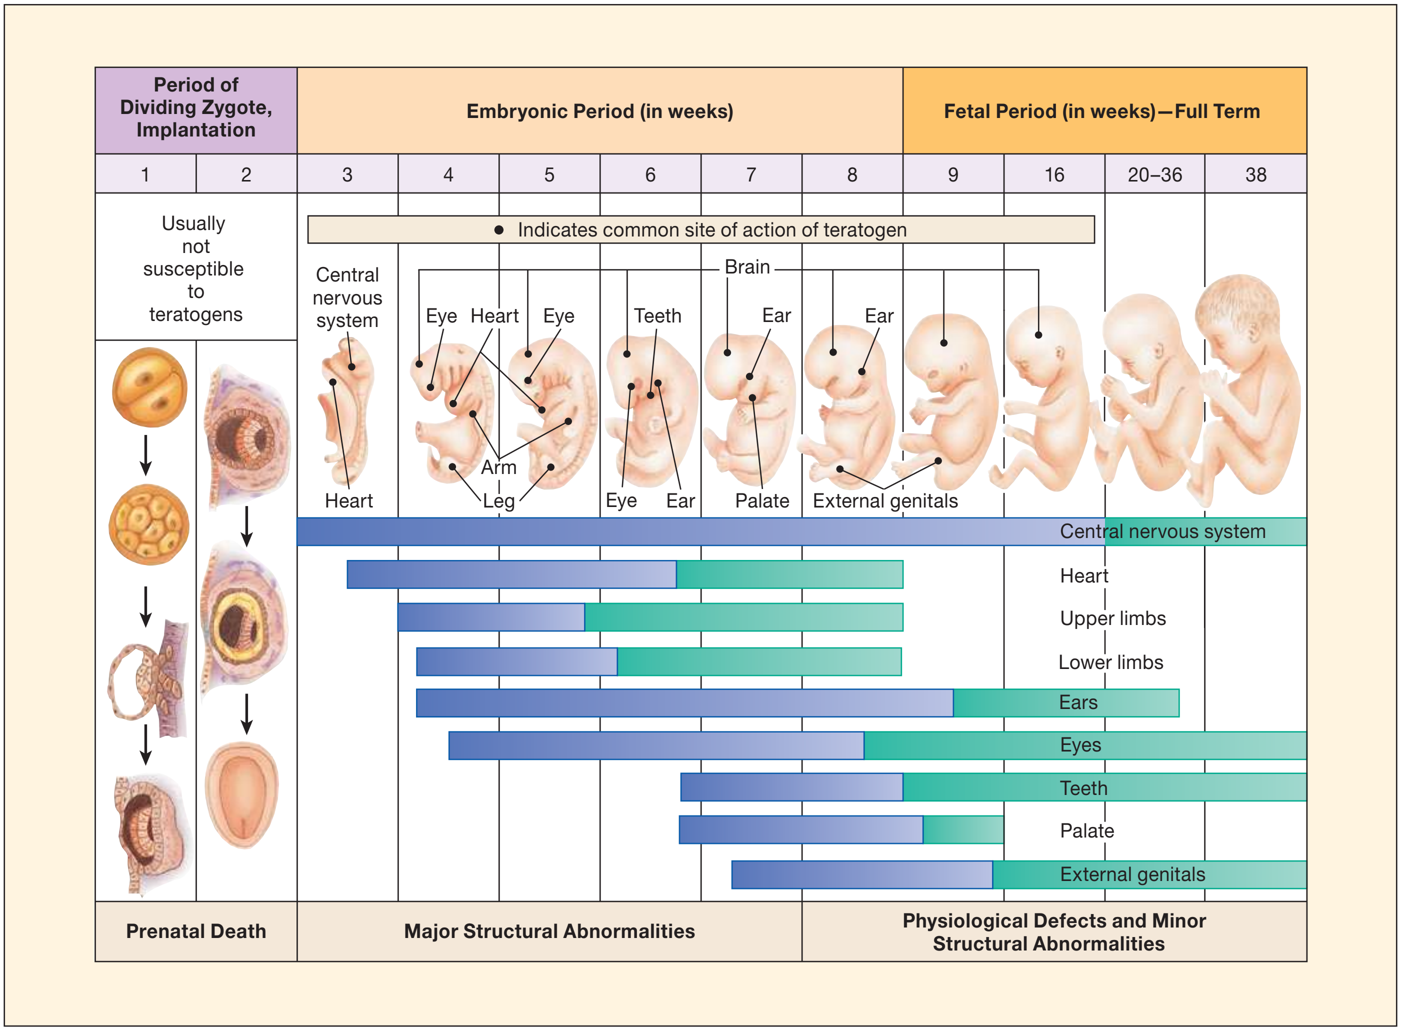
Teratogens

The term **teratogen** refers to any environmental agent that causes damage during the prenatal period. Scientists chose this label (from the Greek word *teras*, meaning "malformation" or "monstrosity") because they first learned about harmful prenatal influences from cases in which babies had been profoundly damaged. But the harm done by teratogens is not always simple and straightforward. It depends on the following factors:

- *Dose*. As we discuss particular teratogens, you will see that larger doses over longer time periods usually have more negative effects.
- *Heredity*. The genetic makeup of the mother and the developing organism plays an important role. Some individuals are better able than others to withstand harmful environments.
- *Other negative influences*. The presence of several negative factors at once, such as additional teratogens, poor nutrition, and lack of medical care, can worsen the impact of a single harmful agent.
- *Age*. The effects of teratogens vary with the age of the organism at time of exposure. To understand this last idea, think of the *sensitive period* concept. Recall that a sensitive period is a limited time span in which a part of the body or a behavior is biologically prepared to develop rapidly. During that time, it is especially sensitive to its surroundings. If the environment is harmful, then damage occurs, and recovery is difficult and sometimes impossible.

Figure 3.8 summarizes prenatal sensitive periods. Look at it carefully, and you will see that some parts of the body, such as the brain and eye, have sensitive periods that extend

FIGURE 3.8 Sensitive periods in prenatal development. Each organ or structure has a sensitive period, during which its development may be disturbed. Blue horizontal bars indicate highly sensitive periods. Green horizontal bars indicate periods that are somewhat less sensitive to teratogens, although damage can occur. (Adapted from *Before We Are Born*, 7th ed., by K. L. Moore and T. V. N. Persaud, p. 313. Copyright © 2008, reprinted with permission from Elsevier, Inc.)



throughout prenatal development. Other sensitive periods, such as those for the limbs and palate, are much shorter. Figure 3.8 also indicates that we can make some general statements about the timing of harmful influences: In the *period of the zygote*, before implantation, teratogens rarely have any impact. If they do, the tiny mass of cells is usually so damaged that it dies. The *embryonic period* is the time when serious defects are most likely to occur because the foundations for all body parts are being laid down. During the *fetal period*, teratogenic damage is usually minor. However, organs such as the brain, ears, eyes, teeth, and genitals can still be strongly affected.

The effects of teratogens go beyond immediate physical damage. Some health outcomes are delayed and may not show up for decades. Furthermore, psychological consequences may occur indirectly, as a result of physical damage. For example, a defect resulting from drugs the mother took during pregnancy can affect others' reactions to the child as well as the child's ability to explore the environment. Over time, parent–child interaction, peer relations, and opportunities to explore may suffer. Furthermore, prenatally exposed children may be less resilient in the face of environmental risks, such as single parenthood, parental emotional disturbance, or maladaptive parenting (Yumoto, Jacobson, & Jacobson, 2008). As a result, their long-term adjustment may be compromised.

Notice how an important idea about development discussed in Chapter 1 is at work here: *bidirectional influences* between child and environment. Now let's look at what scientists have discovered about a variety of teratogens.

Prescription and Nonprescription Drugs

In the early 1960s, the world learned a tragic lesson about drugs and prenatal development. At that time, a sedative called *thalidomide* was widely available in Canada, Europe, and South America. When taken by mothers 4 to 6 weeks after conception, thalidomide produced gross deformities of the embryo's developing arms and legs and, less frequently, damage to the ears, heart, kidneys, and genitals. About 7,000 infants worldwide were affected (Moore & Persaud, 2008). As children exposed to thalidomide grew older, many scored below average in intelligence. Perhaps the drug damaged the central nervous system directly. Or the child-rearing conditions of these severely deformed youngsters may have impaired their intellectual development.

Another medication, a synthetic hormone called *diethylstilbestrol (DES)*, was widely prescribed between 1945 and 1970 to prevent miscarriages. As daughters of these mothers reached adolescence and young adulthood, they showed unusually high rates of cancer of the vagina, malformations of the uterus, and infertility. When they tried to have children, their pregnancies more often resulted in prematurity, low birth weight, and miscarriage than those of non-DES-exposed women. Young men showed an increased risk of genital abnormalities and cancer of the testes (Hammes & Laitman, 2003; Palmer et al., 2001).

Many prescription and nonprescription medications can impair embryonic and fetal development. Before taking any drug, expectant mothers must seriously consider its risks.

© BLEND IMAGES/ALAMY

Currently, the most widely used potent teratogen is a vitamin A derivative called *Accutane* (known by the generic name *isotretinoin*), prescribed to treat severe acne and taken by hundreds of thousands of women of childbearing age in industrialized nations. Exposure during the first trimester of pregnancy results in eye, ear, skull, brain, heart, and immune system abnormalities (Honein, Paulozzi, & Erickson, 2001). Accutane's packaging warns users to avoid pregnancy by using two methods of birth control, but many women do not heed this advice (Garcia-Bournissen et al., 2008).

Indeed, any drug with a molecule small enough to penetrate the placental barrier can enter the embryonic or fetal bloodstream. Yet many pregnant women continue to take over-the-counter medications without consulting their doctors. Aspirin is one of the most common. Several studies suggest that regular aspirin use is linked to low birth weight, infant death around the time of birth, poorer motor development, and lower intelligence test scores in early childhood, although other research fails to confirm these findings (Barr et al., 1990; Kozer et al., 2003; Streissguth et al., 1987). Coffee, tea, cola, and cocoa contain another frequently consumed drug, caffeine. As amounts exceed 100 milligrams per day (equivalent to one cup of coffee), low birth weight and miscarriage increase (CARE Study Group, 2008; Weng, Odouli, & Li, 2008). And antidepressant medications are linked to increased risk of premature delivery and birth complications, including respiratory distress and persistent high blood pressure in infancy (Alwan & Friedman, 2009; Lund, Pedersen, & Henriksen, 2009; Udechuku et al., 2010).

Because children's lives are involved, we must take findings like these seriously. At the same time, we cannot be sure that these frequently used drugs actually cause the problems mentioned. Often mothers take more than one drug. If the embryo or fetus is injured, it is hard to tell which drug might be responsible or whether other factors correlated with drug taking are really at fault. Until we have more information, the safest course for pregnant women is to avoid such drugs entirely. Unfortunately, many women do not know that they are pregnant during the early weeks of the embryonic period, when exposure to medications (and other teratogens) can be of greatest threat.

LOOK and LISTEN

On a trip to your grocery or drugstore, examine the fine print on nonprescription medication labels, such as pain relievers, and on energy drinks containing high levels of caffeine. Are the prenatal risks of these products clearly conveyed?

Illegal Drugs The use of highly addictive mood-altering drugs, such as cocaine and heroin, has become more widespread, especially in poverty-stricken inner-city areas, where these drugs provide a temporary escape from a daily life of hopelessness. About 4 percent of U.S. pregnant women take these substances (Substance Abuse and Mental Health Services Administration, 2010).

Babies born to users of cocaine, heroin, or methadone (a less addictive drug used to wean people away from heroin) are at risk for a wide variety of problems, including prematurity, low birth weight, physical defects, breathing difficulties, and death at or around the time of birth (Bandstra et al., 2010; Howell, Coles, & Kable, 2008; Schuetze & Eiden, 2006). In addition, these infants are born drug-addicted. They are often feverish and irritable and have trouble sleeping, and their cries are abnormally shrill and piercing—a common symptom among stressed newborns (Bauer et al., 2005). When mothers with many problems of their own must care for these babies, who are difficult to calm, cuddle, and feed, behavior problems are likely to persist.

Throughout the first year, heroin- and methadone-exposed infants are less attentive to the environment than nonexposed babies, and their motor development is slow. After infancy, some children get better, whereas others remain jittery and inattentive. The kind of parenting they receive may explain why difficulties continue for some but not for others (Hans & Jeremy, 2001).

Evidence on cocaine suggests that some prenatally exposed babies develop lasting problems. Cocaine constricts the blood vessels, causing oxygen delivery to the developing organism to fall for 15 minutes following a high dose. It also can alter the production and functioning of neurons and the chemical balance in the fetus's brain. These effects may contribute to an array of cocaine-associated physical defects, including eye, bone, genital, urinary tract, kidney, and heart deformities; brain hemorrhages and seizures; and severe growth retardation (Covington et al., 2002; Feng, 2005; Salisbury et al., 2009).

Several studies report perceptual, motor, attention, memory, language, and impulse-control problems that persist into the preschool and school years (Dennis et al., 2006; Lester & Lagasse, 2010; Linares et al., 2006; Singer et al., 2004). And compared to nonexposed infants, cocaine-exposed babies show greater stress reactivity, as indicated by a more rapid rise in saliva concentrations of cortisol to emotionally arousing events (Eiden, Veira, & Granger, 2009). By school age, children with a history of prenatal cocaine exposure display a reduced cortisol response during stressful mental activity (Lester et al., 2010). Recall from Chapter 2 that cortisol levels that are either too high or too low signal a disrupted stress response system—a risk factor for illness and learning and behavior problems.

Other investigations, however, report no major negative effects of prenatal cocaine exposure (Behnke et al., 2006; Frank et al., 2005; Hurt et al., 2009). These contradictory findings indicate how difficult it is to isolate the precise damage caused by illegal drugs. Cocaine users vary greatly in the amount, potency, and purity of the cocaine they ingest. Also, they often take several drugs, display other high-risk behaviors, suffer from poverty and other stressors, and engage in insensitive caregiving—factors that worsen outcomes for children (Jones, 2006). But researchers have yet to determine exactly what accounts for findings of cocaine-related damage in some studies but not in others.

© JIM OLIVE/PETER ARNOLD IMAGES/PHOTOLIBRARY

This 3-day-old infant, born many weeks before his due date, breathes with the aid of a respirator. Prematurity and low birth weight can result from a variety of environmental influences, including maternal drug and tobacco use.

Another illegal drug, marijuana, is used more widely than heroin or cocaine. Researchers have linked prenatal marijuana exposure to smaller head size (a measure of brain growth); to attention, memory, and academic achievement difficulties; to impulsivity and overactivity; and to depression as well as anger and aggression in childhood and adolescence (Goldschmidt et al., 2004; Gray et al., 2005; Huizink & Mulder, 2006; Jutras-Aswad et al., 2009). As with cocaine, however, lasting consequences are not well-established. Overall, the effects of illegal drugs are far less consistent than the impact of two legal substances to which we now turn: tobacco and alcohol.

Tobacco

Although smoking has declined in Western nations, an estimated 14 percent of U.S. women smoke during their pregnancies (Tong et al., 2009). The best-known effect of smoking during the prenatal period is low birth weight. But the likelihood of other serious consequences, such as miscarriage, prematurity, cleft lip and palate, impaired heart rate and breathing during sleep, infant death, and asthma and cancer later in childhood, also increases (Howell, Coles, & Kable, 2008; Jaakkola & Gissler, 2004; Mossey et al., 2009). The more cigarettes a mother smokes, the greater the chances that her baby will be affected. And if a pregnant woman stops smoking at any time, even during the third trimester, she reduces the likelihood that her infant will be born underweight and suffer from future problems (Klesges et al., 2001).

Even when a baby of a smoking mother appears to be born in good physical condition, slight behavioral abnormalities may threaten the child's development. Newborns of smoking mothers are less attentive to sounds, display more muscle tension, are more excitable when touched and visually stimulated, and more often have colic (persistent crying)—findings that suggest subtle negative effects on brain development (Law et al., 2003; Sondergaard et al., 2002). Consistent with this view, prenatally exposed youngsters tend to have shorter attention spans, difficulties with impulsivity and overactivity, poorer memories, lower mental test scores, and higher levels of disruptive, aggressive behavior (Fryer, Crocker, & Mattson, 2008; Lindblad & Hjern, 2010; Nigg & Breslau, 2007).

Exactly how can smoking harm the fetus? Nicotine, the addictive substance in tobacco, constricts blood vessels, lessens blood flow to the uterus, and causes the placenta to grow abnormally. This reduces the transfer of nutrients, so the fetus gains weight poorly. Also, nicotine raises the concentration of carbon monoxide in the bloodstreams of both mother and fetus. Carbon monoxide displaces oxygen from red blood cells, damaging the central nervous system and slowing body growth in the fetuses of laboratory animals (Friedman, 1996). Similar effects may occur in humans.

From one-third to one-half of nonsmoking pregnant women are "passive smokers" because their husbands, relatives, or co-workers use cigarettes. Passive smoking is also related to low birth weight, infant death, childhood respiratory illnesses, and possible long-term attention, learning, and behavior problems (Best, 2009; Pattenden et al., 2006). Clearly, expectant mothers should avoid smoke-filled environments.

Alcohol

In his moving book *The Broken Cord*, Michael Dorris (1989), a Dartmouth University anthropology professor, described what it was like to rear his adopted son Abel (called Adam in the book), whose biological mother died of alcohol poisoning shortly after his birth. A Sioux Indian, Abel was born with **fetal alcohol spectrum disorder (FASD),** a term that encompasses a range of physical, mental, and behavioral outcomes caused by prenatal alcohol exposure. As Table 3.6 shows, children with FASD are given one of three diagnoses, which vary in severity:

1. **Fetal alcohol syndrome (FAS),** distinguished by (a) slow physical growth, (b) a pattern of three facial abnormalities (short eyelid openings; a thin upper lip; a smooth or flattened philtrum, or indentation running from the bottom of the nose to the center of the

TABLE 3.6 Fetal Alcohol Spectrum Disorder: Criteria for Diagnosis

	DIAGNOSTIC CATEGORY		
Criteria	*FAS*	*p-FAS*	*ARND*
Slow physical growth	Yes	No	No
Facial abnormalities: • Short eyelid openings • Thin upper lip • Smooth or flattened philtrum	All three are present	Two of the three are present	None are present
Brain injury	Impairment in a minimum of three areas of functioning	Impairment in a minimum of three areas of functioning	Impairment in a minimum of three areas of functioning

Source: Loock et al., 2005.

upper lip), and (c) brain injury, evident in a small head and impairment in at least three areas of functioning—for example, memory, language and communication, attention span and activity level (overactivity), planning and reasoning, motor coordination, or social skills. Other defects—of the eyes, ears, nose, throat, heart, genitals, urinary tract, or immune system—may also be present. Abel was diagnosed as having FAS. As is typical for this disorder, his mother drank heavily throughout pregnancy.

2. **Partial fetal alcohol syndrome (p-FAS),** characterized by (a) two of the three facial abnormalities just mentioned and (b) brain injury, again evident in at least three areas of impaired functioning. Mothers of children with p-FAS generally drank alcohol in smaller quantities, and children's defects vary with the timing and length of alcohol exposure. Furthermore, recent evidence suggests that paternal alcohol use around the time of conception can induce genetic alterations, thereby contributing to symptoms (Ouko et al., 2009).
3. **Alcohol-related neurodevelopmental disorder (ARND),** in which at least three areas of mental functioning are impaired, despite typical physical growth and absence of facial abnormalities. Again, prenatal alcohol exposure, though confirmed, is less pervasive than in FAS (Chudley et al., 2005; Loock et al., 2005).

Even when provided with enriched diets, FAS babies fail to catch up in physical size during infancy or childhood. Mental impairment associated with all three FASD diagnoses is also permanent: In his teens and twenties, Abel Dorris had trouble concentrating and keeping a routine job, and he suffered from poor judgment. For example, he would buy something and not wait for change or would wander off in the middle of a task. He died in 1991, at age 23, after being hit by a car.

The more alcohol a woman consumes during pregnancy, the poorer the child's motor coordination, speed of information processing, attention, memory, reasoning, and intelligence and achievement test scores during the preschool and school years (Burden, Jacobson, & Jacobson, 2005; Korkman, Kettunen, & Autti-Raemoe, 2003; Mattson, Calarco, & Lang, 2006). In adolescence and early adulthood, FASD is associated with persisting attention and motor-coordination deficits, poor school performance, trouble with the law, inappropriate social and sexual behaviors, alcohol and drug abuse, and lasting mental health problems, including high stress reactivity and depression (Barr et al., 2006; Fryer, Crocker, & Mattson, 2008; Hellemans et al., 2010; Howell et al., 2006; Streissguth et al., 2004).

How does alcohol produce its devastating effects? First, it interferes with production and migration of neurons in the primitive neural tube. EEG and fMRI research reveals reduced brain size, damage to many brain structures, and abnormalities in brain functioning, including the electrical and chemical activity involved in transferring messages from one part of the brain to another (Haycock, 2009; Spadoni et al., 2007). Second, the body uses large quantities of oxygen to metabolize alcohol. A pregnant woman's heavy drinking draws away oxygen that the developing organism needs for cell growth.

Left photo: This toddler's mother drank heavily during pregnancy. Her widely spaced eyes, thin upper lip, and short eyelid openings are typical of fetal alcohol syndrome (FAS). *Right photo:* This 12-year-old has the mental impairments, small head, and facial abnormalities of FAS. She also shows the slow physical growth that accompanies the disorder.

About 25 percent of U.S. mothers report drinking at some time during their pregnancies. As with heroin and cocaine, alcohol abuse is higher in poverty-stricken women. On some Native-American reservations, the incidence of FAS is as high as 10 to 20 percent (Szlemko, Wood, & Thurman, 2006; Tong et al., 2009). Unfortunately, when affected girls later become pregnant, the poor judgment caused by the syndrome often prevents them from understanding why they themselves should avoid alcohol. Thus, the tragic cycle is likely to be repeated in the next generation.

How much alcohol is safe during pregnancy? Even mild drinking, less than one drink per day, is associated with reduced head size and body growth among children followed into adolescence (Jacobson et al., 2004; Martinez-Frias et al., 2004). Recall that other factors, both genetic and environmental, can make some fetuses more vulnerable to teratogens. Therefore, no amount of alcohol is safe. Couples planning a pregnancy and expectant mothers should avoid alcohol entirely.

© CAROLINE PENN/CORBIS

This child's deformities are linked to radiation exposure early in pregnancy, caused by the Chernobyl nuclear power plant disaster in 1986. Prenatal radiation exposure also increases the risk of low intelligence and language and emotional disorders.

Radiation Earlier we saw that ionizing radiation can cause mutation, damaging DNA in ova and sperm. When mothers are exposed to radiation during pregnancy, the embryo or fetus can suffer additional harm. Defects due to radiation were tragically apparent in the children born to pregnant women who survived the atomic bombing of Hiroshima and Nagasaki during World War II. Similar abnormalities surfaced in the nine months following the 1986 Chernobyl, Ukraine, nuclear power plant accident. After each disaster, the incidence of miscarriage and of babies born with underdeveloped brains, physical deformities, and slow physical growth rose dramatically (Hoffmann, 2001; Schull, 2003). Evacuation of residents in areas near the Japanese nuclear facility damaged by the March 2011 earthquake and tsunami was intended to prevent these devastating outcomes.

Even when a radiation-exposed baby seems normal, problems may appear later. For example, even low-level radiation, as the result of industrial leakage or medical X-rays, can increase the risk of childhood cancer (Fattibene et al., 1999). In middle childhood, prenatally exposed Chernobyl children showed abnormal EEG brain-wave activity, lower intelligence test scores, and rates of language and emotional disorders two to three times greater than those of nonexposed Russian children. Furthermore, the more tension parents reported, due to forced evacuation from their homes and worries about living in irradiated areas, the poorer their children's emotional functioning (Loganovskaja & Loganovsky, 1999; Loganovsky et al., 2008). Stressful rearing conditions seemed to combine with the damaging effects of prenatal radiation to impair children's development.

Women should do their best to avoid medical X-rays during pregnancy. If dental, thyroid, chest, or other X-rays are necessary, insisting on the use of an abdominal X-ray shield is a key protective measure.

Environmental Pollution In industrialized nations, an astounding number of potentially dangerous chemicals are released into the environment. More than 75,000 are in common use in the United States, and many new pollutants are introduced each year. When 10 newborns were randomly selected from U.S. hospitals for analysis of umbilical cord blood, researchers uncovered a startling array of industrial contaminants—287 in all! They concluded that many babies are "born polluted" by chemicals that not only impair prenatal development but also increase the chances of health problems and life-threatening diseases later on (Houlihan et al., 2005). Prenatal exposure to traffic-related air pollution due to residence near roadways, for example, is linked to lower birth weight, with complicated pregnancies at greater risk (Rich et al., 2009; Seo et al., 2010).

Certain pollutants cause severe prenatal damage. In the 1950s, an industrial plant released waste containing high levels of *mercury* into a bay providing seafood and water for the town of Minamata, Japan. Many children born at the time displayed physical deformities, mental retardation, abnormal speech, difficulty in chewing and swallowing, and uncoordinated movements. High levels of prenatal mercury exposure disrupt production and migration of neurons, causing widespread brain damage (Clarkson, Magos, & Myers, 2003; Hubbs-Tait et al., 2005). Prenatal mercury exposure from maternal seafood diets, assessed by measuring mercury concentration in umbilical-cord blood and tissue, predicts deficits in speed of cognitive processing and motor, attention, and verbal test performance during the school years (Boucher et al., 2010; Debes et al., 2006). Pregnant women are wise to avoid eating long-lived predatory fish, including swordfish, albacore tuna, and shark, which are heavily contaminated with mercury.

For many years, *polychlorinated biphenyls (PCBs)* were used to insulate electrical equipment, until research showed that, like mercury, they found their way into waterways and entered the food supply. In Taiwan, prenatal exposure to very high levels of PCBs in rice oil resulted in low birth weight, discolored skin, deformities of the gums and nails, EEG brain-wave abnormalities, and delayed cognitive development (Chen & Hsu, 1994; Chen et al., 1994). Steady, low-level PCB exposure is also harmful. Women who frequently ate PCB-contaminated fish, compared with those who ate little or no fish, had infants with lower birth weights, smaller heads, greater stress reactivity, persisting attention and memory difficulties, and lower intelligence test scores in childhood (Boucher, Muckle, & Bastien, 2009; Jacobson & Jacobson, 2003; Stewart et al., 2008).

Another teratogen, *lead*, is present in paint flaking off the walls of old buildings and in certain materials used in industrial occupations. High levels of prenatal lead exposure are consistently related to prematurity, low birth weight, brain damage, and a wide variety of physical defects. Even at low levels, affected infants and children show slightly poorer mental and motor development (Bellinger, 2005; Jedrychowski et al., 2009). The greater the prenatal lead exposure, the lower children's test scores.

Finally, prenatal exposure to *dioxins*—toxic compounds resulting from incineration—is linked to brain, immune system, and thyroid damage in babies and to an increased incidence of breast and uterine cancers in women, perhaps through altering hormone levels (ten Tusscher & Koppe, 2004). Furthermore, even tiny amounts of dioxin in the paternal blood stream cause a dramatic change in the sex ratio of offspring: Affected men father nearly twice as many girls as boys (Ishihara et al., 2007; Mocarelli et al., 2000). Dioxin seems to impair the fertility of Y-bearing sperm prior to conception.

LOOK and LISTEN

Ask several adults who hope someday to be parents to explain what they know about several teratogens. How great is their need for prenatal education?

Maternal Disease Five percent of women catch an infectious disease while pregnant. Most of these illnesses, such as the common cold, seem to have no impact on the embryo or fetus. However, as Table 3.7 on page 102 indicates, certain diseases can cause extensive damage.

TABLE 3.7 Effects of Some Infectious Diseases During Pregnancy

Viruses. In the mid-1960s, a worldwide epidemic of *rubella* (three-day, or German, measles) led to the birth of more than 20,000 American babies with serious defects and to 13,000 fetal and newborn deaths. Consistent with the sensitive-period concept, the greatest damage occurs when rubella strikes during the embryonic period. More than 50 percent of infants whose mothers become ill during that time show deafness; eye deformities, including cataracts; heart, genital, urinary, intestinal, bone, and dental defects; and mental retardation. Infection during the fetal period is less harmful, but low birth weight, hearing loss, and bone defects may still occur. The organ damage inflicted by prenatal rubella often leads to lifelong health problems, including severe mental illness (especially schizophrenia), diabetes, cardiovascular disease, and thyroid and immune-system dysfunction in adulthood (Brown, 2006; Duszak, 2009). Routine vaccination in infancy and childhood has made new rubella outbreaks unlikely in industrialized nations. But an estimated 100,000 cases of prenatal infection continue to occur each year, primarily in developing countries in Africa and Asia with weak or absent immunization programs (Bale, 2009).

The *human immunodeficiency virus (HIV)*, which can lead to *acquired immune deficiency syndrome (AIDS)*, a disease that destroys the immune system, has infected increasing numbers of women over the past two decades. Currently, women account for one-fourth of cases in North America, Western Europe, and East Asia. Although the incidence of AIDS has declined in industrialized nations, the disease is rampant in developing countries, where 95 percent of new infections occur, more than half of which affect women. In South Africa, for example, nearly 30 percent of all pregnant women are HIV-positive (Quinn & Overbaugh, 2005; South African Department of Health, 2009). HIV-infected expectant mothers pass the deadly virus to the fetus 20 to 30 percent of the time.

AIDS progresses rapidly in infants. By 6 months, weight loss, diarrhea, and repeated respiratory illnesses are common. The virus also causes brain damage, as indicated by seizures, gradual loss in brain weight, and delayed mental and motor development. Nearly half of prenatal AIDS babies die by 1 year of age and 90 percent by age 3 (Devi et al., 2009). Antiretroviral drug treatment reduces prenatal AIDS transmission by as much as 95 percent, with no harmful consequences of drug therapy for children. These medications have led to a dramatic decline in prenatally acquired AIDS in Western nations. Although distribution is increasing, antiretroviral drugs are still not widely available in impoverished regions of the world (UNICEF, 2010a).

As Table 3.7 reveals, the developing organism is especially sensitive to the family of herpes viruses, for which no vaccine or treatment exists. Among these, *cytomegalovirus* (the most frequent prenatal infection, transmitted through respiratory or sexual contact) and *herpes simplex 2* (which is sexually transmitted) are especially dangerous. In both, the virus invades the mother's genital tract, infecting babies either during pregnancy or at birth. Both diseases often have no symptoms, very mild symptoms, or symptoms with which people are unfamiliar, thereby increasing the likelihood of contagion. Pregnant women who are not in a mutually monogamous relationship are at greatest risk.

REUTERS/GRANT NEUENBERG/LANDOV

Babies are tested for the HIV virus in a clinic in Mozambique, Africa. Prenatal treatment with antiretroviral drugs reduces transmission of AIDS from mother to child by as much as 95 percent.

Bacterial and Parasitic Diseases. Table 3.7 also includes several bacterial and parasitic diseases. Among the most common is *toxoplasmosis*, caused by a parasite found in many animals. Pregnant women may become infected from eating raw or undercooked meat or from contact with the feces of infected cats. About 40 percent of women who have the disease transmit it to the developing organism. If it strikes during the first trimester, it is likely to cause eye and brain damage. Later infection is linked to mild visual and cognitive impairments. And about 80 percent of affected newborns with no obvious signs of damage develop learning or visual disabilities in later life (Jones, Lopez, & Wilson, 2003). Expectant mothers can avoid toxoplasmosis by making sure that the meat they eat is well-cooked, having pet cats checked for the disease, and turning over care of litter boxes to other family members.

Other Maternal Factors

Besides exposure to teratogens, maternal exercise, nutrition, and emotional well-being affect the embryo and fetus. In addition, many expectant parents wonder how a mother's age affects the course of pregnancy. We examine each of these factors in the following sections.

Exercise

In healthy, physically fit women, regular moderate exercise, such as walking, swimming, biking, or an aerobic workout, is related to increased birth weight and a reduction in risk for certain complications, such as pregnancy-induced maternal diabetes and high blood pressure (Kalisiak & Spitznagle, 2009; Olson et al., 2009). However, frequent, vigorous, extended exercise—working up a sweat for more than 30 minutes, four or five days a week, especially late in pregnancy—results in lower birth weight than in healthy, nonexercising controls (Clapp et al., 2002; Leet & Flick, 2003). Hospital-sponsored childbirth education programs frequently offer exercise classes and suggest appropriate routines that help women prepare for labor and delivery.

During the last trimester, when the abdomen grows very large, mothers have difficulty moving freely and often must cut back on exercise. Most women, however, do not engage in sufficient moderate exercise during pregnancy to promote their own and their baby's health (Poudevigne & O'Connor, 2006). An expectant mother who remains fit experiences fewer physical discomforts, such as back pain, upward pressure on the chest, or difficulty breathing in the final weeks.

Nutrition

During the prenatal period, when children are growing more rapidly than at any other time, they depend totally on the mother for nutrients. A healthy diet that results in a maternal weight gain of 25 to 30 pounds (10 to 13.5 kilograms) helps ensure the health of mother and baby.

© JENNY MATTHEWS/ALAMY

Pregnant women of Sierra Leone share a healthy meal they prepared together. They belong to a support group that seeks to improve maternal and infant health by preventing prenatal malnutrition.

Consequences of Prenatal Malnutrition. During World War II, a severe famine occurred in the Netherlands, giving scientists a rare opportunity to study the impact of nutrition on prenatal development. Findings revealed that the sensitive-period concept operates with nutrition, just as it does with teratogens. Women affected by the famine during the first trimester were more likely to have miscarriages or give birth to babies with physical defects. When women were past the first trimester, fetuses usually survived, but many were born underweight and had small heads (Stein et al., 1975).

Prenatal malnutrition can cause serious damage to the central nervous system. The poorer the mother's diet, the greater the loss in brain weight, especially if malnutrition occurred during the last trimester. During that time, the brain is increasing rapidly in size, and for it to reach its full potential, the mother must have a diet high in all the basic nutrients (Morgane et al., 1993). An inadequate diet during pregnancy can also distort the structure of other organs, including the liver, kidneys, and pancreas, resulting in lifelong health problems, including cardiovascular disease and diabetes in adulthood (Barker, 2008; Whincup et al., 2008).

Because poor nutrition suppresses development of the immune system, prenatally malnourished babies frequently catch respiratory illnesses (Chandra, 1991). In addition, they often are irritable and unresponsive to stimulation. Like drug-addicted newborns, they have a high-pitched cry that is particularly distressing to their caregivers. In poverty-stricken families, these effects quickly combine with a stressful home life. With age, low intelligence test scores and serious learning problems become more apparent (Pollitt, 1996).

Prevention and Treatment. Many studies show that providing pregnant women with adequate food has a substantial impact on the health of their newborn babies. Yet the growth demands of the prenatal period require more than just increased quantity of food. Vitamin–mineral enrichment is also crucial.

For example, taking a folic acid supplement around the time of conception reduces by more than 70 percent abnormalities of the neural tube, such as *anencephaly* and *spina bifida* (see Table 3.5 on page 85). Folic acid supplementation early in pregnancy also reduces the risk of other physical defects, including cleft lip and palate, urinary tract abnormalities, and limb deformities. Furthermore, adequate folic acid intake during the last 10 weeks of pregnancy cuts in half the risk of premature delivery and low birth weight (Goh & Koren, 2008; MCR Vitamin Study Research Group, 1991; Scholl, Hediger, & Belsky, 1996).

Because of these findings, U.S. government guidelines recommend that all women of childbearing age consume 0.4 milligrams of folic acid per day. For women who have previously had a pregnancy affected by neural tube defect, the recommended amount is 4 or 5 milligrams (dosage must be carefully monitored, as excessive intake can be harmful) (American Academy of Pediatrics, 2006). About half of U.S. pregnancies are unplanned, so government regulations mandate that bread, flour, rice, pasta, and other grain products be fortified with folic acid. As Figure 3.9 shows, mandatory grain fortification has resulted in substantial reductions in neural tube defects in the United States and other nations (Berry, 2010).

Other vitamins and minerals also have established benefits. Enriching women's diets with calcium helps prevent maternal high blood pressure and premature births. Adequate magnesium and zinc reduce the risk of many prenatal and birth complications (Durlach, 2004; Kontic-Vucinic, Sulovic, & Radunovic, 2006). Fortifying table salt with iodine virtually eradicates *infantile hypothyroidism*, a condition of stunted growth and cognitive impairment, caused by prenatal iodine deficiency—a common cause of mental retardation in many parts of the developing world (Williams, 2008). Sufficient vitamin C and iron beginning early in pregnancy promote growth of the placenta and healthy birth weight (Christian, 2003). And in Chapter 2, we saw that prenatal iron depletion as a result of maternal diabetes interferes with development of brain structures involved in memory, thereby impairing children's learning (see page 45). Nevertheless, a supplement program should complement, not replace, efforts to improve maternal diets during pregnancy. For women who do not get enough food or an adequate variety of foods, multivitamin tablets are a necessary, but not a sufficient, intervention.

When poor nutrition continues throughout pregnancy, infants usually require more than dietary improvement. In response to their tired, restless behavior, parents tend to be less sensitive and stimulating. The babies, in turn, become even more passive and withdrawn. Successful interventions must break this cycle of apathetic caregiver–baby interaction. Some do so by teaching parents how to interact effectively with their infants; others focus on stimulating infants to promote active engagement with their physical and social surroundings (Grantham-McGregor et al., 1994; Grantham-McGregor, Schofield, & Powell, 1987).

Although prenatal malnutrition is highest in poverty-stricken regions of the world, it is not limited to developing countries. The U.S. Special Supplemental Food Program for Women, Infants, and Children (WIC), which provides food packages and nutrition education to low-income pregnant women, reaches about 90 percent of those who qualify because of their extremely low incomes (U.S. Department of Agriculture, 2009). But many U.S. women who need nutrition intervention are not eligible for WIC.

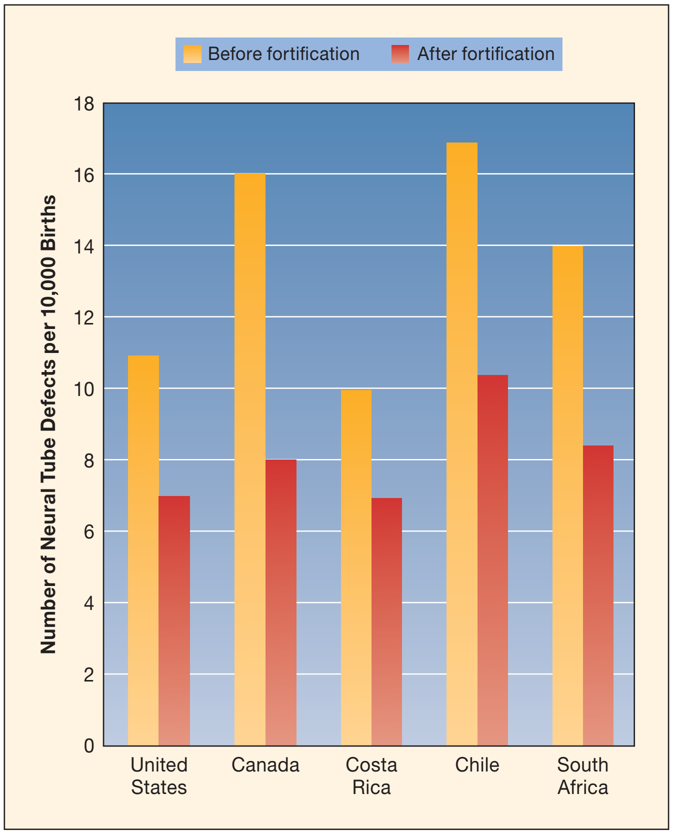

FIGURE 3.9 **Decline in rates of neural tube defects in five countries after introduction of grain fortification with folic acid.** (From J. Berry, 2010, "Fortification of Flour with Folic Acid," *Food and Nutrition Bulletin, 31*, p. S27. Reprinted by permission.)

Emotional Stress When women experience severe emotional stress during pregnancy, their babies are at risk for a wide variety of difficulties. Intense anxiety—especially during the first two trimesters—is associated with higher rates of miscarriage, prematurity, low birth weight, infant respiratory and digestive illnesses, colic (persistent infant crying), sleep disturbances, and irritability during the child's first three years (Field, 2011; Lazinski, Shea, & Steiner, 2008; van der Wal, van Eijsden, & Bonsel, 2007).

How can maternal stress affect the developing organism? **TAKE A MOMENT...** To understand this process, list the changes you sensed in your own body the last time you were under stress. When we experience fear and anxiety, stimulant hormones released into our bloodstream cause us to be "poised for action." Large amounts of blood are sent to parts of the body involved in the defensive response—the brain, the heart, and muscles in the arms, legs, and trunk. Blood flow to other organs, including the uterus, is reduced. As a result, the fetus is deprived of a full supply of oxygen and nutrients.

Maternal stress hormones also cross the placenta, causing a dramatic rise in fetal stress hormones (evident in the amniotic fluid) and in fetal heart rate, blood pressure, blood glucose, and activity level (Kinsella & Monk, 2009; Weinstock, 2008). These processes are believed to increase the lifelong risk of serious illnesses, such as cardiovascular disease and diabetes (Stocker, Arch, & Cawthorne, 2005).

Excessive fetal stress may permanently alter neurological functioning as well, thereby heightening stress reactivity in later life. In several studies, infants and children of mothers who experienced severe prenatal anxiety displayed cortisol levels that were either abnormally high or abnormally low, both of which signal reduced physiological capacity to manage stress. Consistent with these findings, such children are more upset than their agemates when faced with novel or challenging experiences (Brand et al., 2006; Huizink et al., 2008; Yehuda et al., 2005). In other research, adolescents and young adults who had been exposed to stress prenatally continued to display elevated stress reactivity (Entringer et al., 2009;

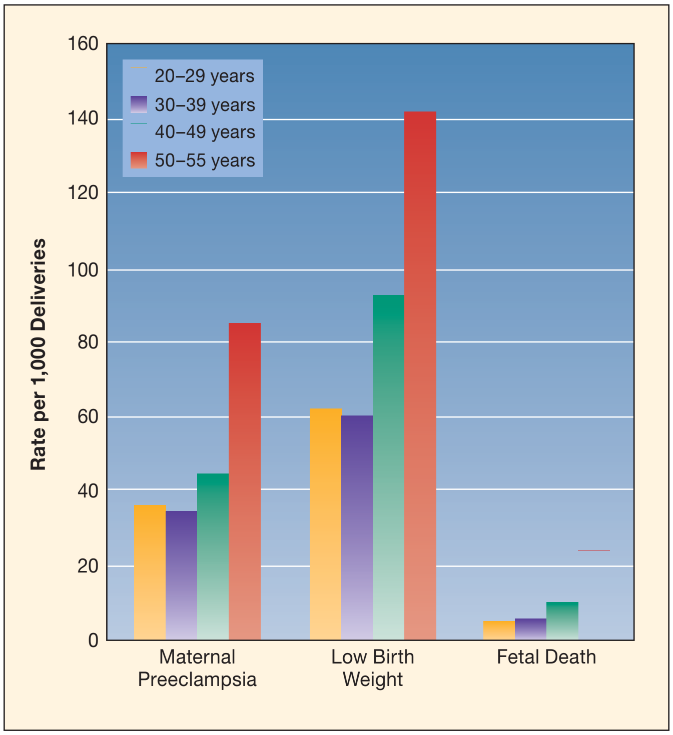

FIGURE 3.10 **Relationship of maternal age to prenatal and birth complications.** Complications increase after age 40, with a sharp rise between 50 and 55 years. Preeclampsia (also known as toxemia) is a serious disorder of the second and third trimesters involving high blood pressure, sudden weight gains, headaches, and swelling of the face, hands, and feet. Without immediate treatment, the condition progresses rapidly and is a leading cause of maternal and infant illness and death. Similarly, low birth weight greatly increases the risk of infant death and health problems. (Adapted from Salihu et al., 2003.)

Van den Bergh et al., 2008). Furthermore, maternal emotional stress during pregnancy predicts childhood anxiety, short attention span, anger, aggression, overactivity, and lower mental test scores, above and beyond the impact of other risks, such as maternal smoking during pregnancy, low birth weight, postnatal maternal anxiety, and low family income (de Weerth & Buitelaar, 2005; Gutteling et al., 2006; Lazinski, Shea, & Steiner, 2008; Van den Bergh, 2004).

But stress-related prenatal complications are greatly reduced when mothers have partners, other family members, and friends who offer social support (Glover, Bergman, & O'Connor, 2008). The relationship of social support to positive pregnancy outcomes and subsequent child development is particularly strong for low-income women, who often lead highly stressful lives (Olds et al., 2002, 2004). Enhancing supportive social networks for pregnant mothers can help prevent prenatal complications.

Maternal Age Over the past thirty years, first births to women in their thirties have increased more than fourfold, and those to women in their early forties have doubled. Many more couples are putting off childbearing until their careers are well-established and they know they can support a child. Recall that women who delay having children until their thirties or forties face increased risk of infertility, miscarriage, and babies born with chromosomal defects. Are other pregnancy complications also more common for older mothers? Research consistently indicates that healthy women in their thirties have about the same rates as those in their twenties (Bianco et al., 1996; Dildy et al., 1996; Prysak, Lorenz, & Kisly, 1995). Thereafter, as Figure 3.10 shows, complication rates increase, with a sharp rise among women age 50 to 55—an age at which, because of menopause and aging reproductive organs, few women can conceive naturally (Salihu et al., 2003; Usta & Nassar, 2008).

In the case of teenage mothers, does physical immaturity cause prenatal problems? As we will see in Chapter 5, nature tries to ensure that once a girl can conceive, she is physically ready to carry and give birth to a baby. Infants born to teenagers have a higher rate of problems, but not directly because of maternal age. Most pregnant teenagers come from low-income backgrounds, where stress, poor nutrition, and health problems are common. Also, many are afraid to seek medical care or, in the United States, do not have access to care because they lack health insurance (U.S. Department of Health and Human Services, 2010a).

As we conclude our discussion of the prenatal environment, refer to Applying What We Know on the following page, which lists "do's and don'ts" for a healthy pregnancy. Public education about these vital precautions can greatly reduce prenatal health problems and their long-term negative consequences.

ASK YOURSELF

Review ■ Why is it difficult to determine the prenatal effects of many environmental agents, such as drugs and pollution?

Connect ■ List teratogens and other maternal factors that affect brain development during the prenatal period. Using Figure 3.9 on page 95, explain why the central nervous system is often affected when the prenatal environment is compromised.

Apply ■ Nora, pregnant for the first time, believes that a few cigarettes and a glass of wine a day won't be harmful. Provide Nora with research-based reasons for not smoking or drinking.

Reflect ■ If you had to choose five environmental influences to publicize in a campaign aimed at promoting healthy prenatal development, which ones would you choose, and why?

APPLYING WHAT WE KNOW

Do's and Don'ts for a Healthy Pregnancy

DO	DON'T
Do make sure that you have been vaccinated against infectious diseases that are dangerous to the embryo and fetus, such as rubella, before you get pregnant. Most vaccinations are not safe during pregnancy.	Don't take any drugs without consulting your doctor.
Do see a doctor as soon as you suspect that you are pregnant, and continue to get regular medical checkups throughout pregnancy.	Don't smoke. If you have already smoked during part of your pregnancy, cut down or, better yet, quit. If other members of your family smoke, ask them to quit or to smoke outside.
Do eat a well-balanced diet and take vitamin–mineral supplements, as prescribed by your doctor, both prior to and during pregnancy. Gain 25 to 30 pounds gradually.	Don't drink alcohol from the time you decide to get pregnant.
Do obtain literature from your doctor, local library, and bookstore about prenatal development and care, and ask questions about anything that concerns you.	Don't engage in activities that might expose your embryo or fetus to environmental hazards, such as radiation or chemical pollutants. If you work in an occupation that involves these agents, ask for a safer assignment or a leave of absence.
Do keep physically fit through moderate exercise. If possible, join a special exercise class for expectant mothers.	Don't engage in activities that might expose your embryo or fetus to harmful infectious diseases, such as toxoplasmosis.
Do avoid emotional stress. If you are a single parent, find a relative or friend you can count on for emotional support.	Don't choose pregnancy as a time to go on a diet.
Do get plenty of rest. An overtired mother is at risk for pregnancy complications.	Don't gain too much weight during pregnancy. A very large weight gain is associated with complications.
Do enroll in a prenatal and childbirth education class with your partner or other companion. When parents know what to expect, the nine months before birth can be one of the most joyful times of life.	

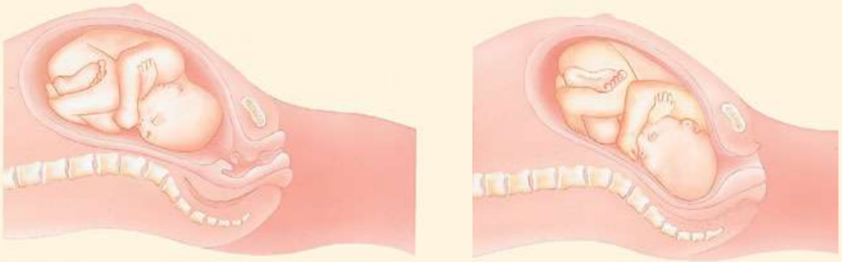
Childbirth

▶ Describe the three stages of childbirth, the baby's adaptation to labor and delivery, and the newborn baby's appearance.

It is not surprising that childbirth is often referred to as labor. It is the hardest physical work that a woman may ever do. A complex series of hormonal exchanges between mother and fetus initiates the process, which divides naturally into three stages (see Figure 3.11 on page 108):

1. *Dilation and effacement of the cervix*. This is the longest stage of labor, lasting an average of 12 to 14 hours with a first birth and 4 to 6 hours with later births. Contractions of the uterus gradually become more frequent and powerful, causing the cervix, or uterine opening, to widen and thin to nothing, forming a clear channel from the uterus into the birth canal, or vagina.
2. *Delivery of the baby*. This second stage is much shorter than the first, lasting about 50 minutes for a first baby and 20 minutes in later births. Strong contractions of the uterus continue, but the mother also feels a natural urge to squeeze and push with her abdominal muscles. As she does so with each contraction, she forces the baby down and out.
3. *Birth of the placenta*. Labor comes to an end with a few final contractions and pushes. These cause the placenta to separate from the wall of the uterus and be delivered in about 5 to 10 minutes.

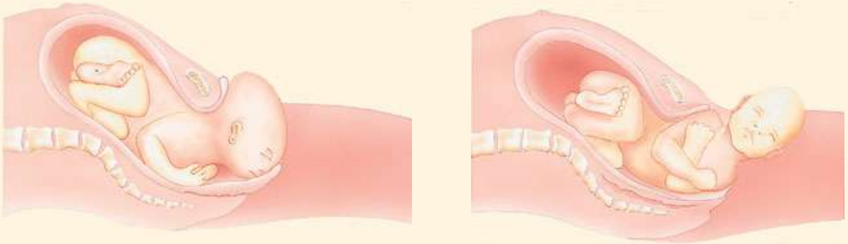
Stage 1



(a) Dilation and Effacement of the Cervix
Contractions of the uterus cause dilation and effacement of the cervix.

(b) Transition
Transition is reached when the frequency and strength of the contractions are at their peak and the cervix opens completely.

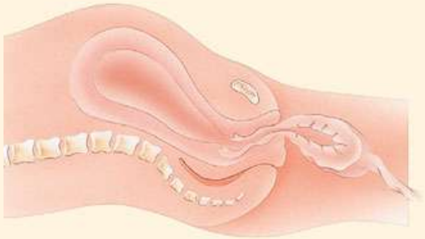
Stage 2



(c) Pushing
With each contraction, the mother pushes, forcing the baby down the birth canal, and the head appears.

(d) Birth of the Baby
Near the end of Stage 2, the shoulders emerge, followed quickly by the rest of the baby's body.

Stage 3



(e) Delivery of the Placenta
With a few final pushes, the placenta is delivered.

FIGURE 3.11 **The three stages of labor.**

The Baby's Adaptation to Labor and Delivery

At first glance, labor and delivery seem like a dangerous ordeal for the baby. The strong uterine contractions expose the head to a great deal of pressure, and they squeeze the placenta and the umbilical cord repeatedly. Each time, the baby's supply of oxygen is temporarily reduced.

Fortunately, healthy babies are equipped to withstand these traumas. The force of the contractions intensifies the baby's production of stress hormones. Unlike during pregnancy, during childbirth high levels of infant cortisol and other stress hormones are adaptive. They help the baby withstand oxygen deprivation by sending a rich supply of blood to the brain and heart (Gluckman, Sizonenko, & Bassett, 1999). In addition, stress hormones prepare the baby to breathe by causing the lungs to absorb any remaining fluid and by expanding the bronchial tubes (passages leading to the lungs). Finally, stress hormones arouse infants into alertness so they are born wide awake, ready to interact with their world (Lagercrantz & Slotkin, 1986).

The Newborn Baby's Appearance

Parents are often surprised at the odd-looking newborn—a far cry from the storybook image many had in their minds. The average newborn is 20 inches long and weighs 7½ pounds; boys tend to be slightly longer and heavier than girls. The head is large in relation to the trunk and legs, which are short and bowed. This combination of a large head (with its well-developed brain) and a small body means that human infants learn quickly in the first few months of life. But unlike most other mammals, they cannot get around on their own until much later.

Even though newborn babies may not match parents' idealized image, some features do make them attractive. Their round faces, chubby cheeks, large foreheads, and big eyes make adults feel like picking them up and cuddling them (Berman, 1980).

© LILLIAN WILSON/GETTY IMAGES/RISER

To accommodate the well-developed brain, a newborn's head is large in relation to the trunk and legs. The round face, chubby cheeks, and big eyes are attractive to adults, inducing them to pick up and cuddle the newborn.

Assessing the Newborn's Physical Condition: The Apgar Scale

Infants who have difficulty making the transition to life outside the uterus need special help at once. To assess the baby's physical condition, doctors and nurses use the **Apgar Scale.** As Table 3.8 shows, a rating of 0, 1, or 2 on each of five characteristics is made at 1 minute and again at 5 minutes after birth. A combined Apgar score of 7 or better indicates that the infant is in good physical condition. If the score is between 4 and 6, the baby requires assistance in establishing breathing and other vital signs. If the score is 3 or below, the infant is in serious danger and requires emergency medical attention. Two Apgar ratings are given because some babies have trouble adjusting at first but do quite well after a few minutes (Apgar, 1953).

TABLE 3.8 The Apgar Scale

	SCORE		
SIGN[a]	**0**	**1**	**2**
Heart rate	No heartbeat	Under 100 beats per minute	100 to 140 beats per minute
Respiratory effort	No breathing for 60 seconds	Irregular, shallow breathing	Strong breathing and crying
Reflex irritability (sneezing, coughing, and grimacing)	No response	Weak reflexive response	Strong reflexive response
Muscle tone	Completely limp	Weak movements of arms and legs	Strong movements of arms and legs
Color[b]	Blue body, arms, and legs	Body pink with blue arms and legs	Body, arms, and legs completely pink

[a] To remember these signs, you may find it helpful to use a technique in which the original labels are reordered and renamed as follows: color = **A**ppearance, heart rate = **P**ulse, reflex irritability = **G**rimace, muscle tone = **A**ctivity, and respiratory effort = **R**espiration. Together, the first letters of the new labels spell **Apgar**.

[b] The skin tone of nonwhite babies makes it difficult to apply the "pink" color criterion. However, newborns of all races can be rated for pinkish glow resulting from the flow of oxygen through body tissues..

Approaches to Childbirth

- Describe natural childbirth and home delivery, and explain the risks of using pain-relieving drugs during labor and delivery.

Childbirth practices, like other aspects of family life, are molded by the society of which mother and baby are a part. In many village and tribal cultures, expectant mothers are well-acquainted with the childbirth process. For example, the Jarara of South America and the Pukapukans of the Pacific Islands treat birth as a vital part of daily life. The Jarara mother

In this Peruvian health clinic, families are encouraged to incorporate traditional village practices into the birth experience. Here, a familiar attendant supports and soothes a new mother as her baby is delivered.

gives birth in full view of the entire community, including small children. The Pukapukan girl is so familiar with the events of labor and delivery that she frequently can be seen playing at it. Using a coconut to represent the baby, she stuffs it inside her dress, imitates the mother's pushing, and lets the nut fall at the proper moment. In most nonindustrialized cultures, women are assisted—though often not by medical personnel—during labor and delivery. Among the Mayans of the Yucatán, the mother leans against a woman called the "head helper," who supports her weight and breathes with her during each contraction. And in Bolivia, a Siriono mother delivers her own baby in a hammock with a crowd of women close by, who keep her company. The father cuts the umbilical cord and joins the mother in tending to the newborn for the first few days (Jordan, 1993; Mead & Newton, 1967; Reed, 2005).

In Western nations, childbirth has changed dramatically over the centuries. Before the late 1800s, birth usually took place at home and was a family-centered event. The industrial revolution brought greater crowding to cities, along with new health problems. As a result, childbirth moved from home to hospital, where the health of mothers and babies could be protected. Once doctors assumed responsibility for childbirth, women's knowledge of it declined, and relatives and friends no longer participated (Borst, 1995).

By the 1950s and 1960s, women had begun to question the medical procedures that had come to be used routinely during labor and delivery. Many felt that use of strong drugs and delivery instruments had robbed them of a precious experience and was often neither necessary nor safe for the baby. Gradually, a natural childbirth movement arose in Europe and spread to North America. Its purpose was to make hospital birth as comfortable and rewarding for mothers as possible. Today, most hospitals offer birth centers that are family-centered and homelike. *Freestanding birth centers*, which permit greater maternal control over labor and delivery, including choice of delivery positions, presence of family members and friends, and early contact between parents and baby, also exist. And a small number of North American women reject institutional birth entirely and choose to have their babies at home.

Natural, or Prepared, Childbirth

Natural, or **prepared, childbirth** consists of a group of techniques aimed at reducing pain and medical intervention and making childbirth as rewarding an experience as possible. Most natural childbirth programs draw on methods developed by Grantly Dick-Read (1959) in England and Ferdinand Lamaze (1958) in France. These physicians recognized that cultural attitudes had taught women to fear the birth experience. An anxious, frightened woman in labor tenses muscles, heightening the pain that usually accompanies strong contractions.

In a typical natural childbirth program, the expectant mother and a companion (a partner, relative, or friend) participate in three activities:

- *Classes*. The expectant mother and her companion attend a series of classes in which they learn about the anatomy and physiology of labor and delivery. Knowledge about the birth process reduces a mother's fear.
- *Relaxation and breathing techniques*. Expectant mothers are taught relaxation and breathing exercises aimed at counteracting the pain of uterine contractions.
- *Labor coach*. The companion learns how to help during childbirth by reminding the mother to relax and breathe, massaging her back, supporting her body, and offering encouragement and affection.

In a hospital birth center, a mother gives birth, assisted by the father. A companion's support is a vital part of natural childbirth, which is associated with shorter labors, fewer complications, and a more rewarding birth experience.

Social Support and Natural Childbirth

Social support is important to the success of natural childbirth techniques. In Guatemalan and American hospitals that routinely isolated patients during childbirth, some mothers were randomly assigned a doula—a Greek word referring to a trained lay attendant—who stayed with them throughout labor and delivery, talking to them, holding their hands, and rubbing their backs to promote relaxation. These mothers had fewer birth complications, and their labors were several hours shorter than those of women who did not have supportive companionship. Guatemalan mothers who received doula support also interacted more positively with their babies after delivery, talking, smiling, and gently stroking (Kennell et al., 1991; Sosa et al., 1980).

Other studies indicate that mothers who are supported during labor and delivery—either by a lay birth attendant or by a relative or friend with doula training—less often have instrument-assisted or cesarean (surgical) deliveries or need medication to control pain. Also, their babies' Apgar scores are higher, and they are more likely to be breastfeeding at a two-month follow-up (Campbell et al., 2006, 2007; Hodnett et al., 2003; McGrath & Kennell, 2008). The continuous rather than intermittent support of a doula during labor and delivery strengthens these outcomes. It is particularly helpful during a first childbirth, when mothers are more anxious (Scott, Berkowitz, & Klaus, 1999). And this aspect of natural childbirth makes Western hospital-birth customs more acceptable to women from parts of the world where assistance from family and community members is the norm (Dundek, 2006).

LOOK and LISTEN

Talk to several mothers about social supports available to them during labor and delivery. From the mothers' perspectives, how did those supports (or lack of support) affect the birth experience?

Positions for Delivery

When natural childbirth is combined with delivery in a birth center or at home, mothers often give birth in an upright, sitting position rather than lying flat on their backs with their feet in stirrups (the traditional hospital delivery room practice). Use of special seats to enable an upright birth has become more common. When mothers are upright, labor is shortened because contractions are stronger and pushing is more effective. The baby benefits from a richer supply of oxygen because blood flow to the placenta is increased (Lawrence et al., 2009). Because the mother can see the delivery, she can work with the doctor or midwife, adjusting her pushing to ensure that the baby's head and shoulders emerge slowly, which reduces the chances of tearing the mother's tissues. Compared with those who give birth lying on their backs, women who choose an upright position are less likely to use pain-relieving medication (Romano & Lothian, 2008).

In another increasingly popular method, water birth, the mother sits in a warm tub of water, which supports her weight, relaxes her, and provides her with the freedom to move into any position she finds most comfortable. Water birth is associated with reduced maternal stress, shorter labor, and greater likelihood of medication-free delivery than both back-lying and seated positions (Cluett & Burns, 2009). As long as water birth is carefully managed by health professionals, it poses no additional risk of infection or safety to mothers or babies (Zanetti-Daellenbach et al., 2007).

© FRANCE KEYSER/IN VISU/CORBIS

An increasingly popular childbirth option is water birth. Sitting in a warm tub of water relaxes this mother, supports her weight, and gives her the freedom to move into a comfortable position.

Home Delivery

Home birth has always been popular in certain industrialized nations, such as England, the Netherlands, and Sweden. The number of American women choosing to have their babies at home rose during the 1970s and 1980s but remains small, at less than 1 percent (U.S. Department of Health and Human Services, 2010a). These mothers want birth to be an important part of family life, to avoid unnecessary medical procedures, and to have greater control over their own care and that of their babies than hospitals permit. Although some home births are attended by doctors, many more are handled by *certified nurse–midwives*, who have degrees in nursing and additional training in childbirth management.

Is it just as safe to give birth at home as in a hospital? For healthy women who are assisted by a well-trained doctor or midwife, it seems so because complications rarely occur (Fullerton, Navarro, & Young, 2007; Wax, Pinette, & Cartin, 2010). However, if attendants are not carefully trained and prepared to handle emergencies, the rate of infant death is high (Mehlmadrona & Madrona, 1997). When mothers are at risk for any kind of complication, the appropriate place for labor and delivery is the hospital, where life-saving treatment is available.

Labor and Delivery Medication

Although natural childbirth techniques lessen or eliminate the need for pain-relieving drugs, some form of medication is used in more than 80 percent of U.S. births (Althaus & Wax, 2005). *Analgesics*, drugs used to relieve pain, may be given in mild doses during labor to help a mother relax. *Anesthetics* are a stronger type of painkiller that blocks sensation. Currently, the most common approach to controlling pain during labor is *epidural analgesia*, in which a regional pain-relieving drug is delivered continuously through a catheter into a small space in the lower spine. Unlike older spinal block procedures, which numb the entire lower half of the body, epidural analgesia limits pain reduction to the pelvic region. Because the mother retains the capacity to feel the pressure of contractions and to move her trunk and legs, she is able to push during the second stage of labor.

Although pain-relieving drugs help women cope with childbirth and enable doctors to perform essential medical interventions, they also cause problems. Epidural analgesia, for example, weakens uterine contractions. As a result, labor is prolonged, and the chances of cesarean (surgical) delivery increase (Nguyen et al., 2010). And because drugs rapidly cross the placenta, exposed newborns tend to have lower Apgar scores, to be sleepy and withdrawn, to suck poorly during feedings, and to be irritable when awake (Caton et al., 2002; Eltzschig, Lieberman, & Camann, 2003; Emory, Schlackman, & Fiano, 1996). Although no confirmed long-term consequences for development exist, the negative impact of these drugs on the newborn's adjustment supports the current trend to limit their use.

ASK YOURSELF

Review ■ Describe the features and benefits of natural childbirth. What aspect contributes greatly to favorable outcomes, and why?

Connect ■ Contrast the positive impact of the baby's production of stress hormones during childbirth with the negative impact of maternal stress on the fetus, discussed on pages 105–106.

Apply ■ On seeing her newborn baby for the first time, Caroline exclaimed, "Why is she so out of proportion?" What observations prompted Caroline to ask this question? Explain why her baby's appearance is adaptive.

Reflect ■ If you were an expectant parent, would you choose home birth? Why or why not?

▶ What risks are associated with oxygen deprivation and with preterm and low-birth-weight infants, and what factors can help infants who survive a traumatic birth?

Birth Complications

We have seen that some babies—in particular, those whose mothers are in poor health, do not receive good medical care, or have a history of prenatal problems—are especially likely to experience birth complications. Inadequate oxygen, a pregnancy that ends too early, and low birth weight pose serious risks to development that we have touched on many times. Let's look at the impact of each complication on later development.

Oxygen Deprivation

A small number of infants experience *anoxia*, or inadequate oxygen supply, during the birth process. Sometimes the problem results from a failure to start breathing within a few minutes. Healthy newborns can survive periods of little or no oxygen longer than adults can; they reduce their metabolic rate, thereby conserving the limited oxygen available. Nevertheless, brain damage is likely if regular breathing is delayed more than 10 minutes (Kendall & Peebles, 2005).

At other times, anoxia occurs during labor. A common cause is squeezing of the umbilical cord, a condition that is especially likely when infants are in **breech position**—turned in such a way that the buttocks or feet would be delivered first (1 in every 25 births). Because of this danger, breech babies often experience a cesarean (surgical) delivery. An additional cause of oxygen deprivation is *placenta abruptio*, or premature separation of the placenta (complicating about 1 percent of pregnancies), a life-threatening event that requires immediate delivery. Factors related to it include multiple fetuses, advanced maternal age (40 and older), and teratogens that cause abnormal development of the placenta, such as tobacco and cocaine (Oyelese & Ananth, 2006).

Still another condition that can lead to anoxia is **Rh factor incompatibility** between the mother's and baby's blood types. When the mother is Rh negative (lacks the Rh protein) and the father is Rh positive (has the Rh protein), the baby may inherit the father's Rh-positive blood type. If even a little of a fetus's Rh-positive blood crosses the placenta into the Rh-negative mother's bloodstream, she begins to form antibodies to the foreign protein. If these enter the fetus's system, they destroy red blood cells, reducing the supply of oxygen. Mental retardation, miscarriage, heart damage, and infant death can occur. It takes time for the mother to produce antibodies, so firstborn children are rarely affected. The danger increases with each pregnancy. Fortunately, Rh incompatibility can be prevented in most cases. After the birth of each Rh-positive baby, Rh-negative mothers are given a vaccine to prevent the buildup of antibodies.

After initial brain injury from anoxia, another phase of cell death can occur several hours later. Placing anoxic newborns in a head-cooling device shortly after birth for 72 hours substantially reduces this secondary brain damage (detected through MRI brain scans) and increases scores on a newborn behavioral assessment (Hoehn et al., 2008; Lin et al., 2006). Another alternative—whole-body cooling by having anoxic newborns lie on a precooled water blanket—leads to an impressive reduction in death and disability rates during the first two years (Shankaran et al., 2005).

PHOTO COURTESY OF SUSAN MERRELL

Treatment for this newborn, who experienced oxygen deprivation, combines a cooling head cap with a cooling water blanket to lower body temperature, which helps prevent brain damage.

How do children who experience anoxia during labor and delivery fare as they get older? Research suggests that the greater the oxygen deprivation, the poorer children's cognitive and language skills in early and middle childhood (Hopkins-Golightly, Raz, & Sander, 2003). Although effects of even mild to moderate anoxia often persist, many children improve over time (Bass et al., 2004; Raz, Shah, & Sander, 1996).

When development is severely impaired, the anoxia was probably extreme. Perhaps it was caused by prenatal insult to the baby's respiratory system, or it may have happened because the infant's lungs were not yet mature enough to breathe. For example, babies born more than six weeks early commonly have *respiratory distress syndrome* (otherwise known as *hyaline membrane disease*). Their tiny lungs are so poorly developed that the air sacs collapse, causing serious breathing difficulties. Today, mechanical respirators keep many such infants alive. In spite of these measures, some babies suffer permanent brain damage from lack of oxygen, and in other cases their delicate lungs are harmed by the treatment itself. Respiratory distress syndrome is only one of many risks for babies born too soon, as we will see in the following section.

Preterm and Low-Birth-Weight Infants

Babies born three weeks or more before the end of a full 38-week pregnancy or who weigh less than 5½ pounds (2,500 grams) have for many years been referred to as "premature." A wealth of research indicates that premature babies are at risk for many problems. Birth weight is the best available predictor of infant survival and healthy development. Although outcomes have improved over the past several decades, many newborns who weigh less than 3½ pounds (1,500 grams) experience difficulties that are not overcome—an effect that

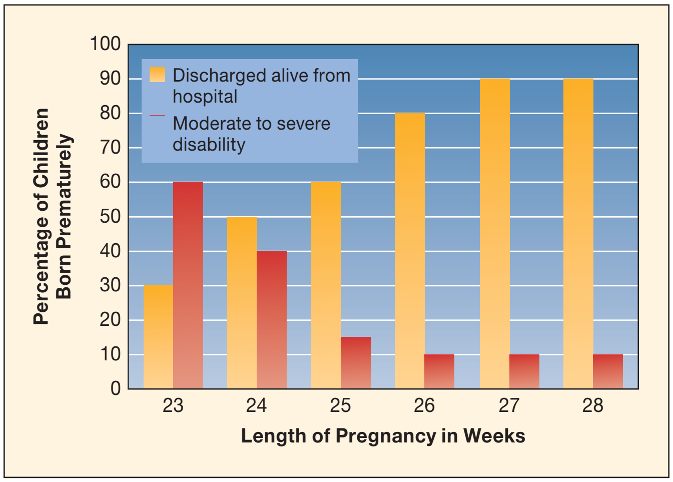

FIGURE 3.12 Rates of infant survival and child disabilities by length of pregnancy. In a follow-up of more than 2,300 babies born between 23 and 28 weeks gestation, the percentage who displayed moderate to severe disabilities (assessed during the preschool years) increased with reduced length of pregnancy. Severe disabilities included cerebral palsy (unlikely to ever walk), severely delayed mental development, deafness, and blindness. Moderate disabilities included cerebral palsy (able to walk with assistance), moderately delayed mental development, and hearing impairments partially correctable with a hearing aid. (Adapted from Bolisetty et al., 2006.)

strengthens as length of pregnancy and birth weight decrease (see Figure 3.12) (Baron & Rey-Casserly, 2010; Bolisetty et al., 2006; Dombrowski, Noonan, & Martin, 2007). Brain abnormalities, frequent illness, inattention, overactivity, sensory impairments, poor motor coordination, language delays, low intelligence test scores, deficits in school learning, and emotional and behavior problems are some of the difficulties that persist through childhood and adolescence and into adulthood (Aarnoudse-Moens, Weisglas-Kuperus, & van Goudoever, 2009; Clark et al., 2008; Delobel-Ayoub et al., 2009; Nosarti et al., 2011).

About 1 in 13 American infants is born underweight. The problem can strike unexpectedly, but it is highest among poverty-stricken women (U.S. Department of Health and Human Services, 2010f). These mothers, as indicated earlier, are more likely to be undernourished, under stress, and exposed to other harmful environmental influences—factors strongly linked to low birth weight. In addition, they often do not receive the prenatal care necessary to protect their vulnerable babies.

Prematurity is also common in multiple births. About 60 percent of twins and more than 90 percent of triplets are born early and low birth weight (U.S. Department of Health and Human Services, 2010f). Because space inside the uterus is restricted, twins gain less weight than singletons in the second half of pregnancy.

Preterm versus Small-for-Date Infants Although low-birth-weight infants face many obstacles to healthy development, most go on to lead normal lives; about half of those born at 23 to 24 weeks gestation and weighing only a couple of pounds at birth have no disability (refer again to Figure 3.13). To better understand why some babies do better than others, researchers divide them into two groups. **Preterm infants** are those born several weeks or more before their due date. Although they are small, their weight may still be appropriate, based on time spent in the uterus. **Small-for-date infants** are below their expected weight considering length of the pregnancy. Some small-for-date infants are actually full-term. Others are preterm babies who are especially underweight.

Of the two types of babies, small-for-date infants usually have more serious problems. During the first year, they are more likely to die, catch infections, and show evidence of brain damage. By middle childhood, they are smaller in stature, have lower intelligence test scores, are less attentive, achieve more poorly in school, and are socially immature (Hediger et al., 2002; O'Keefe et al., 2003; Sullivan et al., 2008). Small-for-date infants probably experienced inadequate nutrition before birth. Perhaps their mothers did not eat properly, the placenta did not function normally, or the babies themselves had defects that prevented them from growing as they should. In some of these babies, an abnormally functioning placenta permitted ready transfer of stress hormones from mother to fetus. Consequently, small-for-date infants are especially likely to suffer from neurological impairments that permanently weaken their capacity to manage stress (Wust et al., 2005).

Even among preterm newborns whose weight is appropriate for length of pregnancy, just seven more days—from 34 to 35 weeks—greatly reduces rates of illness, costly medical procedures, and lengthy hospital stays (although they need greater medical intervention than full-term babies) (Gladstone & Katz, 2004). And despite being relatively low-risk for disabilities, a substantial number of 34-week preterms are below average in physical growth and mildly to moderately delayed in cognitive development in early and middle childhood (Morse et al., 2009; Pietz et al., 2004; Stephens & Vohr, 2009). Yet doctors often induce births several weeks preterm, under the misconception that these babies are developmentally "mature."

Consequences for Caregiving Imagine a scrawny, thin-skinned infant whose body is only a little larger than the size of your hand. You try to play with the baby by stroking and talking softly, but he is sleepy and unresponsive. When you feed him, he sucks poorly. During the short, unpredictable periods in which he is awake, he is usually irritable.

The appearance and behavior of preterm babies can lead parents to be less sensitive and responsive in caring for them. Compared to full-term infants, preterm babies—especially those who are very ill at birth—are less often held close, touched, and talked to gently. At times, mothers of these infants resort to interfering pokes and verbal commands, in an effort to obtain a higher level of response from the baby (Barratt, Roach, & Leavitt, 1996; Feldman, 2007c). This may explain why preterm babies as a group are at risk for child abuse.

Research reveals that distressed, emotionally reactive preterm infants are especially susceptible to the effects of parenting quality: Among a sample of preterm 9-month-olds, the combination of infant negativity and angry or intrusive parenting yielded the highest rates of behavior problems at 2 years of age. But with warm, sensitive parenting, distressed preterm babies' rates of behavior problems were the lowest (Poehlmann et al., 2011). When preterm infants are born to isolated, poverty-stricken mothers who cannot provide good nutrition, health care, and parenting, the likelihood of unfavorable outcomes escalates. In contrast, parents with stable life circumstances and social supports usually can overcome the stresses of caring for a preterm infant. In these cases, even sick preterm babies have a good chance of catching up in development by middle childhood (Ment et al., 2003).

These findings indicate that how well preterm infants fare has a great deal to do with the parent–child relationship. Consequently, interventions directed at supporting both sides of this tie are more likely to help these infants recover.

Interventions for Preterm Infants

A preterm baby is cared for in a special Plexiglas-enclosed bed called an *isolette*. Temperature is carefully controlled because these infants cannot yet regulate their own body temperature effectively. To help protect the baby from infection, air is filtered before it enters the isolette. When a preterm infant is fed through a stomach tube, breathes with the aid of a respirator, and receives medication through an intravenous needle, the isolette can be very isolating indeed! Physical needs that otherwise would lead to close contact and other human stimulation are met mechanically.

Special Infant Stimulation. In proper doses, certain kinds of stimulation can help preterm infants develop. In some intensive care nurseries, preterm babies can be seen rocking in suspended hammocks or lying on waterbeds designed to replace the gentle motion they would have received while still in the mother's uterus. Other forms of stimulation have also been used—an attractive mobile or a tape recording of a heartbeat, soft music, or the mother's voice. These experiences promote faster weight gain, more predictable sleep patterns, and greater alertness (Arnon et al., 2006; Marshall-Baker, Lickliter, & Cooper, 1998; Standley, 1998).

Touch is an especially important form of stimulation. In baby animals, touching the skin releases certain brain chemicals that support physical growth—effects believed to occur in humans as well. When preterm infants were massaged several times each day in the hospital, they gained weight faster and, at the end of the first year, were more advanced in mental and motor development than preterm infants not given this stimulation (Field, 2001; Field, Hernandez-Reif, & Freedman, 2004).

In developing countries where hospitalization is not always possible, skin-to-skin "kangaroo care" is the most readily available intervention for promoting the survival and recovery of preterm babies. It involves placing the infant in a vertical position between the mother's breasts or next to the father's chest (under the parent's clothing) so the parent's body functions as a human incubator. Kangaroo care offers fathers a unique opportunity to increase their involvement in caring for the preterm newborn. Because of its many physical and psychological benefits, the technique is often used in Western nations as a supplement to hospital intensive care.

Kangaroo skin-to-skin contact fosters improved oxygenation of the baby's body, temperature regulation, sleep, breastfeeding, alertness, and infant survival (Feldman, 2007b; Lawn et al., 2010). In addition, the kangaroo position provides the baby with gentle stimulation of all sensory modalities: hearing (through the parent's voice), smell (through proximity to the parent's body), touch (through skin-to-skin contact), and visual (through the upright position). Mothers and fathers practicing kangaroo care feel more confident about caring for their fragile babies, interact more sensitively and affectionately, and feel more attached to them (Dodd, 2005; Feldman et al., 2002, 2003).

Together, these factors may explain why preterm babies given many hours of kangaroo care in their early weeks, compared to those given little or no such care, are more likely to explore novel toys and also score higher on measures of mental and motor development during the first year (Charpak, Ruiz-Peláez, & Figueroa, 2005; Feldman, 2007b; Tessier et al., 2003). Because of its diverse benefits, more than 80 percent of U.S. hospital nurseries now offer kangaroo care to preterm newborns (Field et al., 2006).

In Western nations, kangaroo care is used as a supplement to hospital intensive care. *Bottom photo:* A U.S. mother engages in the technique with her fragile newborn.

Training Parents in Infant Caregiving Skills. Interventions that support parents of preterm infants generally teach them about the infant's characteristics and promote caregiving skills. For parents with adequate economic and personal resources to care for a preterm infant, just a few sessions of coaching in recognizing and responding to the baby's needs are linked to enhanced parent–infant interaction, reduced infant crying and improved sleep, more rapid language development in the second year, and steady gains in mental test scores that equal those of full-term children by middle childhood (Achenbach, Howell, & Aoki, 1993; Newnham, Milgrom, & Skouteris, 2009).

When preterm infants live in stressed, low-income households, long-term intensive intervention is necessary. In the Infant Health and Development Project, preterm babies born into poverty received a comprehensive intervention that combined medical follow-up, weekly parent training sessions, and cognitively stimulating child care from 1 to 3 years of age. More than four times as many intervention children as no-intervention controls (39 versus 9 percent) were within normal range at age 3 in intelligence, psychological adjustment, and physical growth (Bradley et al., 1994). In addition, mothers in the intervention group were more affectionate and more often encouraged play and cognitive mastery in their children—one reason their 3-year-olds may have been developing so favorably (McCarton, 1998).

At ages 5 and 8, children who had attended the child-care program regularly—for more than 350 days over the three-year period—continued to show better intellectual functioning. The more they attended, the higher they scored, with greater gains among those whose birth weights were higher (see Figure 3.13). In contrast, children who attended only sporadically gained little or even lost ground (Hill, Brooks-Gunn, & Waldfogel, 2003). In a follow-up at age 18, the higher-birth-weight participants remained advantaged over controls in academic achievement. They also engaged in fewer risky behaviors, such as unprotected sexual activity and alcohol and drug use (McCormick et al., 2006).

These findings confirm that babies who are both preterm and economically disadvantaged require *intensive* intervention. And special strategies, such as extra adult–child interaction, may be necessary to achieve lasting changes in children with the lowest birth weights.

Very Low Birth Weight, Environmental Advantages, and Long-Term Outcomes

Although very low-birth-weight babies often have lasting problems, in a Canadian study, young adults who had weighed between 1 and 2.2 pounds (500 to 1,000 grams) at birth were doing well in overall quality of life (Saigal et al., 2006). At 22 to 25 years of age, they resembled normal-birth-weight individuals in educational attainment, rates of marriage and parenthood, and (for those who had no neurological or sensory impairments) employment status. Researchers believe that home, school, and societal advantages combine to explain these excellent outcomes (Hack & Klein, 2006). Most participants in this study were reared in two-parent middle-class homes, attended good schools where they received special services, and benefited from Canada's universal health-care system.

But even the best environments cannot "fix" the enormous biological risks associated with very low birth weight. A better course of action would be to prevent this serious threat to infant survival and development. The high rate of underweight babies in the United States—one of the worst in the industrialized world—could be greatly reduced by improving the health and social conditions described in the Social Issues: Health box on pages 118–119.

Birth Complications, Parenting, and Resilience

In the preceding sections, we considered a variety of birth complications. Now let's try to put the evidence together. Can any general principles help us understand how infants who survive a traumatic birth are likely to develop? A landmark study carried out in Hawaii provides some answers.

In 1955, Emmy Werner began to follow the development of nearly 700 infants on the island of Kauai who had experienced mild, moderate, or severe birth complications. Each was matched, on the basis of family economic status and ethnicity, with a healthy newborn (Werner & Smith, 1982). Findings showed that the likelihood of long-term difficulties increased if birth trauma was severe. But among mildly to moderately stressed children, those growing up in stable families did almost as well on measures of intelligence and psychological adjustment as those with no birth problems. Those exposed to poverty, family disorganization, and mentally ill parents often developed serious learning difficulties, behavior problems, and emotional disturbance.

The Kauai study tells us that as long as birth injuries are not overwhelming, a supportive home environment can restore children's growth. But the most intriguing cases in this study were the handful of exceptions. A few children with fairly serious birth complications and troubled family environments grew into competent adults who fared as well as controls in career attainment and psychological adjustment. Werner found that these children relied on factors outside the family and within themselves to overcome stress. Some had attractive personalities that drew positive responses from relatives, neighbors, and peers. In other instances, a grandparent, aunt, uncle, or babysitter provided the needed emotional support (Werner, 1989; Werner & Smith, 1992, 2001).

Do these outcomes remind you of the characteristics of resilient children, discussed in Chapter 1? The Kauai study and other similar investigations reveal that the impact of early biological risks often wanes as children's personal characteristics and social experiences contribute increasingly to their functioning (Laucht, Esser, & Schmidt, 1997; Resnick et al., 1999). In sum, when the overall balance of life events tips toward the favorable side, children with serious birth problems can develop successfully. And when negative factors outweigh positive ones, even a sturdy newborn can become a lifelong casualty.

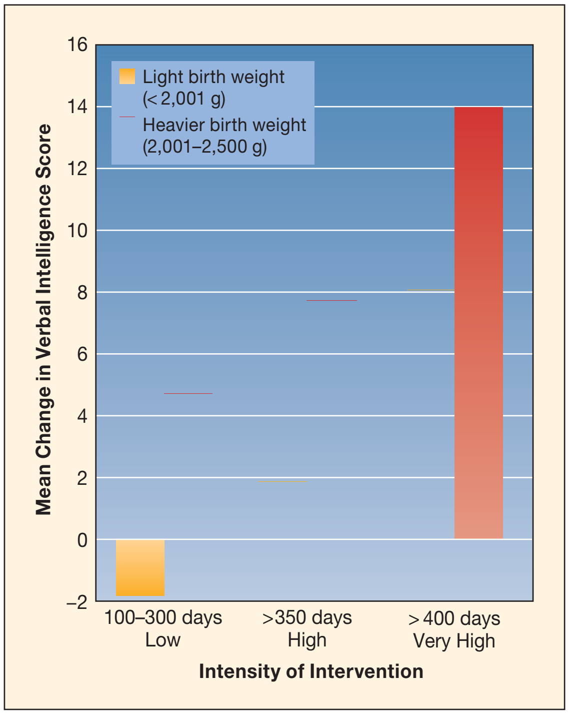

FIGURE 3.13 Influence of intensity of early intervention for low-income, preterm babies on intellectual functioning at age 8. Infants born preterm received cognitively stimulating child care from 1 through 3 years of age. Those who attended the program sporadically gained little in intellectual functioning (heavier-weight babies) or lost ground (lighter-weight babies). The more often children attended, the greater their intellectual gains. Heavier babies consistently gained more than lighter babies. But boosting the intensity of intervention above 400 days led to a dramatic increase in the performance of the light-weight group. (Adapted from Hill, Brooks-Gunn, & Waldfogel, 2003.)

ASK YOURSELF

Review ■ Sensitive care can help preterm infants recover, but they are less likely than full-term newborns to receive such care. Explain why.

Connect ■ List factors discussed in this chapter that increase the chances that an infant will be born underweight. How many of these factors could be prevented by better health care for expectant mothers and babies?

Apply ■ Cecilia and Adena each gave birth to a 3-pound baby seven weeks preterm. Cecilia is single and poverty-stricken. Adena and her partner are happily married and earn a good income. Plan an intervention appropriate for helping each baby develop.

Reflect ■ Many people object to the use of extraordinary medical measures to save extremely low-birth-weight babies because of their high risk of developing serious physical, cognitive, and emotional problems. Do you agree or disagree? Explain.

SOCIAL ISSUES: HEALTH

A Cross-National Perspective on Health Care and Other Policies for Parents and Newborn Babies

© KAREN PULFER FOCHT/THE COMMERCIAL APPEAL/LANDOV

This doctor in Memphis, Tennessee, works with high-risk pregnancies, delivering babies whose poverty-stricken mothers have had little or no prenatal care. Nations that provide government-sponsored health-care benefits for all citizens outrank the United States in infant survival.

Infant mortality—the number of deaths in the first year of life per 1,000 live births—is an index used around the world to assess the overall health of a nation's children. Although the United States has the most up-to-date health-care technology in the world, it has made less progress in reducing infant deaths than many other countries. Over the past three decades, it has slipped in the international rankings, from seventh in the 1950s to twenty-eighth in 2011. Members of America's poor ethnic minorities are at greatest risk. African-American and Native-American babies are twice as likely as white infants to die in the first year of life (U.S. Census Bureau, 2011a, 2011b).

Neonatal mortality, the rate of death within the first month of life, accounts for 67 percent of the infant death rate in the United States. Two factors are largely responsible for neonatal mortality. The first is serious physical defects, most of which cannot be prevented. The percentage of babies born with physical defects is about the same in all ethnic and income groups. The second leading cause of neonatal mortality is low birth weight, which is largely preventable. African-American and Native-American babies are more than twice as likely as white infants to be born early and underweight (U.S. Census Bureau, 2011b).

Widespread poverty and weak health-care programs for mothers and young children are largely responsible for these trends. Unfortunately, 8 percent of pregnant women in the United States wait until after the first trimester to seek prenatal care or receive none at all. More than 10 percent of low-income minority mothers, and nearly 30 percent of adolescent mothers, receive inadequate prenatal care (Hueston, Geesey, & Diaz, 2008; U.S. Department of Health and Human Services, 2010a). Many of these mothers lack health insurance, and although the poorest are eligible for government-sponsored health services, many other low-income women do not qualify.

Besides financial hardship, some mothers have other reasons for not seeking early prenatal care. These include both *situational barriers* (difficulty finding a doctor, getting an appointment, and arranging transportation, and insensitive or unsatisfying experiences with clinic staff) and *personal barriers* (psychological stress, the demands of caring for other young children, family crises, lack of knowledge about signs of pregnancy and benefits of prenatal care, and ambivalence about the pregnancy). Many also engage in high-risk behaviors, such as smoking and drug abuse, which they do not want to reveal to health professionals (Maupin et al., 2004).

Each country listed in Figure 3.14 that outranks the United States in infant survival provides all its citizens with government-sponsored health-care benefits. And each takes extra steps to make sure that pregnant mothers and babies have access to good nutrition, high-quality medical care, and social and economic supports that promote effective parenting.

For example, all Western European nations guarantee women a certain number of prenatal visits at very low or no cost. After a baby is born, a health professional routinely visits the home to provide counseling about infant care and to arrange continuing medical services. Home assistance is especially extensive in the Netherlands. For a token fee, each mother is granted a specially trained maternity helper, who assists with infant care, shopping, housekeeping, meal preparation, and the care of other children during the days after delivery (Zwart, 2007).

Paid, job-protected employment leave is another vital societal intervention for new parents. Canadian mothers are eligible for 15 weeks' maternity leave at 55 percent of prior earnings (up to a maximum of $413 per week), and Canadian mothers or fathers can take an additional 35 weeks of parental leave at the same rate. Paid leave is widely available in other industrial-

- Explain the various ways heredity and environment may combine to influence complex traits.

Heredity, Environment, and Behavior: A Look Ahead

Throughout this chapter, we have discussed a wide variety of genetic and early environmental influences, each of which has the power to alter the course of development. When we consider them together, it may seem surprising that any newborn babies arrive intact. Yet the vast majority—over 90 percent in North America—do. These developing members of the human species, even those born into the same family—and who therefore share both genes ized nations as well. Sweden has the most generous parental leave program in the world. Mothers can begin maternity leave 60 days prior to expected delivery, extending it to six weeks after birth; fathers are granted two weeks of birth leave. In addition, either parent can take full leave for 16 months at 80 percent of prior earnings, followed by an additional three months at a modest flat rate. Each parent is also entitled to another 18 months of unpaid leave. Furthermore, many countries supplement basic paid leave. In Germany, for example, after a fully paid three-month leave, a parent may take one more year at a flat rate and three additional years at no pay (OECD, 2006; Waldfogel, 2001).

Yet in the United States, the federal government mandates *only 12 weeks of unpaid leave* for employees in companies with at least 50 workers. Most women, however, work in smaller businesses, and many of those who work in large enough companies cannot afford to take this much unpaid leave (Hewlett, 2003). Similarly, though paternal leave predicts fathers' increased involvement in infant care at the end of the first year, many fathers take little or none at all (Nepomnyaschy & Waldfogel, 2007; OECD, 2006). In 2002, California became the first state to guarantee a mother or father paid leave—up to six weeks at half salary, regardless of the size of the company. Since then, Hawaii, New Jersey, New York, Rhode Island, and the territory of Puerto Rico have passed similar legislation.

Nevertheless, six weeks of childbirth leave (the norm in the United States) is not enough. When a family is stressed by a baby's arrival, leaves of six weeks or less are linked to increased maternal anxiety, depression, conflict between work and family responsibilities, and negative interactions with the baby. A longer leave (12 weeks or more) predicts favorable maternal mental health, supportive marital interaction, and sensitive caregiving (Feldman, Sussman, & Zigler, 2004; Hyde et al., 2001). Single women and their babies are most hurt by the absence of a generous national paid-leave policy. These mothers, who are usually the sole source of support for their families, can least afford to take time from their jobs.

In countries with low infant mortality rates, expectant mothers need not wonder how or where they will get health care and other resources to support their baby's development. The powerful impact of universal, high-quality health care, generous parental leave, and other social services on maternal and infant well-being provides strong justification for these policies.

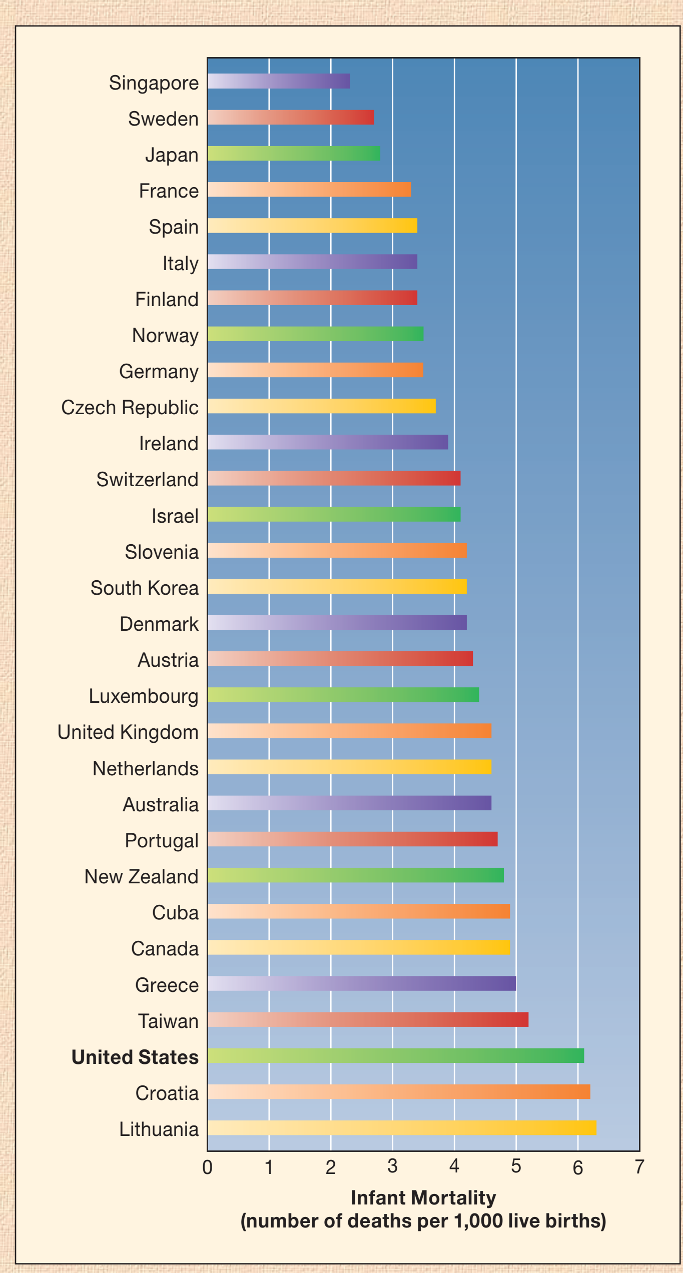

FIGURE 3.14 **Infant mortality in 30 nations.** Despite its advanced health-care technology, the United States ranks poorly. It is twenty-eighth in the world, with a death rate of 6.1 infants per 1,000 births. (Adapted from U.S. Census Bureau, 2011a.)

and environment—vary greatly in characteristics. We also know that some are affected more than others by their homes, neighborhoods, and communities. How do scientists explain the impact of heredity and environment when they seem to work in so many different ways?

Behavioral genetics is a field devoted to uncovering the contributions of nature and nurture to this diversity in human traits and abilities. All contemporary researchers agree that both heredity and environment are involved in every aspect of development. But for polygenic traits (those due to many genes) such as intelligence and personality, scientists are a long way from knowing the precise hereditary influences involved. Although they are making progress in identifying variations in DNA sequences associated with complex traits, so far these genetic markers explain only a small amount of variation in human behavior, and a minority of cases of most psychological disorders (Plomin, 2005; Plomin & Davis, 2009). For the most part, scientists are still limited to investigating the impact of genes on complex characteristics indirectly.

Some believe that it is useful and possible to answer the question of *how much each factor contributes* to differences among children. A growing consensus, however, regards that question as unanswerable. These investigators believe that heredity and environment are inseparable (Gottlieb, Wahlsten, & Lickliter, 2006; Lerner & Overton, 2008). The important question, they maintain, is *how nature and nurture work together*. Let's consider each position in turn.

The Question, "How Much?"

To infer the role of heredity in complex human characteristics, researchers use special methods. The most common is the *heritability estimate*. Let's look closely at the information this procedure yields, along with its limitations.

Heritability

Heritability estimates measure the extent to which individual differences in complex traits in a specific population are due to genetic factors. We will take a brief look at heritability findings on intelligence and personality here and will return to them in later chapters, when we consider these topics in greater detail. Heritability estimates are obtained from **kinship studies,** which compare the characteristics of family members. The most common type of kinship study compares identical twins, who share all their genes, with fraternal twins, who share only some. If people who are genetically more alike are also more similar in intelligence and personality, then the researcher assumes that heredity plays an important role.

Kinship studies of intelligence provide some of the most controversial findings in the field of child development. Some experts claim a strong genetic influence, whereas others believe that heredity is barely involved. Currently, most kinship findings support a moderate role for heredity. When many twin studies are examined, correlations between the scores of identical twins are consistently higher than those of fraternal twins. In a summary of more than 10,000 twin pairs, the correlation for intelligence was .86 for identical twins and .60 for fraternal twins (Plomin & Spinath, 2004).

Researchers use a complex statistical procedure to compare these correlations, arriving at a heritability estimate ranging from 0 to 1.00. The value for intelligence is about .50 for child and adolescent twin samples in Western industrialized nations. This suggests that differences in genetic makeup explain half the variation in intelligence. Adopted children's mental test scores are more strongly related to their biological parents' scores than to those of their adoptive parents, offering further support for the role of heredity (Petrill & Deater-Deckard, 2004).

Heritability research also reveals that genetic factors are important in personality. For frequently studied traits, such as sociability, anxiety, agreeableness, and activity level, heritability estimates obtained on child, adolescent, and young adult twins are moderate, in the .40s and .50s (Caspi & Shiner, 2006; Rothbart & Bates, 2006; Wright et al., 2008).

Twin studies of schizophrenia—a psychological disorder involving delusions and hallucinations, difficulty distinguishing fantasy from reality, and irrational and inappropriate behaviors—consistently yield high heritabilities, around .80. The role of heredity in antisocial behavior and major depression, though still apparent, is less strong, with heritabilities in the .30s and .40s (Faraone, 2008). Again, adoption studies support these results. Biological relatives of schizophrenic and depressed adoptees are more likely than adoptive relatives to share the same disorder (Plomin et al., 2001; Ridenour, 2000; Tienari et al., 2003).

© JACQUIE HEMMERDINGER/THE NEW YORK TIMES/REDUX

Adriana and Tamara, identical twins separated at birth by adoption, were unaware of each other's existence. When they met at age 20, they discovered many similarities—academic achievement, love of dancing, and even taste in clothing. Clearly, heredity contributes to psychological characteristics. Nevertheless, generalizing from twin evidence to the population is controversial.

Limitations of Heritability The accuracy of heritability estimates depends on the extent to which the twin pairs studied reflect genetic and environmental variation in the population. Within a population in which all people have very similar home, school, and community experiences, individual differences in intelligence and personality would be largely genetic, and heritability estimates would be close to 1.00. Conversely, the more environments vary, the more likely they are to account for individual differences, yielding lower heritability estimates. In twin studies, most twin pairs are reared together under highly similar conditions. Even when separated twins are available for study, social service agencies have often placed them in advantaged homes that are alike in many ways (Rutter et al., 2001). Because the environments of most twin pairs are less diverse than those of the general population, heritability estimates are likely to exaggerate the role of heredity.

Heritability estimates are controversial measures because they can easily be misapplied. For example, high heritabilities have been used to suggest that ethnic differences in intelligence, such as the poorer performance of black children compared to white children, have a genetic basis (Jensen, 1969, 1985, 1998; Rushton & Jensen, 2005, 2006). Yet this line of reasoning is widely regarded as incorrect. Heritabilities computed on mostly white twin samples do not tell us what causes test score differences between ethnic groups. We have already seen that large economic and cultural differences are involved. In Chapter 8, we will discuss research indicating that when black children are adopted into economically advantaged homes at an early age, their mental test scores are well above average and substantially higher than those of children growing up in impoverished families.

Perhaps the most serious criticism of heritability estimates has to do with their limited usefulness. They give us no precise information on how intelligence and personality develop or how children might respond to environments designed to help them develop as far as possible (Baltes, Lindenberger, & Staudinger, 2006). Indeed, the heritability of children's intelligence increases as parental education and income increase—that is, as children grow up in conditions that allow them to make the most of their genetic endowment. In impoverished environments, children are prevented from realizing their potential. Consequently, enhancing their experiences through interventions, such as increasing parent education and income and providing high-quality preschool or child care, has a greater impact on the development of economically disadvantaged than advantaged children (Bronfenbrenner & Morris, 2006; Turkheimer et al., 2003).

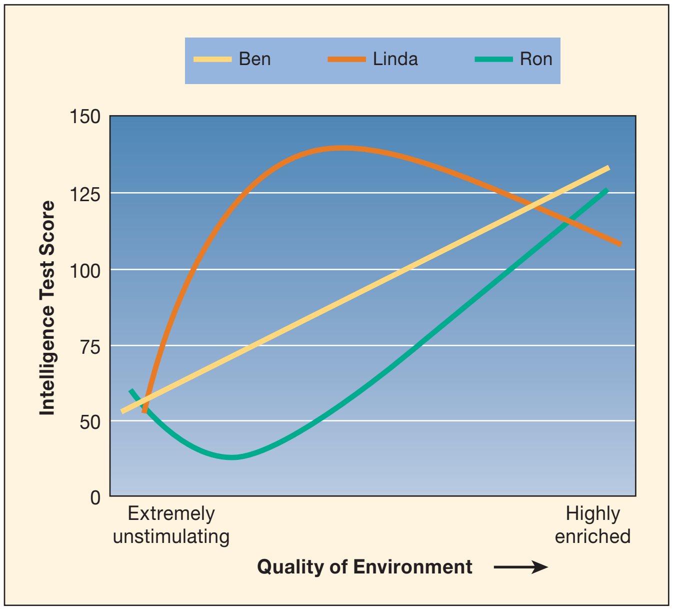
In sum, although heritability estimates confirm that heredity contributes to a broad array of complex traits, they tell us nothing about how environment can modify genetic influences. Still, scientists often rely on positive heritabilities before initiating more costly molecular analyses in search of specific genes that contribute to personality traits and disorders.

The Question, "How?"

Today, most researchers view development as the result of a dynamic interplay between heredity and environment. How do nature and nurture work together? Several concepts shed light on this question.

Gene–Environment Interaction The first of these ideas is **gene–environment interaction,** which means that because of their genetic makeup, individuals differ in their responsiveness to qualities of the environment (Rutter, 2011). In other words, children have unique, genetically influenced reactions to particular experiences. Let's explore this idea in Figure 3.15. Gene–environment interaction can apply to any characteristic; here it is illustrated for intelligence. Notice that when environments vary from extremely unstimulating to highly enriched, Ben's intelligence test score increases steadily, Linda's rises sharply and then falls off, and Ron responds only after the environment becomes modestly stimulating.

FIGURE 3.15 **Gene–environment interaction, illustrated for intelligence by three children who differ in responsiveness to quality of the environment.** As environments vary from extremely unstimulating to highly enriched, Ben's intelligence test score increases steadily, Linda's rises sharply and then falls off, and Ron's begins to increase only after the environment becomes modestly stimulating.



Gene–environment interaction highlights two important points. First, it shows that because each of us has a unique genetic makeup, we respond differently to the same environment. Notice in Figure 3.16 how a poor environment results in similarly low scores for all three individuals. But when the environment provides a moderate level of stimulation, Linda is by far the best-performing child. And in a highly enriched environment, Ben does best, followed by Ron, both of whom now outperform Linda. Second, sometimes different gene–environment combinations can make two children look the same! For example, if Linda is reared in a minimally stimulating environment, her score will be about 100—average for children in general. Ben and Ron can also obtain this score, but to do so, they must grow up in a fairly enriched home (Gottlieb, Wahlsten, & Lickliter, 2006).

Recently, researchers have made strides in identifying gene–environment interactions in personality development. Recall the finding reported on page 115—that distressed, emotionally negative preterm infants are more responsive than other babies to both inept and good parenting. Similarly, in Chapter 10 we will see that young children with a gene that increases their risk of an emotionally reactive temperament respond especially strongly to variations in parenting quality (Pluess & Belsky, 2011). When parenting is favorable, they gain control over their emotions and adjust as well or better than other children. But when parenting is unfavorable, they become increasingly irritable, difficult, and poorly adjusted, more so than children not at genetic risk.

Canalization

Another way of understanding how heredity and environment combine comes from the concept of **canalization**—the tendency of heredity to restrict the development of some characteristics to just one or a few outcomes. A behavior that is strongly canalized develops similarly in a wide range of environments; only strong environmental forces can change it (Waddington, 1957). For example, infant perceptual and motor development seems to be strongly canalized because all normal human babies eventually roll over, reach for objects, sit up, crawl, and walk. It takes extreme conditions to modify these behaviors or cause them not to appear. In contrast, intelligence and personality are less strongly canalized; they vary much more with changes in the environment.

When we look at behaviors constrained by heredity, we can see that canalization is highly adaptive. Through it, nature ensures that children will develop certain species-typical skills under a wide range of rearing conditions, thereby promoting survival.

© LOU CYPHER/CORBIS

This mother shares her love of the piano with her daughter, who also may have inherited her mother's musical talent. When heredity and environment are correlated, the influence of one cannot be separated from the influence of the other.

Gene–Environment Correlation

A major problem in trying to separate heredity and environment is that they are often correlated (Rutter, 2011; Scarr & McCartney, 1983). According to the concept of **gene–environment correlation,** our genes influence the environments to which we are exposed. The way this happens changes with age.

Passive and Evocative Correlation. At younger ages, two types of gene–environmental correlation are common. The first is called passive correlation because the child has no control over it. Early on, parents provide environments influenced by their own heredity. For example, parents who are good athletes emphasize outdoor activities and enroll their children in swimming and gymnastics. Besides being exposed to an "athletic environment," the children may have inherited their parents' athletic ability. As a result, they are likely to become good athletes for both genetic and environmental reasons.

The second type of gene–environment correlation is *evocative*. The responses children evoke from others are influenced by the child's heredity, and these responses strengthen the child's original style. For example, an active, friendly baby is likely to receive more social stimulation than a passive, quiet infant. And a cooperative, attentive child probably receives more patient and sensitive interactions from parents than an inattentive, distractible child. In support of this idea, the less genetically alike siblings are, the more their parents treat them differently, in both warmth and negativity. Thus, parents' treatment of identical twins is highly similar, whereas their treatment of fraternal twins and nontwin biological siblings is only moderately so. And little resemblance exists in parents' warm and negative interactions with unrelated stepsiblings (see Figure 3.16) (Reiss, 2003).

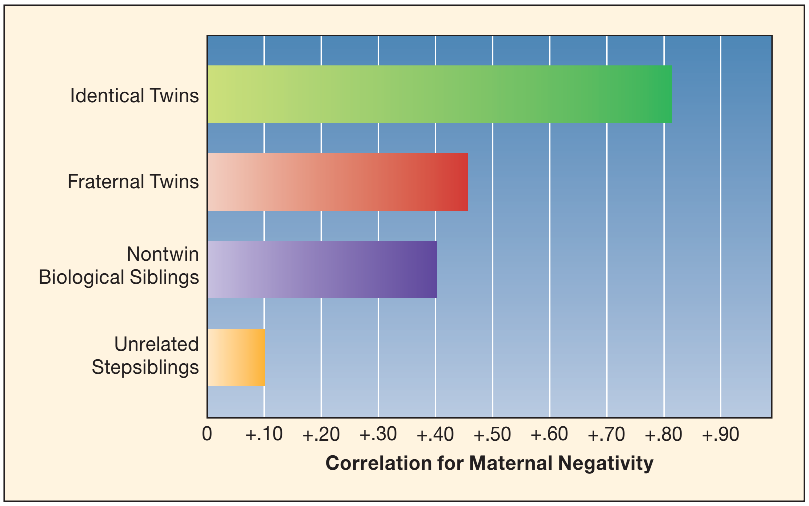


FIGURE 3.16 **Similarity in mothers' interactions for pairs of siblings differing in genetic relatedness.** The correlations shown are for maternal negativity. The pattern illustrates evocative genetic–environmental correlation. Identical twins evoke similar maternal treatment because of their identical heredity. As genetic resemblance between siblings declines, the strength of the correlation drops. Mothers vary their interactions as they respond to each child's unique genetic makeup. (Adapted from Reiss, 2003.)

Active Correlation. In older children, *active* gene–environment correlation becomes common. As children extend their experiences beyond the immediate family and are given the freedom to make more choices, they actively seek environments that fit with their genetic tendencies. The well-coordinated, muscular child spends more time at after-school sports, the musically talented youngster joins the school orchestra and practices his violin, and the intellectually curious child is a familiar patron at her local library.

This tendency to actively choose environments that complement our heredity is called **niche-picking** (Scarr & McCartney, 1983). Infants and young children cannot do much niche-picking because adults select environments for them. In contrast, older children and adolescents are much more in charge of their environments.

Niche-picking explains why pairs of identical twins reared apart during childhood and later reunited may find, to their surprise, that they have similar hobbies, food preferences, and vocations—a trend that is especially marked when twins' environmental opportunities are similar (Plomin, 1994). Niche-picking also helps us understand why identical twins become somewhat more alike, and fraternal twins and adopted siblings less alike, in intelligence with age (Bouchard, 2004; Loehlin, Horn, & Willerman, 1997). And niche-picking sheds light on why adolescent identical twin pairs—far more often than same-sex fraternal pairs, ordinary siblings, or adopted siblings—report similar stressful life events influenced by personal decisions and actions, such as failing a course, quitting a job, or getting in trouble for drug-taking (Bemmels et al., 2008).

The influence of heredity and environment is not constant but changes over time. With age, genetic factors may become more important in influencing the environments we experience and choose for ourselves.

Environmental Influences on Gene Expression

Notice how, in the concepts just considered, heredity is granted priority. In gene–environment interaction, it affects responsiveness to particular environments. In canalization, it *restricts* the development of certain behaviors. Similarly, gene–environmental correlation is viewed as *driven* by genetics, in that children's genetic makeup causes them to receive, evoke, or seek experiences that actualize their hereditary tendencies (Plomin, 2009; Rutter, 2011).

A growing number of researchers take issue with the supremacy of heredity, arguing that it does not dictate children's experiences or development in a rigid way. In one study, boys with a genetic tendency toward antisocial behavior (based on the presence of a gene on the X chromosome known to predispose both animals and humans to aggression) were no more aggressive than boys without this gene, *unless* they also had a history of severe child abuse (Caspi et al., 2002). Boys with and without the gene did not differ in their experience of abuse, indicating that the "aggressive genotype" did not increase exposure to abuse. And in a large Finnish adoption study, children of schizophrenic mothers reared by healthy adoptive parents showed little mental illness—no more than a control group with healthy biological and adoptive parents. In contrast, schizophrenia and other psychological impairments piled up in adoptees whose biological and adoptive parents were both disturbed (Tienari et al., 2003; Tienari, Wahlberg, & Wynne, 2006).

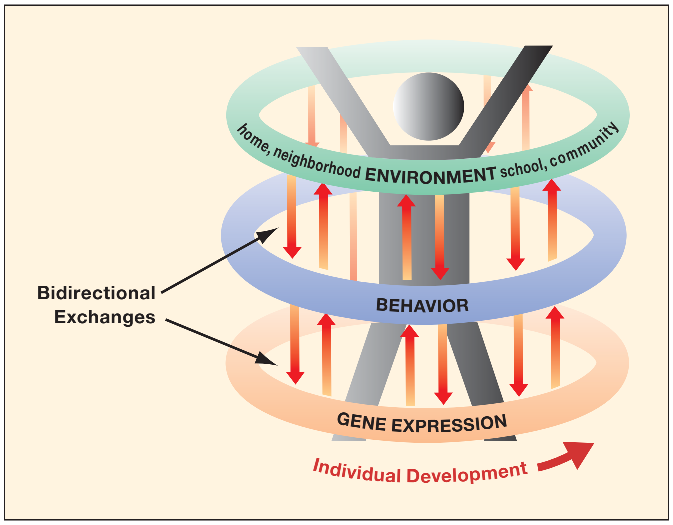

FIGURE 3.17 **The epigenetic framework.** Development takes place through ongoing, bidirectional exchanges between heredity and all levels of the environment. Genes affect behavior and experiences. Experiences and behavior also affect gene expression. (Adapted from Gottlieb, 2007.)

Furthermore, parents and other caring adults can uncouple adverse gene–environment correlations. They often provide children with positive experiences that modify the expression of heredity, yielding favorable outcomes. For example, in a study that tracked the development of 5-year-old identical twins, pair members resembled each other in aggression. And the more aggression they displayed, the more maternal anger and criticism they received (a gene–environment correlation). Nevertheless, some mothers treated their twins differently. When followed up at age 7, twins who had been targets of more maternal negativity engaged in even more antisocial behavior. In contrast, their better-treated, genetically identical counterparts showed a reduction in disruptive acts (Caspi et al., 2004). Good parenting protected them from a spiraling, antisocial course of development.

Accumulating evidence reveals that the relationship between heredity and environment is not a one-way street, from genes to environment to behavior. Rather, like other system influences considered in this and the previous chapter, it is *bidirectional:* Genes affect children's behavior and experiences, but their experiences and behavior also affect gene expression (Diamond, 2009; Gottlieb, 2003; Rutter, 2007). Stimulation—both *internal* to the child (activity within the cytoplasm of the cell, release of hormones into the bloodstream) and *external* to the child (home, neighborhood, school, and society)—modifies gene activity.

Researchers call this view of the relationship between heredity and environment the *epigenetic framework* (Gottlieb, 1998, 2007). It is depicted in Figure 3.17. **Epigenesis** means development resulting from ongoing, bidirectional exchanges between heredity and all levels of the environment. To illustrate, providing a baby with a healthy diet increases brain growth, which translates into new connections between nerve cells, which transform gene expression. This opens the door to new gene–environment exchanges—for example, advanced exploration of objects and interaction with caregivers, which further enhance brain growth and gene expression. These ongoing, bidirectional influences foster cognitive and social development. In contrast, harmful environments can negatively affect gene expression (see the Biology and Environment box on the following page for an example). And at times, the impact is so profound that later experiences can do little to change characteristics (such as intelligence and personality) that originally were flexible.

A major reason that researchers are interested in the nature–nurture issue is that they want to improve environments so that children can develop as far as possible. The concept of epigenesis reminds us that development is best understood as a series of complex exchanges between nature and nurture. Although children cannot be changed in any way we might desire, environments can modify genetic influences. The success of any attempt to improve development depends on the characteristics we want to change, the genetic makeup of the child, and the type and timing of our intervention.

ASK YOURSELF

Review ■ What is epigenesis, and how does it differ from gene–environment interaction and gene–environment correlation? Provide an example of each.

Connect ■ Explain how each of the following concepts supports the conclusion that genetic influences on human characteristics are not constant but change over time: somatic mutation (page 81), niche-picking (page 123), and epigenesis (page 124).

Apply ■ Bianca's parents are accomplished musicians. At age 4, Bianca began taking piano lessons. By age 10, she was accompanying the school choir. At age 14, she asked if she could attend a special music high school. Explain how gene–environment correlation promoted Bianca's talent.

Reflect ■ What aspects of your own development—for example, interests, hobbies, college major, or vocational choice—are probably due to niche-picking? Explain.

BIOLOGY and ENVIRONMENT

A Case of Epigenesis: Smoking During Pregnancy Alters Gene Expression

A wealth of experimental research with animals confirms that environment can modify the genome in ways that have no impact on a gene's sequence of base pairs but nevertheless affect the operation of that gene (Zhang & Meaney, 2010). This epigenetic interplay, in which a gene's impact on the individual's phenotype depends on the gene's context, is now being vigorously investigated in humans.

Maternal smoking during pregnancy is among the risk factors for *attention-deficit hyperactivity disorder (ADHD)*—one of the most common disorders of childhood, which we will take up in greater detail in Chapter 7. ADHD symptoms—inattention, impulsivity, and overactivity—typically result in serious academic and social problems. Some studies report that individuals who are homozygous for a chromosome-5 gene (DD) containing a special repeat of base pairs are at increased risk for ADHD, though other research has not confirmed any role for this gene (Fisher et al., 2002; Gill et al., 1997; Waldman et al., 1998).

Animal evidence suggests that one reason for this inconsistency may be that environmental influences associated with ADHD—such as prenatal exposure to toxins—modify the gene's activity. To test this possibility, researchers recruited several hundred mothers and their 6-month-old babies, obtaining infant blood samples for molecular genetic analysis and asking mothers whether they smoked regularly during pregnancy (Kahn et al., 2003). At a 5-year follow-up, parents responded to a widely used behavior rating scale that assesses children for ADHD symptoms.

Findings revealed that by itself, the DD genotype was unrelated to impulsivity, overactivity, or oppositional behavior. But children whose mothers had smoked during pregnancy scored higher in these behaviors than children of nonsmoking mothers. Furthermore, as Figure 3.19 shows, 5-year-olds with both prenatal nicotine exposure and the DD genotype obtained substantially higher impulsivity, overactivity, and oppositional scores than all other groups—outcomes that persisted even after a variety of other factors (quality of the home environment and maternal ethnicity, marital status, and post-birth smoking) had been controlled.

Another investigation following participants into adolescence obtained similar findings, suggesting that the epigenetic effect persists (Becker et al., 2008). What processes might account for it? In animal research, tobacco smoke stimulates the DD genotype to release chemicals in the brain that that promote impulsivity and overactivity (Ernst, Moolchan, & Robinson, 2001). These behaviors, in turn, often evoke harsh, punitive parenting, which can trigger defiance in children.

The DD genotype is widespread, present in more than 50 percent of people. Thus, the majority of children prenatally exposed to nicotine are at high risk for learning and behavior problems (refer to page 98). Growing evidence indicates that other genes, in epigenetic interplay with as yet unknown environmental factors, also contribute to ADHD symptoms (Hudziak & Rettew, 2009).

© IMAGE SOURCE/GETTY IMAGES

Because his mother smoked during pregnancy, this baby may be at risk for attention-deficit hyperactivity disorder (ADHD). Prenatal nicotine exposure seems to alter expression of a chromosome-5 gene in ways that greatly heighten impulsivity, overactivity, and oppositional behavior.

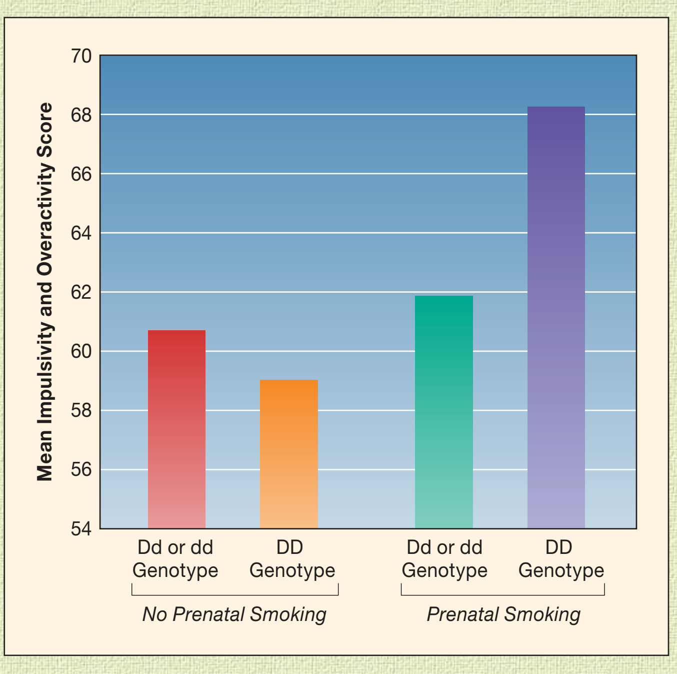

FIGURE 3.18 Combined influence of maternal prenatal smoking and genotype on impulsivity and overactivity at age 5. In the absence of prenatal smoking, 5-year-olds who were homozygous for a chromosome-5 gene (DD) showed no elevation in impulsivity and overactivity (orange bar) compared with children of other genotypes (Dd or dd) (red bar). Among children of all genotypes, prenatal smoking was associated with an increase in these behaviors (green and purple bars). And the combination of prenatal smoking and DD genotype greatly magnified impulsivity and overactivity (purple bar). Children's oppositional behavior followed a similar epigenetic pattern. (Adapted from Kahn et al., 2003.)

SUMMARY

Genetic Foundations (p. 73)

What are genes, and how are they transmitted from one generation to the next?

- Each individual's **phenotype,** or directly observable characteristics, is a product of both **genotype** and environment. **Chromosomes,** rodlike structures within the cell nucleus, contain our hereditary endowment. Along their length are **genes,** segments of **deoxyribonucleic acid (DNA)** that send instructions for making a rich assortment of proteins to the cell's cytoplasm.
- **Gametes,** or sex cells, are produced through a cell division process called **meiosis. Crossing over** and chance assortment of chromosomes into gametes ensure that each gamete receives a unique set of genes from each parent. Once sperm and ovum unite, the resulting **zygote** starts to develop into a complex human being through cell duplication, or **mitosis.**
- If the fertilizing sperm carries an X chromosome, the child will be a girl; if it contains a Y chromosome, a boy.

Describe various patterns of genetic inheritance.

- **Homozygous** individuals have two identical **alleles.** If the alleles differ, the individual is **heterozygous,** and relationships between the alleles determine the phenotype. In **dominant–recessive inheritance,** only the dominant allele affects the child's phenotype; a child must inherit two recessive alleles to display the recessive trait. Heterozygous individuals become **carriers** of the recessive trait. In **incomplete dominance,** both alleles are expressed in the phenotype. **Modifier genes** enhance or dilute the effects of other genes.
- In **X-linked inheritance,** a harmful allele is carried on the X chromosome. Males are more likely than females to be affected. In **genomic imprinting,** one parent's allele is activated, regardless of its makeup.
- Harmful genes arise from **mutation,** which can occur spontaneously or be caused by hazardous environmental agents. Human traits that vary on a continuum, such as intelligence and personality, result from **polygenic inheritance**—the effects of many genes.

Describe major chromosomal abnormalities, and explain how they occur.

- Most chromosomal abnormalities are due to errors during meiosis. The most common is Down syndrome, which results in physical defects and mental retardation. **Sex chromosome** abnormalities, such as XYY, triple X, Klinefelter, and Turner syndromes, are milder than defects of the **autosomes.**

Reproductive Choices (p. 84)

What procedures can assist prospective parents in having healthy children?

- **Genetic counseling** helps couples at risk for giving birth to children with genetic abnormalities consider appropriate options. **Prenatal diagnostic methods** allow early detection of genetic problems.

© MICHELLE DEL GUERCIO/ PHOTO RESEARCHERS, INC.

- Reproductive technologies, such as donor insemination, in vitro fertilization, surrogate motherhood, and postmenopausal-assisted childbirth, enable individuals to become parents who otherwise would not, but they raise serious legal and ethical concerns.

Prenatal Development (p. 88)

List the three periods of prenatal development, and describe the major milestones of each.

- The period of the zygote lasts about two weeks, from fertilization until the blastocyst becomes deeply implanted in the uterine lining. During this time, structures that will support prenatal growth begin to form, including the **placenta** and the **umbilical cord.**
- During the period of the **embryo,** from weeks 2 to 8, the foundations for all body structures are laid down. The nervous system develops fastest, as the neural tube forms. Other organs follow rapidly. By the end of this period, production of neurons occurs at an astounding pace, and the embryo responds to touch and can move.
- The period of the **fetus,** lasting until the end of pregnancy, involves a dramatic increase in body size and completion of physical structures. At the end of the second trimester, most of the brain's neurons are in place.
- The fetus reaches the **age of viability** at the beginning of the final trimester, between 22 and 26 weeks. The brain continues to develop rapidly, and new sensory and behavioral capacities emerge. Gradually, the lungs mature, the fetus fills the uterus, and birth is near.

Prenatal Environmental Influences (p. 94)

Cite factors that influence the impact of teratogens, noting agents that are known teratogens.

- The impact of **teratogens** varies with the amount and length of exposure, genetic makeup of mother and fetus, presence or absence of other harmful agents, and age of the organism at time of exposure. Drugs, tobacco, alcohol, radiation, environmental pollution, and maternal diseases are teratogens that can endanger the developing organism.
- Babies born to users of heroin, methadone, or cocaine are at risk for prematurity, low birth weight, and physical defects and are born drug-addicted. Evidence on long-term effects, however, is mixed.
- Infants whose parents use tobacco are often born underweight, may have physical defects, and are at risk for attention, learning, and behavior problems in childhood.
- Maternal alcohol consumption can lead to **fetal alcohol spectrum disorder (FASD). Fetal alcohol syndrome (FAS)** involves slow physical growth, facial abnormalities, and mental impairments. Milder forms—**partial fetal alcohol syndrome (p-FAS)** and **alcohol-related neurodevelopmental disorder (ARND)**—affect children whose mothers consumed smaller quantities of alcohol.
- Prenatal exposure to high levels of radiation, mercury, lead, dioxins, and PCBs leads to physical malformations and severe brain damage. Low-level exposure has been linked to cognitive deficits and emotional and behavior disorders.
- Among infectious diseases, rubella causes wide-ranging abnormalities. Babies with prenatally transmitted HIV rapidly develop AIDS, leading to brain damage and early death. Cytomegalovirus, herpes simplex 2, and toxoplasmosis can also be devastating to the embryo and fetus.

Describe the impact of additional maternal factors on prenatal development.

- Prenatal malnutrition can lead to low birth weight, damage to the brain and other organs, and suppression of immune system development. Maternal vitamin–mineral supplementation, including folic acid, can prevent prenatal and birth complications.
- Severe emotional stress is associated with many pregnancy complications and may permanently alter fetal neurological functioning. Its impact can be reduced by providing mothers with social support.

- Aside from the risk of chromosomal abnormalities in older women, maternal age through the thirties is not a major cause of prenatal problems. Poor health and environmental risks associated with poverty are the strongest predictors of pregnancy complications in both teenagers and older women.

Childbirth (p. 107)

Describe the three stages of childbirth, the baby's adaptation to labor and delivery, and the newborn baby's appearance.

- In the first stage of childbirth, contractions widen and thin the cervix. In the second stage, the mother feels an urge to push the baby through the birth canal. In the final stage, the placenta is delivered. During labor, infants produce high levels of stress hormones, which help them withstand oxygen deprivation, clear the lungs for breathing, and arouse them into alertness at birth.
- Newborn babies have large heads and small bodies. The **Apgar Scale** is used to assess their physical condition at birth.

Approaches to Childbirth (p. 109)

Describe natural childbirth and home delivery, and explain the risks of using pain-relieving drugs during labor and delivery.

- In **natural,** or **prepared, childbirth,** the expectant mother and a companion attend classes about labor and delivery, master relaxation and breathing techniques to counteract pain, and prepare for coaching during childbirth. Social support from a partner, relative, or doula reduces the length of labor and the incidence of birth complications.
- Home birth is as safe as hospital birth for healthy mothers who are assisted by a well-trained doctor or midwife.
- The use of analgesics and anesthetics during childbirth can prolong labor and cause newborns to be withdrawn and irritable and to feed poorly.

Birth Complications (p. 112)

What risks are associated with oxygen deprivation and with preterm and low-birth-weight infants, and what factors can help infants who survive a traumatic birth?

- Inadequate oxygen supply during labor and delivery can damage the brain and other organs. Effects of even mild to moderate anoxia often persist, although many children improve over time.

PHOTO COURTESY OF SUSAN MERRELL

- Low birth weight, a major cause of **neonatal** and **infant mortality** and wide-ranging developmental problems, is most common in infants born to poverty-stricken women and in multiple births. Compared with **preterm infants,** whose weight is appropriate for time spent in the uterus, **small-for-date infants** usually have longer-lasting difficulties.
- Interventions include providing special stimulation in the intensive care nursery and teaching parents how to care for and interact with their babies. Preterm infants in stressed, low-income households need long-term, intensive intervention.
- When infants experience birth trauma, a supportive family environment or relationships with other caring adults can help restore their growth. Even infants with serious birth complications can recover with the help of positive life events.

Heredity, Environment, and Behavior: A Look Ahead (p. 118)

Explain the various ways heredity and environment may combine to influence complex traits.

- **Behavioral genetics** looks at the contributions of nature and nurture to complex traits. Researchers use **kinship studies** to compute **heritability estimates,** which show that genetic factors contribute to such traits as intelligence and personality. However, the accuracy and usefulness of these estimates have been challenged, and they tell us nothing about how environment can modify genetic influences.
- According to the concepts of **gene-environment interaction** and **canalization,** heredity influences children's responsiveness to varying environments. **Gene–environment correlation** and **niche-picking** describe how children's genes affect the environments to which they are exposed. **Epigenesis** reminds us that development is best understood as a series of complex exchanges between nature and nurture.

CHAPTER 4

“Playing by Tops”

Takashi Hariya, 5 years, Japan

With wide-eyed eagerness and curiosity, these young children explore a fascinating pair of spinning tops. Research confirms that infants are remarkably capable beings who rapidly make sense of constantly changing sounds, shapes, patterns, and surfaces in their surroundings.

Early Deprivation and Enrichment: Is Infancy a Sensitive Period of Development?

Enthralled with their new baby, Yolanda and Jay came to my child development class when Joshua was 4 weeks old to share their reactions to new parenthood. Holding little Joshua over his shoulder while patting him gently, Jay remarked, "When we first saw him—a tiny bundle with his arms and legs all scrunched up, so helpless looking—we couldn't imagine how we would ever figure out how to meet his needs. But you know, almost from the start, Joshua has been able to help us!"

Yolanda demonstrated by speaking softly to Joshua. "Look how he perks up and turns toward the sound of our voices!" she said. As she touched Joshua's palm, he grasped at her fingers and the edge of her sleeve. "And look!" Yolanda continued. "See how he grasps at whatever comes near his hand, and how tightly he holds on."

As Joshua snuggled against Jay's chest, Jay noted, "When he's unhappy, we hold him so he can feel our heartbeats." Joshua whimpered, so Jay began walking around the room. "When he's bored, we carry him to a new place and sing to him. Usually, that's enough to quiet him. His cry is becoming a language we can understand."

Jay placed Joshua on his tummy on a blanket-covered table. "See," he announced proudly, "he can lift his head and do little half push-ups." When Jay turned Joshua on his back, Joshua stared at Yolanda's bright pink blouse, his face utterly absorbed. Lifting Joshua and giving him a kiss, Jay exclaimed, "He's just determined to master his world!"

As Yolanda's and Jay's observations confirm, our view of infancy—the period of development that spans the first year of life—has changed drastically over the past century. At one time, the newborn, or *neonate,* was considered a passive, incompetent being whose world was, in the words of turn-of-the-twentieth-century psychologist William James, "a blooming, buzzing confusion." Careful observations of infants' behavior and more refined methods enabling researchers to test babies' capacities confirm that, from the outset, infants display many complex abilities.

Infant development proceeds at an astonishing pace. Excited relatives who visit just after birth and then return a few months later often remark that the baby does not seem like the same individual! Although researchers agree that infants are competent, fervent debates continue over questions like these: What capacities are present from the beginning? Which mature with the passage of time? And which result from the baby's constant interaction with her physical and social worlds? In this chapter, we explore the infant's early reflexes, ability to learn, motor skills, and perceptual capacities—along with the debates that surround these remarkable competencies.

The Organized Infant

The newborn baby, as we saw in Chapter 3, is homely looking, with a head that appears too large in relation to the potbellied trunk and bowlegged lower body. Yet a few hours spent with a neonate reveal a wide variety of capacities that are crucial for survival and for evoking care and attention from adults. In relating to their physical and social worlds, babies are active from the very start.

- Explain the functions of newborn reflexes, and describe changing states of arousal during infancy, emphasizing sleep and crying.
- Why is neonatal behavioral assessment useful?
- Describe infant learning capacities, the conditions under which they occur, and the unique value of each.

Reflexes

A **reflex** is an inborn, automatic response to a particular form of stimulation. Reflexes are the neonate's most obvious organized patterns of behavior. When a father, changing his newborn baby's diaper, bumps the side of the table, the infant flings her arms wide, then brings them back toward her body. As a mother softly strokes her infant's cheek, the baby turns his head in her direction. **TAKE A MOMENT...** Look at Table 4.1, and see if you can identify the newborn reflexes described here and the ones Joshua displayed in the introduction to this chapter. Then let's consider the meaning and purpose of these curious behaviors.

Adaptive Value of Reflexes

Some reflexes have survival value. The rooting reflex helps a breastfed baby find the mother's nipple. Babies display it only when hungry and touched by another person, not when they touch themselves (Rochat & Hespos, 1997). At birth, babies adjust their sucking pressure to how easily milk flows from the nipple (Craig & Lee, 1999). And if sucking were not automatic, our species would be unlikely to survive for a single generation! The swimming reflex helps a baby who is accidentally dropped into water stay afloat, increasing the chances of retrieval by the caregiver.

Other reflexes probably helped babies survive during our evolutionary past. For example, the Moro, or "embracing," reflex is believed to have helped infants cling to their mothers when they were carried about all day. If the baby happened to lose support, the reflex caused the infant to embrace and, along with the palmar grasp reflex (so strong during the first

TABLE 4.1 Some Newborn Reflexes

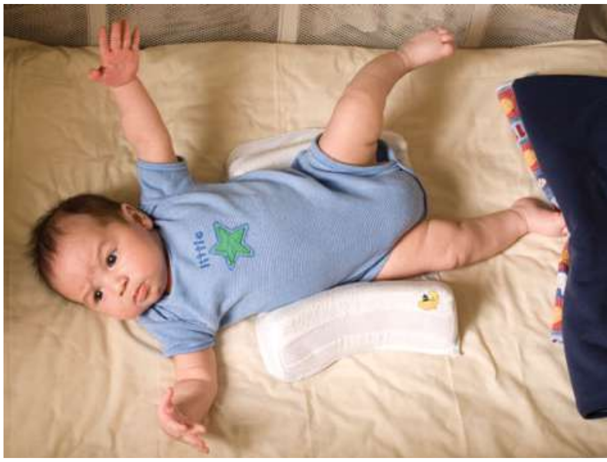
REFLEX	STIMULATION	RESPONSE	AGE OF DISAPPEARANCE	FUNCTION
Eye blink	Shine bright light at eyes or clap hand near head.	Infant quickly closes eyelids.	Permanent	Protects infant from strong stimulation
Rooting	Stroke cheek near corner of mouth.	Head turns toward source of stimulation.	3 weeks (becomes voluntary head turning at this time)	Helps infant find the nipple
Sucking	Place finger in infant's mouth.	Infant sucks finger rhythmically.	Replaced by voluntary sucking after 4 months	Permits feeding
Swimming[a]	Occurs when infant is face down in pool of water.	Baby paddles and kicks in swimming motion.	4–6 months	Helps infant survive if dropped into water
Moro	Hold infant horizontally on back and let head drop slightly, or produce a sudden loud sound against surface supporting infant.	Infant makes an "embracing" motion by arching back, extending legs, throwing arms outward, and then bringing arms in toward the body.	6 months	In human evolutionary past, may have helped infant cling to mother
Palmar grasp	Place finger in infant's hand, and press against palm.	Infant spontaneously grasps finger.	3–4 months	Prepares infant for voluntary grasping
Tonic neck	Turn baby's head to one side while infant is lying awake on back.	Infant lies in a "fencing position." One arm is extended in front of eyes on side to which head is turned, other arm is flexed.	4 months	May prepare infant for voluntary reaching
Stepping	Hold infant under arms, and permit bare feet to touch a flat surface.	Infant lifts one foot after another in stepping response.	2 months in infants who gain weight quickly; sustained in lighter infants	Prepares infant for voluntary walking
Babinski	Stroke sole of foot from toe toward heel.	Toes fan out and curl as foot twists in.	8–12 months	Unknown

[a] Placing infants in a pool of water is dangerous. See discussion on page 131.

Sources: Knobloch & Pasamanick, 1974; Prechtl & Beintema, 1965; Thelen, Fisher, & Ridley-Johnson, 1984.

week that it can support the baby's entire weight), regain her hold on the mother's body (Kessen, 1967; Prechtl, 1958).

Several reflexes help parents and infants establish gratifying interaction. A baby who searches for and successfully finds the nipple, sucks easily during feedings, and grasps when her hand is touched encourages parents to respond lovingly and feel competent as caregivers. Reflexes can also help parents comfort the baby because they permit infants to control distress and amount of stimulation. As any new parent who makes sure to bring along a pacifier on an outing with a young baby knows, sucking helps quiet a fussy infant.



© LAURA DWIGHT PHOTOGRAPHY

In the Moro reflex, loss of support or a sudden loud sound causes the baby to extend the legs and throw the arms outward in an "embracing" motion.

Reflexes and the Development of Motor Skills A few reflexes form the basis for complex motor skills that will develop later. For example, the tonic neck reflex may prepare the baby for voluntary reaching. When infants lie on their backs in this "fencing position," they naturally gaze at the hand in front of their eyes. The reflex may encourage them to combine vision with arm movements and, eventually, reach for objects (Knobloch & Pasamanick, 1974).

Certain reflexes—such as the palmar grasp, swimming, and stepping—drop out early, but the motor functions involved are renewed later. The stepping reflex, for example, looks like a primitive walking response. Unlike other reflexes, it appears in a wide range of situations—with the newborn's body in a sideways or upside-down position, with feet touching walls or ceilings, and even with legs dangling in the air (Adolph & Berger, 2006). One reason that babies frequently engage in the alternating leg movements of stepping is their ease compared with other movement patterns; repetitive movement of one leg or of both legs at once requires more effort.

In infants who gain weight quickly in the weeks after birth, the stepping reflex drops out because thigh and calf muscles are not strong enough to lift the baby's chubby legs. But if the lower part of the infant's body is dipped in water, the reflex reappears because the buoyancy of the water lightens the load on the baby's muscles (Thelen, Fisher, & Ridley-Johnson, 1984). When stepping is exercised regularly, babies display more spontaneous stepping movements and gain muscle strength. Consequently, they tend to walk several weeks earlier than if stepping is not practiced (Zelazo et al., 1993). However, there is no special need for infants to practice the stepping reflex—all normal babies walk in due time.

In the case of the swimming reflex, trying to build on it is risky. Although young babies placed in a swimming pool will paddle and kick, they swallow large amounts of water. This lowers the concentration of salt in the baby's blood, which can cause brain swelling and seizures. Despite this remarkable reflex, swimming lessons are best postponed until at least 3 years of age.

The Importance of Assessing Reflexes Look at Table 4.1 again, and you will see that most newborn reflexes disappear during the first six months. Researchers believe that this is due to a gradual increase in voluntary control over behavior as the cerebral cortex develops. Pediatricians test reflexes carefully, especially if a newborn has experienced birth trauma, because reflexes can reveal the health of the baby's nervous system. Weak or absent reflexes, overly rigid or exaggerated reflexes, and

The palmar grasp reflex is so strong during the first week after birth that many infants can use it to support their entire weight.

reflexes that persist beyond the point in development when they should normally disappear can signal brain damage (Schott & Rossor, 2003; Zafeiriou, 2000). However, individual differences in reflexive responses exist that are not cause for concern. An observer must assess newborn reflexes along with other characteristics to distinguish normal from abnormal central nervous system functioning (Touwen, 1984).

States

Throughout the day and night, newborn infants move in and out of five **states of arousal,** or degrees of sleep and wakefulness, described in Table 4.2. During the first month, these states alternate frequently. The most fleeting is quiet alertness, which usually moves quickly toward fussing and crying. Much to the relief of their fatigued parents, newborns spend the greatest amount of time asleep—about 16 to 18 hours a day. Because the fetus tends to synchronize periods of rest and activity with those of the mother, newborns—even those who are 4 to 6 weeks preterm—sleep more at night than during the day (Heraghty et al., 2008; Rivkees, 2003). Nevertheless, young babies' sleep–wake cycles are affected more by fullness–hunger than by darkness–light (Davis, Parker, & Montgomery, 2004; Goodlin-Jones, Burnham, & Anders, 2000).

Between birth and 2 years, the organization of sleep and wakefulness changes substantially. Total sleep time declines slowly; the average 2-year-old still needs 12 to 13 hours per day. But periods of sleep and wakefulness become fewer but longer, and the sleep–wake pattern increasingly conforms to a *circadian rhythm,* or 24-hour schedule. By 2 to 3 months, infants respond more to darkness–light. Babies of this age who are exposed to more bright sunlight—for example, through regular early-afternoon stroller rides—sleep better at night (Harrison, 2004). Most 6- to 9-month-olds take two daytime naps; by about 18 months, children generally need only one nap. Finally, between 3 and 5 years, napping subsides (Iglowstein et al., 2003).

These changing arousal patterns are due to brain development, but they are also affected by culturally influenced beliefs and practices and individual parents' needs (Super & Harkness, 2002). In interviews of Dutch and U.S. middle-class parents that focused on their babies' sleep, the Dutch parents viewed sleep regularity as far more important than the U.S. parents

TABLE 4.2 Infant States of Arousal

STATE	DESCRIPTION	DAILY DURATION IN NEWBORN
Regular, or NREM, sleep	The infant is at full rest and shows little or no body activity. The eyelids are closed, no eye movements occur, the face is relaxed, and breathing is slow and regular.	8–9 hours
Irregular, or REM, sleep	Gentle limb movements, occasional stirring, and facial grimacing occur. Although the eyelids are closed, occasional rapid eye movements can be seen beneath them. Breathing is irregular.	8–9 hours
Drowsiness	The infant is either falling asleep or waking up. Body is less active than in irregular sleep but more active than in regular sleep. The eyes open and close; when open, they have a glazed look. Breathing is even but somewhat faster than in regular sleep.	Varies
Quiet alertness	The infant's body is relatively inactive, with eyes open and attentive. Breathing is even.	2–3 hours
Waking activity and crying	The infant shows frequent bursts of uncoordinated body activity. Breathing is very irregular; face may be relaxed or tense and wrinkled. Crying may occur.	1–4 hours

Source: Wolff, 1966.

did. And whereas the U.S. parents regarded a predictable sleep schedule as emerging naturally from within the child, the Dutch parents were convinced—on the basis of Dutch infant-care traditions—that a schedule had to be imposed, or the baby's development might suffer (Super et al., 1996; Super & Harkness, 2010). At age 6 months, the Dutch babies were put to bed earlier and slept, on average, 2 hours more per day than their U.S. counterparts.

Motivated by demanding work schedules and other needs, many Western parents try to get their babies to sleep through the night as early as age 3 to 4 months by offering an evening feeding before putting them down in a separate, quiet room. In this way, they push young infants to the limits of their neurological capacities. Not until the middle of the first year is the secretion of *melatonin,* a hormone within the brain that promotes drowsiness, much greater at night than during the day (Sadeh, 1997).

Furthermore, as the Cultural Influences box on page 134 reveals, isolating infants to promote sleep is rare elsewhere in the world. When babies sleep with their parents, their average sleep period remains constant at three hours from 1 to 8 months of age. Only at the end of the first year, as REM sleep (the state that usually prompts waking) declines, do infants move in the direction of an adultlike sleep–waking schedule (Ficca et al., 1999).

Even after infants sleep through the night, they continue to wake occasionally. In sleep observations and in surveys of parents in Australia, Israel, and the United States, night wakings increased around 6 months and again between 1½ and 2 years and then declined (Armstrong, Quinn, & Dadds, 1994; Scher, Epstein, & Tirosh, 2004; Scher et al., 1995). As Chapter 10 will reveal, around the middle of the first year, infants are forming a clear-cut attachment to their familiar caregiver and begin protesting when he or she leaves. And the challenges of toddlerhood—the ability to range farther from the caregiver and increased awareness of the self as separate from others—often prompt anxiety, evident in disturbed sleep and clinginess. When parents offer comfort, these behaviors subside.

Although arousal states become more organized with age, striking individual differences in daily rhythms exist that affect parents' attitudes toward and interactions with the baby. A few newborns sleep for long periods, increasing the energy their well-rested parents have for sensitive, responsive care. Other babies wake frequently and cry often, and their parents must exert great effort to soothe them. If these parents do not succeed, they may feel less competent and positive toward their infant—responses that pose serious risks to parent and family well-being (Sadeh et al., 2007; Smart & Hiscock, 2007).

LOOK and LISTEN

Interview a parent of a baby about sleep challenges. What strategies has the parent tried to ease these difficulties? Are the techniques likely to be effective, in view of evidence on infant sleep development?

Arousal patterns also have implications for early cognitive progress. Babies who spend more time quietly alert probably receive more social stimulation and opportunities to explore and, therefore, may be slightly ahead in mental development (Gertner et al., 2002). And as with adults, sleep enhances babies' learning and memory. Because newborns spend so much time sleeping, the capacity to learn about external stimuli during sleep may be essential for infants' adaptation to their surroundings. In one study, eye movements and ERP brain-wave recordings confirmed that sleeping newborns readily learned that a tone would be followed by a puff of air to the eye (Fifer et al., 2010). And 15-month-olds who took hour-long naps after listening to short, similarly structured "sentences" of nonsense words were better than their non-napping agemates at recognizing the common structure in new sentences and remembering it after a 24-hour delay (Gómez, Bootzin, & Nadel, 2006; Hupbach et al., 2009). Napping facilitated retention of higher-order word patterns—a skill essential for language development.

Of the states listed in Table 4.2, the two extremes—sleep and crying—have been of greatest interest to researchers. Each tells us something about normal and abnormal early development.

Sleep Sleep is made up of at least two states. During irregular, or **rapid-eye-movement (REM) sleep,** brain-wave activity, measured with the EEG, is remarkably similar to that of the waking state. The eyes dart beneath the lids; heart rate, blood pressure, and breathing are uneven; and slight body movements occur. The expression "sleeping like a baby" was probably not meant to describe this state! In contrast, during regular, or **non-rapid-eye-movement (NREM) sleep,** the body is almost motionless, and heart rate, breathing, and brain-wave activity are slow and even.

CULTURAL INFLUENCES

Cultural Variation in Infant Sleeping Arrangements

While awaiting the birth of a new baby, North American parents typically furnish a room as the infant's sleeping quarters. For decades, child-rearing advice from experts strongly encouraged nighttime separation of baby from parent. For example, the most recent edition of Benjamin Spock's *Baby and Child Care* recommends that babies sleep in their own room by 3 months of age, explaining, "By 6 months, a child who regularly sleeps in her parents' room may become dependent on this arrangement" (Spock & Needlman, 2004, p. 60). And the American Academy of Pediatrics (2005) has issued a controversial warning that parent–infant bedsharing may increase the risk of sudden infant death syndrome (SIDS).

Yet parent–infant "cosleeping" is the norm for approximately 90 percent of the world's population, in cultures as diverse as the Japanese, the rural Guatemalan Maya, the Inuit of northwestern Canada, and the !Kung of Botswana. Japanese and Korean children usually lie next to their mothers in infancy and early childhood, and many continue to sleep with a parent or other family member until adolescence (Takahashi, 1990; Yang & Hahn, 2002). Among the Maya, mother–infant cosleeping is interrupted only by the birth of a new baby, at which time the older child is moved next to the father or to another bed in the same room (Morelli et al., 1992). Cosleeping is also common in U.S. ethnic minority families (McKenna & Volpe, 2007). African-American children, for example, frequently fall asleep with their parents and remain with them for part or all of the night (Buswell & Spatz, 2007).

Cultural values strongly influence infant sleeping arrangements. In one study, researchers interviewed Guatemalan Mayan mothers and American middle-class mothers about their sleeping practices. Mayan mothers stressed the importance of promoting an *interdependent self* (see page 35 in Chapter 1), explaining that cosleeping builds a close parent–child bond, which is necessary for children to learn the ways of people around them. In contrast, American mothers emphasized an *independent self,* mentioning their desire to instill early autonomy, prevent bad habits, and protect their own privacy (Morelli et al., 1992).

Over the past two decades, cosleeping has increased in Western nations. In the United States, an estimated 13 percent of infants routinely bedshare, and an additional 30 to 35 percent sometimes do so (Buswell & Spatz, 2007; Willinger et al., 2003). Proponents of the practice say that it helps infants sleep, makes breastfeeding more convenient, and provides valuable bonding time—especially for employed parents who have limited contact with their baby during the day (McKenna & Volpe, 2007).

During the night, cosleeping babies breastfeed three times longer than infants who sleep alone. Because infants arouse to nurse more often when sleeping next to their mothers, some researchers believe that cosleeping may actually help safeguard babies at risk for sudden infant death syndrome (SIDS) (see the Social Issues: Health box on page 136). Consistent with this view, SIDS is rare in Asian cultures where cosleeping is widespread, including Cambodia, China, Japan, Korea, Thailand, and Vietnam (McKenna, 2002; McKenna & McDade, 2005). And contrary to popular belief, cosleeping does not decrease mothers' total sleep time, although they experience more brief awakenings, which permit them to check on their baby (Mao et al., 2004).

Infant sleeping practices affect other aspects of family life. For example, Mayan babies doze off in the midst of ongoing family activities and are carried to bed by their mothers. In contrast, for many American parents, bedtime often involves a lengthy, elaborate ritual. Perhaps bedtime struggles, so common in Western homes but rare elsewhere in the world, are related to the stress young children feel when they must fall asleep without assistance (Latz, Wolf, & Lozoff, 1999).

Critics of bedsharing warn that cosleeping children will develop emotional problems, especially excessive dependency. Yet a longitudinal study following children from the end of pregnancy through age 18 showed that young people who had bedshared in the early years were no different from others in any aspect of adjustment (Okami, Weisner, & Olmstead, 2002). Another concern is that infants might become trapped under the parent's body or in soft covers and suffocate. Parents who are obese or who use alcohol, tobacco, or illegal drugs do pose a serious risk to their sleeping babies, as does the use of quilts and comforters or an overly soft mattress (Willinger et al., 2003).

But with appropriate precautions, parents and infants can cosleep safely (McKenna & Volpe, 2007). In cultures where cosleeping is widespread, parents and infants usually sleep with light covering on hard surfaces, such as firm mattresses, floor mats, and wooden planks, or infants sleep in a cradle or hammock next to the parents' bed (McKenna, 2001, 2002). And when sharing the same bed, infants typically lie on their back or side facing the mother—positions that promote frequent, easy communication between parent and baby and arousal if breathing is threatened.

Finally, breastfeeding mothers usually assume a distinctive sleeping posture: They face the infant, with knees drawn up under the baby's feet and arm above the baby's head. Besides facilitating feeding, the position prevents the infant from sliding down under covers or up under pillows (Ball, 2006). Because this posture is also seen in female great apes while sharing sleeping nests with their infants, researchers believe it may have evolved to enhance infant safety.

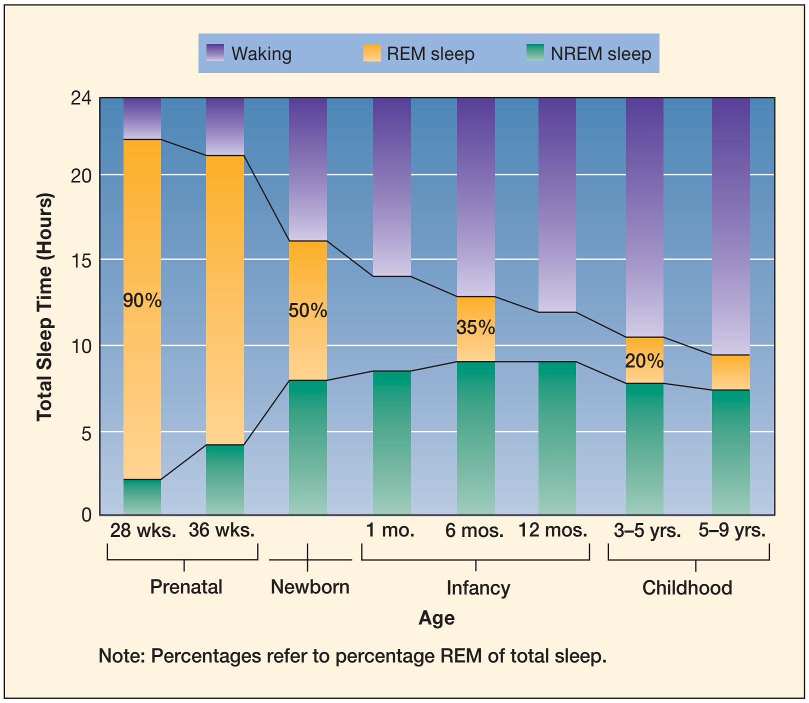
This Cambodian father and child sleep together, a practice common in diverse cultures. Many parents believe that cosleeping promotes a close parent–child bond.

Like children and adults, newborns alternate between REM and NREM sleep. However, as Figure 4.1 shows, they spend far more time in the REM state than they ever will again. REM sleep accounts for 50 percent of the newborn baby's sleep time. By 3 to 5 years, it has declined to an adultlike level of 20 percent (Louis et al., 1997).

Why do young infants spend so much time in REM sleep? In older children and adults, the REM state is associated with dreaming. Babies probably do not dream, at least not in the same way we do. But researchers believe that the stimulation of REM sleep is vital for growth of the central nervous system. Young infants seem to have a special need for this stimulation because they spend little time in an alert state, when they can get input from the environment. In support of this idea, the percentage of REM sleep is especially great in the fetus and in preterm babies, who are even less able than full-term newborns to take advantage of external stimulation (de Weerd & van den Bossche, 2003; Peirano, Algarin, & Uauy, 2003).



Note: Percentages refer to percentage REM of total sleep.

FIGURE 4.1 **Changes in REM sleep, NREM sleep, and the waking state from the prenatal period to middle childhood.** REM sleep declines steadily over the prenatal period and the first few years of life. Between 3 and 5 years, it accounts for about the same percentage of sleep time as it does in adulthood. (Adapted from de Weerd & van den Bossche, 2003; Roffwarg, Muzio, & Dement, 1996.)

While the brain-wave activity of REM sleep safeguards the central nervous system, the rapid eye movements protect the health of the eye. Eye movements cause the vitreous (gelatin-like substance within the eye) to circulate, thereby delivering oxygen to parts of the eye that do not have their own blood supply (Blumberg & Lucas, 1996). During sleep, when the eye and the vitreous are still, visual structures are at risk for anoxia. As the brain cycles through REM-sleep periods, rapid eye movements stir up the vitreous, ensuring that the eye is fully oxygenated.

Because newborn babies' normal sleep behavior is organized and patterned, observations of sleep states can help identify central nervous system abnormalities. In infants who are brain-damaged or who have experienced birth trauma, disturbed REM–NREM sleep cycles are often present. Babies with poor sleep organization are likely to be behaviorally disorganized and, therefore, to have difficulty learning and eliciting caregiver interactions that enhance their development. In follow-ups during the preschool years, they show delayed motor, cognitive, and language development (de Weerd & van den Bossche, 2003; Feldman, 2006; Holditch-Davis, Belyea, & Edwards, 2005). And the brain-functioning problems that underlie newborn sleep irregularities may culminate in sudden infant death syndrome, a major cause of infant mortality (see the Social Issues: Health box on page 136).

Crying Crying is the first way that babies communicate, letting parents know that they need food, comfort, and stimulation. During the weeks after birth, all babies have some fussy periods when they are difficult to console. But most of the time, the nature of the cry, combined with the experiences that led up to it, helps guide parents toward its cause. The baby's cry is a complex auditory stimulus that varies in intensity, from a whimper to a message of all-out distress (Gustafson, Wood, & Green, 2000; Wood, 2009). As early as the first few weeks, infants can be identified by the unique vocal "signature" of their cries, which helps parents locate their baby from a distance (Gustafson, Green, & Cleland, 1994).

Young infants usually cry because of physical needs. Hunger is the most common cause, but babies may also cry in response to temperature change when undressed, a sudden noise, or a painful stimulus. An infant's state also affects proneness to cry. A baby who, when quietly alert, regards a colorful or noise-making object with interest may burst into tears when confronted with the same object while in a state of mild discomfort. And newborns (as well as older infants) often cry at the sound of another crying baby (Dondi, Simion, & Caltran, 1999; Geangu et al., 2010). Some researchers believe that this response reflects an inborn

SOCIAL ISSUES: HEALTH

The Mysterious Tragedy of Sudden Infant Death Syndrome

Millie awoke with a start one morning and looked at the clock. It was 7:30, and Sasha had missed both her night waking and her early morning feeding. Wondering if she was all right, Millie and her husband, Stuart, tiptoed into the room. Sasha lay still, curled up under her blanket. She had died silently during her sleep.

Sasha was a victim of **sudden infant death syndrome (SIDS),** the unexpected death, usually during the night, of an infant younger than 1 year of age that remains unexplained after thorough investigation. In industrialized nations, SIDS is the leading cause of infant mortality between 1 week and 12 months, accounting for about 20 percent of these deaths in the United States (Mathews & MacDorman, 2008).

SIDS victims usually show physical problems from the beginning. Early medical records of SIDS babies reveal higher rates of prematurity and low birth weight, poor Apgar scores, and limp muscle tone. Abnormal heart rate and respiration and disturbances in sleep–wake activity and in REM–NREM cycles while asleep are also involved (Cornwell & Feigenbaum, 2006; Kato et al., 2003). At the time of death, many SIDS babies have a mild respiratory infection (Blood-Siegfried, 2009). This seems to increase the chances of respiratory failure in an already vulnerable baby.

Mounting evidence suggests that impaired brain functioning is a major contributor to SIDS. Between 2 and 4 months, when SIDS is most likely to occur, reflexes decline and are replaced by voluntary, learned responses. Neurological weaknesses may prevent SIDS babies from acquiring behaviors that replace defensive reflexes (Lipsitt, 2003). As a result, when breathing difficulties occur during sleep, the infants do not wake up, shift their position, or cry out for help. Instead, they simply give in to oxygen deprivation and death. In support of this interpretation, autopsies reveal that the brains of SIDS babies contain unusually low levels of serotonin (a brain chemical that assists with arousal when survival is threatened) as well as other abnormalities in centers that control breathing and arousal (Duncan et al., 2010).

Several environmental factors are linked to SIDS. Maternal cigarette smoking, both during and after pregnancy, as well as smoking by other caregivers, doubles risk of the disorder. Babies exposed to cigarette smoke arouse less easily from sleep and have more respiratory infections (Richardson, Walker, & Horne, 2009; Shah, Sullivan, & Carter, 2006). Prenatal abuse of drugs that depress central nervous system functioning (alcohol, opiates, and barbiturates) increases the risk of SIDS as much as fifteenfold (Hunt & Hauck, 2006). Babies of drug-abusing mothers are especially likely to display SIDS-related brain abnormalities (Kinney, 2009).

SIDS babies are also more likely to sleep on their stomachs than on their backs and often are wrapped very warmly in clothing and blankets. Infants who sleep on their stomachs less often wake when their breathing is disturbed (Richardson, Walker, & Horne, 2008). In other cases, healthy babies sleeping face down on soft bedding may die from continually breathing their own exhaled breath.

Quitting smoking and drug taking, changing an infant's sleeping position, and removing a few bedclothes can reduce the incidence of SIDS. For example, if women refrained from smoking while pregnant, an estimated 30 percent of SIDS cases would be prevented. Public education campaigns that encourage parents to put babies down on their backs have cut the incidence of SIDS in half in many Western nations (Moon, Horne, & Hauck, 2007). Another protective measure is pacifier use: Sleeping babies who suck arouse more easily in response to breathing and heart-rate irregularities (Li et al., 2006). Nevertheless, compared with white infants, SIDS rates are two to six times higher in poverty-stricken minority groups, where parental stress, substance abuse, reduced access to health care, and lack of knowledge about safe sleep practices are widespread (Colson et al., 2009; Pickett, Luo, & Lauderdale, 2005).

When SIDS does occur, surviving family members require a great deal of help to overcome a sudden and unexpected death. As Millie commented six months after Sasha's death, "It's the worst crisis we've ever been through. What's helped us most are the comforting words of others who've experienced the same tragedy."

© BANANASTOCK/JUPITERIMAGES

Public education campaigns encouraging parents to place infants on their backs to sleep have cut the incidence of SIDS in half in many Western nations.

capacity to react to the suffering of others. Furthermore, crying typically increases during the early weeks, peaks at about 6 weeks, and then declines (Barr, 2001). Because this trend appears in many cultures with vastly different infant care practices, researchers believe that normal readjustments of the central nervous system underlie it.

Adult Responsiveness to Infant Cries. **TAKE A MOMENT...** The next time you hear a baby cry, notice your own reaction. The sound stimulates strong feelings of arousal and discomfort in men and women, parents and nonparents alike (Murray, 1985). This powerful response is probably innately programmed to help ensure that babies receive the care and protection they need to survive.

APPLYING WHAT WE KNOW

Soothing a Crying Baby

TECHNIQUE	EXPLANATION
Talk softly or play rhythmic sounds.	Continuous, monotonous, rhythmic sounds (such as a clock ticking, a fan whirring, or peaceful music) are more effective than intermittent sounds.
Offer a pacifier.	Sucking helps babies control their own level of arousal.
Massage the baby's body.	Stroking the baby's torso and limbs with continuous, gentle motions relaxes the baby's muscles.
Swaddle the baby.	Restricting movement and increasing warmth often soothe a young infant.
Lift the baby to the shoulder and rock or walk.	This combination of physical contact, upright posture, and motion is an effective soothing technique, causing young infants to become quietly alert.
Take the baby for a short car ride or a walk in a baby carriage; swing the baby in a cradle.	Gentle, rhythmic motion of any kind helps lull the baby to sleep.
Combine several of the methods just listed.	Stimulating several of the baby's senses at once is often more effective than stimulating only one.
If these methods do not work, let the baby cry for a short period.	Occasionally, a baby responds well to just being put down and will, after a few minutes, fall asleep.

Sources: Campos, 1989; Evanoo, 2007; Lester, 1985; Reisman, 1987.

Although parents do not always interpret their baby's cry correctly, their accuracy improves with experience. As babies get older, parents react to more subtle cues in the cry—not just intensity but also whimpering and calling sounds (Thompson & Leger, 1999). These cues, together with the context of the cry, help them figure out what is wrong. If the baby has not eaten for several hours, she is likely to be hungry. If a period of wakefulness and stimulation preceded the cry, the infant may be tired. A sharp, piercing, sustained cry usually means the baby is in pain and prompts caregivers to rush to the infant. Very intense cries are rated as more unpleasant and produce greater physiological arousal in adults (Crowe & Zeskind, 1992). These adaptive reactions help ensure that an infant in danger will quickly get help.

At the same time, parents vary widely in responsiveness. Parents who are high in empathy (ability to take the perspective of others in distress) and who hold "child-centered" attitudes toward infant care (for example, believe that babies cannot be spoiled by being picked up) are more likely to respond quickly and sensitively to a crying baby (Leerkes, 2010; Zeifman, 2003). And in one study, mothers who believed that they could easily control the crying of an artificial baby (whose quieting was unrelated to the mother's behavior) had difficulty detecting changes in cry sounds, engaged in less sensitive infant care, and had infants who developed into uncooperative toddlers (Donovan, Leavitt, & Walsh, 1997, 2000). The internal state of these mothers—who reacted defensively when they couldn't calm the artificial baby—seemed to interfere with their ability to cope effectively with infant crying.

Soothing a Crying Infant. Fortunately, there are many ways to soothe a crying baby when feeding and diaper changing do not work (see Applying What We Know above). The technique that Western parents usually try first, lifting the infant to the shoulder and rocking or walking, is highly effective. Another common soothing method is swaddling—wrapping the baby snugly in a blanket. The Quechua, who live in the cold, high-altitude desert regions of Peru, dress young babies in several layers of clothing and blankets that cover the head and body, a technique that reduces crying and promotes sleep (Tronick, Thomas, & Daltabuit, 1994). It also allows the baby to conserve energy for early growth in the harsh Peruvian highlands.

To soothe his crying infant, this father holds the baby upright against his gently moving body. The combination of physical contact, upright posture, and motion causes babies to stop crying and become quietly alert.

Will reacting promptly and consistently to infant cries give babies a sense of confidence that their needs will be met and, over time, reduce fussing and complaining? Or will it strengthen crying behavior and produce a miniature tyrant? Answers are contradictory.

According to *ethological theory,* parental responsiveness is adaptive in that it ensures that the infant's basic needs will be met (see Chapter 1, page 24). At the same time, it brings the baby into close contact with the caregiver, who encourages the infant to communicate through means other than crying. In support of this view, two studies showed that mothers who were slow or failed to respond to their young baby's cries had infants who cried more at the end of the first year (Bell & Ainsworth, 1972; Hubbard & van IJzendoorn, 1991). Furthermore, in many tribal and village societies and in non-Western developed nations (such as Japan), where babies are in physical contact with their caregivers nearly continuously, infants show shorter bouts of crying than their American counterparts (Barr, 2001). When Western parents choose to practice "proximal care" by holding their babies extensively, amount of crying in the early months is reduced by about one-third (St James-Roberts et al., 2006).

But not all research indicates that rapid parental responsiveness reduces infant crying (van IJzendoorn & Hubbard, 2000). The conditions that prompt crying are complex, and parents must make reasoned choices about what to do on the basis of culturally accepted practices, the suspected reason for the cry, and the context in which it occurs—for example, in the privacy of their own home or while having dinner at a restaurant. Fortunately, with age, crying declines and occurs more often for psychological (demands for attention, expressions of frustration) than physical reasons. Virtually all researchers agree that parents can lessen older babies' need to cry by encouraging more mature ways of expressing their desires, such as gestures and vocalizations.

Abnormal Crying. Like reflexes and sleep patterns, the infant's cry offers a clue to central nervous system distress. The cries of brain-damaged babies and those who have experienced prenatal and birth complications are often shrill, piercing, and shorter in duration than those of healthy infants (Boukydis & Lester, 1998; Green, Irwin, & Gustafson, 2000). Even neonates with a fairly common problem—*colic,* or persistent crying—tend to have high-pitched, harsh-sounding cries (Zeskind & Barr, 1997). Although the cause of colic is unknown, certain newborns, who react especially strongly to unpleasant stimuli, are susceptible. Because their crying is intense, they find it harder to calm down than other babies. Colic generally subsides between 3 and 6 months (Barr et al., 2005; St James-Roberts, 2007).

In an intervention aimed at reducing colic, nurses made periodic home visits, providing parents with help in identifying their baby's early warning signs of becoming overly aroused, in using effective soothing techniques, and in modifying light, noise, and activity in the home to promote predictable sleep–wake cycles (Keefe et al., 2005). Colicky infants who received the intervention spent far less time crying than no-intervention controls—1.3 versus 3 hours per day.

Most parents try to respond to a crying baby's call for help with extra care and attention, but sometimes the cry is so unpleasant and the infant so difficult to soothe that parents become frustrated, resentful, and angry. Preterm and ill babies are more likely to be abused by highly stressed parents, who sometimes mention a high-pitched, grating cry as one factor that caused them to lose control and harm the baby (St James-Roberts, 2007; Zeskind & Lester, 2001). We will discuss a host of additional influences on child abuse in Chapter 14.

LOOK and LISTEN

In a public setting, watch several parents soothe their crying babies. What techniques did the parents use, and how successful were they?

Neonatal Behavioral Assessment

A variety of instruments enable doctors, nurses, and researchers to assess the organized functioning of newborn babies. The most widely used of these tests, T. Berry Brazelton's **Neonatal Behavioral Assessment Scale (NBAS),** evaluates the baby's reflexes, muscle tone, state changes, responsiveness to physical and social stimuli, and other reactions (Brazelton

& Nugent, 1995). A recently developed instrument consisting of similar items, the *Neonatal Intensive Care Unit Network Neurobehavioral Scale (NNNS),* is specially designed for use with newborns at risk for developmental problems because of low birth weight, preterm delivery, prenatal substance exposure, or other conditions (Lester & Tronick, 2004). Scores are used to recommend appropriate interventions and to guide parents in meeting their baby's unique needs.

The NBAS has been given to many infants around the world. As a result, researchers have learned about individual and cultural differences in newborn behavior and how child-rearing practices can maintain or change a baby's reactions. For example, NBAS scores of Asian and Native-American babies reveal that they are less irritable than Caucasian infants. Mothers in these cultures encourage their babies' calm dispositions through swaddling, close physical contact, and nursing at the first signs of discomfort (Murett-Wagstaff & Moore, 1989; Small, 1998). The Kipsigis of rural Kenya, who highly value infant motor maturity, massage babies regularly and begin exercising the stepping reflex shortly after birth. These customs contribute to Kipsigis babies' strong but flexible muscle tone at 5 days of age (Super & Harkness, 2009). In Zambia, Africa, maternal care can quickly change the poor NBAS scores of undernourished infants. The Zambian mother carries her baby about on her hip all day, providing a rich variety of sensory stimulation. As a result, an unresponsive newborn often becomes an alert, contented 1-week-old (Brazelton, Koslowski, & Tronick, 1976).

This mother of the El Molo people of northern Kenya carries her baby in a sling all day. This practice, also adopted by many Western parents, provides rich sensory stimulation and promotes an alert, calm disposition.

TAKE A MOMENT... Using these examples, can you explain why a single neonatal assessment score is not a good predictor of later development? Because newborn behavior and parenting combine to influence development, *changes in scores* over the first week or two of life (rather than a single score) provide the best estimate of the baby's ability to recover from the stress of birth. NBAS "recovery curves" predict normal brain functioning (as assessed by EEG and fMRI), intelligence, and absence of emotional and behavior problems with moderate success well into the preschool years (Brazelton, Nugent, & Lester, 1987; Ohgi et al., 2003a, 2003b).

In some hospitals, health professionals use the NBAS or the NNNS to help parents get to know their newborns through discussion or demonstration of the capacities these instruments assess. Parents who participate in these programs, compared with no-intervention controls, interact more effectively with their babies—more often establishing eye contact, smiling, vocalizing, and soothing in response to infant signals (Browne & Talmi, 2005; Bruschweiler-Stern, 2004). Although lasting effects on development have not been demonstrated, neonatal behavioral assessment interventions are useful in helping the parent–infant relationship get off to a good start.

Learning Capacities

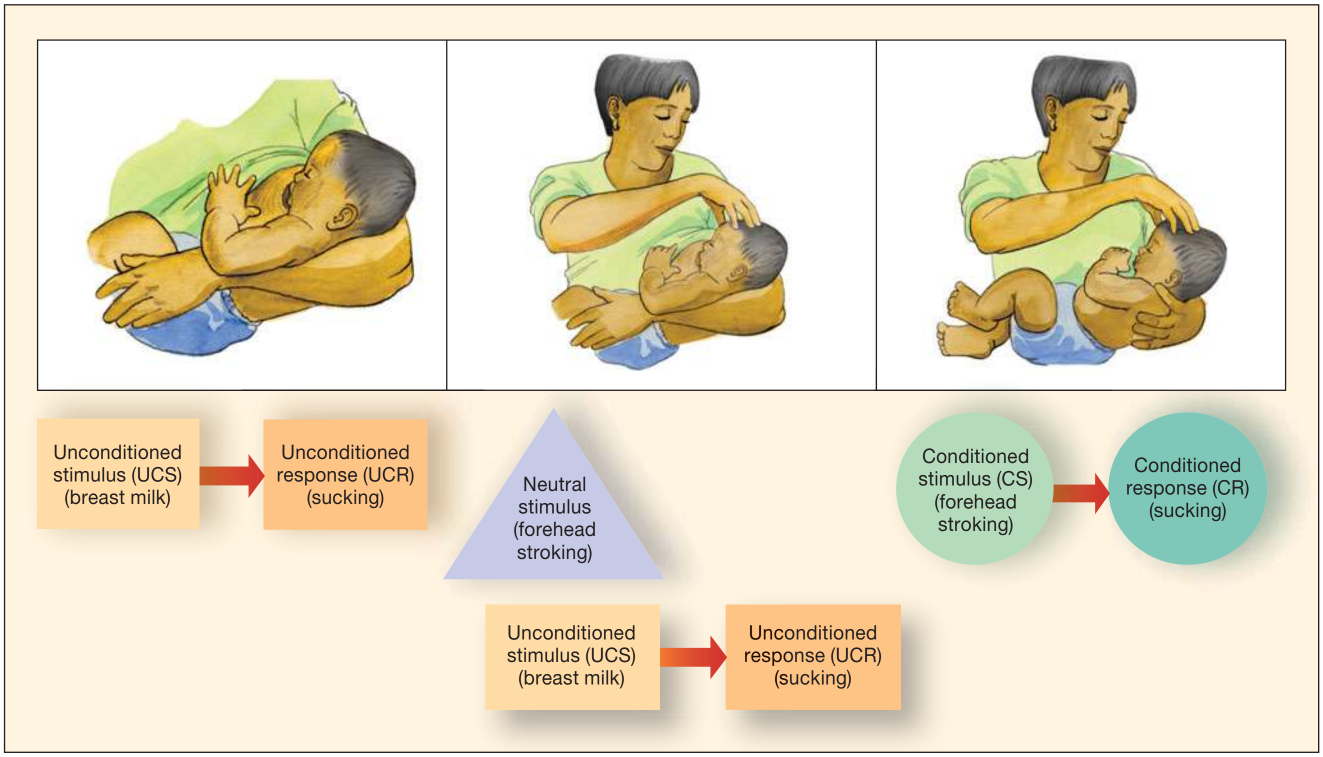
Learning refers to changes in behavior as the result of experience. Babies come into the world with built-in learning capacities that permit them to profit from experience immediately. Infants are capable of two basic forms of learning, which were introduced in Chapter 1: classical and operant conditioning. They also learn through their natural preference for novel stimulation. Finally, shortly after birth, babies learn by observing others; they can imitate the facial expressions and gestures of adults.

Classical Conditioning Newborn reflexes make **classical conditioning** possible in the young infant. In this form of learning, a neutral stimulus is paired with a stimulus that leads to a reflexive response. Once the baby's nervous system makes the connection between the two stimuli, the new stimulus produces the behavior by itself. Classical conditioning helps infants recognize which events usually occur together in the everyday world, so they can anticipate what is about to happen next. As a result, the environment becomes more orderly and predictable. Let's take a closer look at the steps of classical conditioning.

Imagine a mother who gently strokes her infant's forehead each time she settles down to nurse the baby. Soon the mother notices that each time the baby's forehead is stroked, he makes active sucking movements. The infant has been classically conditioned. Here is how it happened (see Figure 4.2):

- Before learning takes place, an **unconditioned stimulus (UCS)** must consistently produce a reflexive, or **unconditioned, response (UCR).** In our example, the stimulus of sweet breast milk (UCS) resulted in sucking (UCR).
- To produce learning, a *neutral stimulus* that does not lead to the reflex is presented just before, or at about the same time as, the UCS. The mother stroked the baby's forehead as each nursing period began. The stroking (neutral stimulus) was paired with the taste of milk (UCS).
- If learning has occurred, the neutral stimulus alone produces a response similar to the reflexive response. The neutral stimulus is then called a **conditioned stimulus (CS),** and the response it elicits is called a **conditioned response (CR).** We know that the baby has been classically conditioned because stroking his forehead outside the feeding situation (CS) results in sucking (CR).

If the CS is presented alone enough times, without being paired with the UCS, the CR will no longer occur, an outcome called **extinction.** In other words, if the mother repeatedly strokes the infant's forehead without feeding him, the baby will gradually stop sucking in response to stroking.



Unconditioned stimulus (UCS) (breast milk)
Unconditioned response (UCR) (sucking)
Neutral stimulus (forehead stroking)
Unconditioned stimulus (UCS) (breast milk)
Unconditioned response (UCR) (sucking)
Conditioned stimulus (CS) (forehead stroking)
Conditioned response (CR) (sucking)

FIGURE 4.2 **The steps of classical conditioning.** The example here shows how a mother classically conditioned her baby to make sucking movements by stroking his forehead at the beginning of feedings.

Young infants can be classically conditioned most easily when the association between two stimuli has survival value. Learning which stimuli regularly accompany feeding improves the infant's ability to get food and survive (Blass, Ganchrow, & Steiner, 1984). In contrast, some responses, such as fear, are very difficult to classically condition in young babies. Until infants have the motor skills to escape unpleasant events, they have no biological need to form these associations. After age 6 months, however, fear is easy to condition. **TAKE A MOMENT...** Return to Chapter 1, page 17, to review John Watson's famous experiment in which he conditioned Little Albert to withdraw and cry at the sight of a furry white rat. Then test your knowledge of classical conditioning by identifying the UCS, UCR, CS, and CR in Watson's study. In Chapter 10, we will discuss the development of fear, as well as other emotional reactions.

Operant Conditioning In classical conditioning, babies build expectations about stimulus events in the environment, but their behavior does not influence the stimuli that occur. In **operant conditioning,** infants act, or *operate,* on the environment, and stimuli that follow their behavior change the probability that the behavior will occur again. A stimulus that increases the occurrence of a response is called a **reinforcer.** For example, sweet liquid *reinforces* the sucking response in newborns. Removing a desirable stimulus or presenting an unpleasant one to decrease the occurrence of a response is called **punishment.** A sour-tasting fluid *punishes* newborns' sucking response. It causes them to purse their lips and stop sucking entirely.

Many stimuli besides food can serve as reinforcers of infant behavior. For example, newborns will suck faster on a nipple when doing so produces interesting sights and sounds, including visual designs, music, or human voices (Floccia, Christophe, & Bertoncini, 1997). Even preterm babies will seek reinforcing stimulation. In one study, they increased their contact with a soft teddy bear that "breathed" at a rate reflecting the infant's respiration, whereas they decreased their contact with a nonbreathing bear (Thoman & Ingersoll, 1993). As these findings suggest, operant conditioning is a powerful tool for finding out what stimuli babies can perceive and which ones they prefer.

As infants get older, operant conditioning includes a wider range of responses and stimuli. For example, researchers have hung special mobiles over the cribs of 2- to 6-month-olds. When the baby's foot is attached to the mobile with a long cord, the infant can, by kicking, make the mobile turn. Under these conditions, it takes only a few minutes for infants to start kicking vigorously. This technique has yielded important information about infant memory. Two-month-olds remember how to activate the mobile for 1 to 2 days after training, and 3-month-olds for one week. By 6 months, memory increases to two weeks (Rovee-Collier, 1999; Rovee-Collier & Bhatt, 1993). Around the middle of the first year, babies can manipulate switches or buttons to control stimulation. When 6- to 18-month-olds pressed a lever to make a toy train move around a track, duration of memory continued to increase with age; 13 weeks after training, 18-month-olds still remembered how to press the lever (Hartshorn et al., 1998b). Figure 4.3 shows this dramatic rise in retention of operant responses over the first year and a half.

Even after 2- to 6-month-olds forget an operant response, they need only a brief prompt—an adult who shakes the mobile—to reinstate the memory (Hildreth & Rovee-Collier, 2002). And when 6-month-olds are given a chance to reactivate the response themselves for just a couple of minutes—jiggling the mobile by kicking or moving the train by

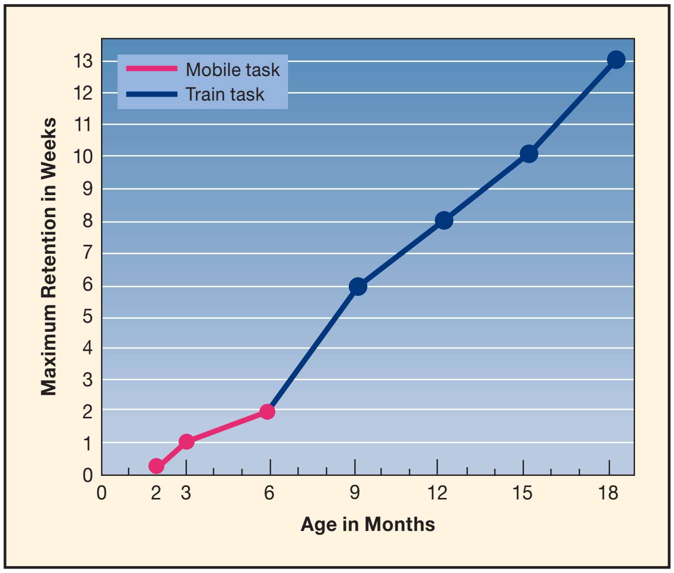


FIGURE 4.3 **Increase in retention of operant responses in two tasks from 2 to 18 months.** Two- to 6-month-olds were trained to make a kicking response that turned a mobile. Six- to 18-month-olds were trained to press a lever that made a toy train move around a track. Six-month-olds learned both responses and retained them for an identical length of time, indicating that the tasks are comparable. Consequently, researchers could plot a single line tracking gains in retention of operant responses from 2 to 18 months of age. The line shows that memory improves dramatically. (From C. Rovee-Collier & R. Barr, 2001, "Infant Learning and Memory," in G. Bremner & A. Fogel, eds., *Blackwell Handbook of Infant Development,* Oxford, U.K.: Blackwell, p. 150. Reprinted by permission of Blackwell Publishing Ltd.)

lever-pressing—their memory not only returns but extends dramatically, to about 17 weeks (Hildreth, Sweeney, & Rovee-Collier, 2003). Furthermore, with just five widely spaced adult-provided reminders of the train task scheduled over 1½ years, babies trained at age 6 months still remembered the response after reaching their second birthday (Hartshorn, 2003).

At first, infants' memory for operant responses is highly *context dependent.* If 2- to 6-month-olds are not tested in the same situation in which they were trained—with the same mobile and crib bumper and in the same room—they remember poorly (Hayne, 2004; Hayne & Rovee-Collier, 1995). This specificity of infant memory also applies to imitation; young babies will imitate adult-modeled actions on a toy only when given a toy identical in color and features to the one the adult used. After 9 months, the importance of context declines. Older infants and toddlers remember how to push a button to make a toy train move or how to make a toy animal emit a sound even when the toy's features are altered and testing takes place in a different room (Hartshorn et al., 1998a; Hayne, Boniface, & Barr, 2000; Learmonth, Lamberth, & Rovee-Collier, 2004). Crawling is strongly associated with 9-month-olds' formation of an increasingly context-free memory (Herbert, Gross, & Hayne, 2007). As babies move on their own and experience frequent changes in context, they apply learned responses more flexibly, generalizing them to relevant new situations.

COURTESY OF CAROLYN ROVEE-COLLIER

This 12-month-old has learned to press a lever to make a toy train move around a track—a response she is likely to remember when re-exposed to the task after increasingly long intervals.

As Chapter 6 will make clear, operant conditioning has also been used to study babies' ability to group similar stimuli into categories. It plays a vital role in the formation of social relationships as well. As the baby gazes into the adult's eyes, the adult looks and smiles back, and then the infant looks and smiles again. The behavior of each partner reinforces the other, so both continue their pleasurable interaction. In Chapter 10, we will see that this contingent responsiveness contributes to the development of infant–caregiver attachment.

Habituation At birth, the human brain is set up to be attracted to novelty. Infants tend to respond more strongly to a new element that has entered their environment, an inclination that ensures that they will continually add to their knowledge base. **Habituation** refers to a gradual reduction in the strength of a response due to repetitive stimulation. Looking, heart rate, and respiration rate may all decline, indicating a loss of interest. Once this has occurred, a new stimulus—a change in the environment—causes the habituated response to return to a high level, an increase called **recovery.** For example, when you walk through a familiar space, you notice things that are new or different—a recently hung picture on the wall or a piece of furniture that has been moved. Habituation and recovery make learning more efficient by focusing our attention on those aspects of the environment we know least about.

Window into Early Attention, Memory, and Knowledge. Researchers studying infants' understanding of the world rely on habituation and recovery more than any other learning capacity. For example, a baby who first *habituates* to a visual pattern (a photo of a baby) and then *recovers* to a new one (a photo of a bald man) appears to remember the first stimulus and perceive the second one as new and different from it. This method of studying infant attention, perception, and memory, illustrated in Figure 4.4a, can be used with newborns, including preterm infants (Kavsek & Bornstein, 2010). It has even been used to study the fetus's sensitivity to external stimuli—for example, by measuring changes in fetal heart rate when various repeated sounds are presented (Dirix et al., 2009). Habituation to an auditory stimulus is evident in the third trimester of pregnancy.

Preterm and newborn babies require a long time—about three or four minutes—to habituate and recover to novel visual stimuli. By 4 or 5 months, however, they need as little as 5 to 10 seconds to take in a complex visual stimulus and recognize it as different from a previous one. Yet a fascinating exception to this trend exists: Two-month-olds actually take

FIGURE 4.4 Using habituation to study infant perception and memory. In the habituation phase, infants view a photo of a baby until their looking declines. In the test phase, infants are again shown the baby photo, but this time it appears alongside a photo of a bald-headed man. (a) When the test phase occurs soon after the habituation phase (within minutes, hours, or days, depending on the age of the infants), participants who remember the baby face and distinguish it from the man's face show a *novelty preference;* they recover to the new stimulus. (b) When the test phase is delayed for weeks or months, infants who continue to remember the baby face shift to a *familiarity preference;* they recover to the familiar baby face rather than to the novel man's face.

longer to habituate to novel visual forms than do newborns and older infants (Colombo, 2002). Later we will see that 2 months is also a time of dramatic gains in visual perception. Perhaps when young babies are first able to perceive certain information, they require more time to take it in. Another factor contributing to the long habituation times of young babies is their difficulty disengaging attention from a stimulus. By 4 months, attention becomes more flexible—a change believed to be due to development of structures in the cerebral cortex controlling eye movements (Blaga & Colombo, 2006; Posner & Rothbart, 2007a). (Nevertheless, as will be apparent shortly, a few babies continue to have trouble shifting attention.)

Recovery to a new stimulus, or *novelty preference,* assesses infants' *recent memory.* **TAKE A MOMENT...** Think about what happens when you return to a place you have not seen for a long time. Instead of attending to novelty, you are likely to focus on aspects that are familiar: "I recognize that. I've been here before!" Like adults, infants shift from a novelty preference to a familiarity preference as more time intervenes between the habituation and test phases in research. That is, babies recover to the familiar stimulus rather than to a novel stimulus (see Figure 4.4b) (Bahrick & Pickens, 1995; Courage & Howe, 1998; Flom & Bahrick, 2010; Richmond, Colombo, & Hayne, 2007). By focusing on that shift, researchers can also use habituation to assess *remote memory,* or memory for stimuli to which infants were exposed weeks or months earlier.

With age, infants detect and remember an extraordinarily wide range of stimuli from the constantly changing flow of objects, actions, and events in their surroundings. They are especially attentive to the movements of objects and people, and they retain such information over many weeks. In one study, 5½-month-old babies habituated to a video in which they saw the face of a woman performing an action (either brushing teeth, blowing bubbles, or brushing hair) (Bahrick, Gogate, & Ruiz, 2002). In a test phase one minute later and again after a seven-week delay, infants watched the familiar video next to a novel video, in which the action changed while the woman's face remained the same. As Figure 4.5 on page 144 indicates, infants clearly remembered the action. At one minute, most showed a *novelty preference,* looking longer at the new action than the old action. But at seven weeks, most showed a *familiarity preference,* looking longer at the familiar action than the new action. In fact, the babies were so attentive to the woman's action that they ignored her face! In an additional test phase assessing face recognition in a novel video (the woman's face changed while her original action remained the same), infants showed no facial preference.

These findings, and others in this chapter, confirm that infants find motion so captivating that they attend to and remember an action far better than the features of the person engaging in it! Later we also will see that

A 5-month-old watches intently as his mother blows bubbles. Infants are captivated by people's actions and remember them for an impressively long time.

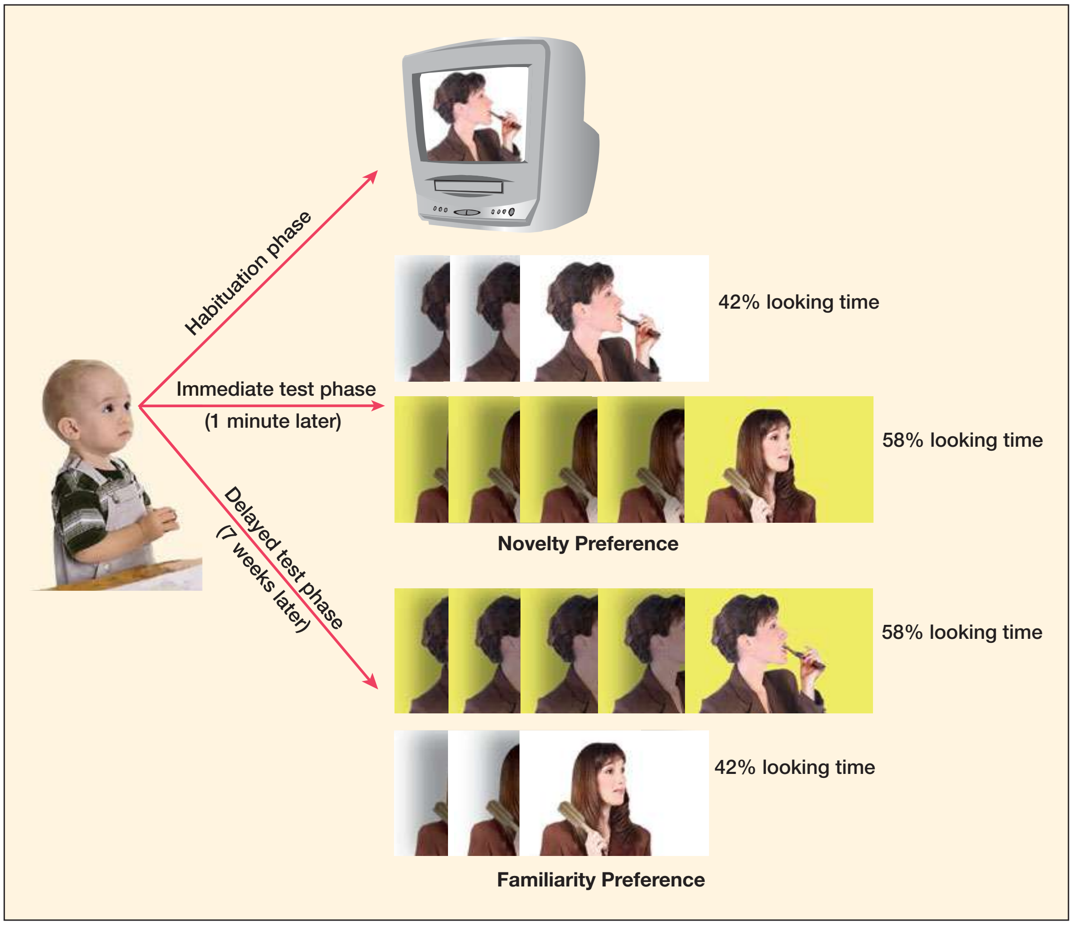

FIGURE 4.5 **Infants' recent and remote memory for human actions.** Infants 5½ months old habituated to a video that showed the face of a woman while she performed an action, such as brushing teeth. In two test phases, they saw the familiar video next to a novel video, in which the action changed—for example, to brushing hair—while the woman's face remained the same. In the *immediate test phase* (one minute later), which assessed *recent memory,* infants displayed a novelty preference; they looked longer at the novel action than the familiar action. In the delayed test phase (seven weeks later), which assessed *remote memory,* infants showed a *familiarity preference;* they looked longer at the familiar action than the novel action. These findings reveal that young infants remember human actions for an impressively long time. (Adapted from Bahrick, Gogate, & Ruiz, 2002.)

babies are excellent at discriminating faces in static displays (such as the ones in Figure 4.4). However, infants' memory for the faces of unfamiliar people and for other static patterns is short-lived—at 3 months, only about 24 hours, and at the end of the first year, several days to a few weeks (Fagan, 1973; Pascalis, de Haan, & Nelson, 1998). In comparison, 3-month-olds' memory for the unusual movements of objects (such as a metal nut tied to the end of a string, swinging back and forth) persists for at least three months (Bahrick, Hernandez-Reif, & Pickens, 1997).

Note that in habituation research, infants retain certain information over much longer time spans than they do in operant conditioning studies (refer again to Figure 4.3 on page 141). Clearly, infants learn and remember a great deal just by watching objects and events around them. They need not be physically active to acquire new information (although, as will become clear later, motor activity facilitates certain aspects of perception and cognition).

Habituation and recovery have been used to assess a wide range of infant perceptual and cognitive capacities—speech perception, musical and visual pattern perception, object perception, categorization, and knowledge of the social world. These studies reveal yet another disparity with operant conditioning research: When assessed through habituation, infant learning is not as *context dependent.* In this and subsequent chapters, we will see many examples of infants' *detection of relationships*—for example, speech sounds that often occur together, objects that belong to the same category, and the match between an object's rhythm and tempo of movement and its sounds. As early as 3 months, infants use their current awareness of relationships to make sense of new information (Bahrick, 2010).

Despite the strengths of habituation research, its findings are not clear-cut. When looking, sucking, or heart rate declines and recovers, what babies actually know about the stimuli to which they responded is sometimes uncertain. We will return to this difficulty in Chapter 6.

Habituation and Later Mental Development. Habituation and recovery to visual stimuli are among the earliest available predictors of intelligence in childhood, adolescence, and young adulthood. Correlations between the speed of these responses in infancy and the mental test scores of 3- to 21-year-olds consistently range from the .30s to the .60s (Fagan, Holland, & Wheeler, 2007; Kavsek, 2004; McCall & Carriger, 1993). In one study, the speed with which fetal startle reactions in the third trimester of pregnancy declined to a repeatedly presented loud sound was modestly associated with cognitive performance (assessed through recovery to novel photos of human faces) at 6 and 9 months of age (Gaultney & Gingras, 2005).

Habituation and recovery seem to be an especially effective early index of intelligence because they assess memory as well as quickness and flexibility of thinking, which underlie intelligent behavior at all ages. Compared with infants who habituate and recover quickly, infants who are "long lookers" on these tasks have difficulty redirecting their attention from one spot to another. Instead of taking in the overall arrangement of a stimulus followed by its finer details, they get stuck on certain small features and, consequently, process much less information (Colombo, 2002; Colombo et al., 2004). When researchers used a red spotlight to induce 5-month-old long lookers to attend to all parts of a complex design, the babies changed their approach and scanned visual stimuli just as "short lookers" do. As a result, they improved in discrimination and memory for visual stimuli (Jankowski, Rose, & Feldman, 2001). Investigators have yet to explore the impact of such early intervention on intellectual development.

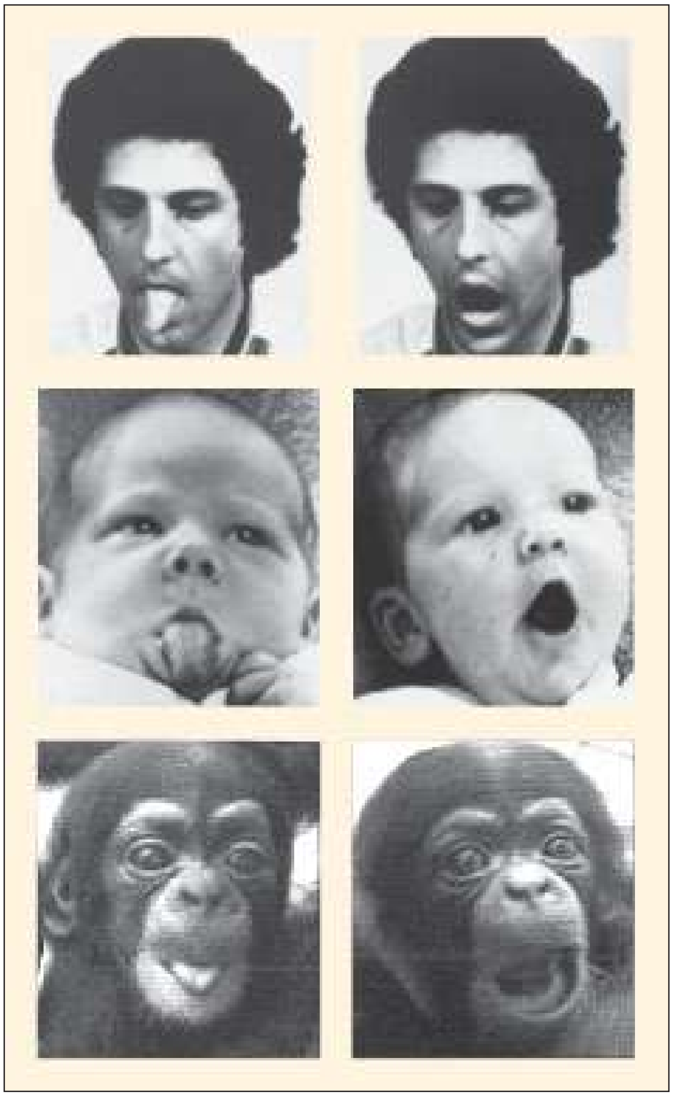
So far, we have considered only one type of memory—*recognition.* It is the simplest form of memory: All the baby has to do is indicate (by looking, kicking, or pressing a lever) whether a new stimulus is identical or similar to a previous one. A second, more challenging form of memory is *recall*—remembering something not present. Can infants engage in recall? By the middle of the first year, they can, as indicated by their ability to find hidden objects and imitate the actions of others hours or days after they observed the behavior. We will take up recall in Chapter 7.

Newborn Imitation

Babies come into the world with a primitive ability to learn through **imitation**—by copying the behavior of another person. For example, Figure 4.6 shows a human newborn imitating two adult facial expressions (Meltzoff & Moore, 1977). The newborn's capacity to imitate extends to certain gestures, such as head and index-finger movements, and has been demonstrated in many ethnic groups and cultures (Meltzoff & Kuhl, 1994; Nagy et al., 2005). As the figure reveals, even newborn chimpanzees, our closest evolutionary ancestors, imitate some behaviors (Myowa-Yamakoshi et al., 2004).

Although newborns' capacity to imitate is widely accepted, a few studies have failed to reproduce the human findings (see Anisfeld, 2005). And because newborn mouth and tongue movements occur with increased frequency to almost any arousing change in stimulation (such as lively music or flashing lights), some researchers argue that certain newborn "imitative" responses are actually mouthing—a common early exploratory response to interesting stimuli (Jones, 2009). Furthermore, imitation is harder to induce in babies 2 to 3 months old than just after birth. Therefore, skeptics believe that the newborn imitative capacity is little more than an automatic response that declines with age, much like a reflex (Heyes, 2005).

FIGURE 4.6 Imitation by human and chimpanzee newborns. The human infants in the middle row imitating (left) tongue protrusion and (right) mouth opening are 2 to 3 weeks old. The chimpanzee imitating both facial expressions is 2 weeks old. (From A. N. Meltzoff & M. K. Moore, 1977, "Imitation of Facial and Manual Gestures by Human Neonates," *Science, 198,* p. 75. Reprinted by permission of the publisher and A. N. Meltzoff. And from M. Myowa-Yamakoshi et al., 2004, "Imitation in Neonatal Chimpanzees [Pan Troglodytes]." *Developmental Science, 7,* p. 440. Copyright © 1977 by AAAS, copyright 2004 by Blackwell Publishing. Reprinted by permission.)



Others claim that newborns imitate a variety of facial expressions and head movements with effort and determination, even after short delays—when the adult is no longer demonstrating the behavior (Hayne, 2002; Meltzoff & Moore, 1999). Furthermore, these investigators argue that imitation—unlike reflexes—does not decline. Human babies several months old often do not imitate an adult's behavior right away because they first try to play familiar social games—mutual gazing, cooing, smiling, and waving their arms. But when an adult models a gesture repeatedly, older human infants soon get down to business and imitate (Meltzoff & Moore, 1994). Similarly, imitation declines in baby chimps around 9 weeks of age, when mother–baby mutual gazing and other face-to-face exchanges increase.

According to Andrew Meltzoff, newborns imitate much as older children and adults do—by actively trying to match body movements they *see* with ones they *feel* themselves make (Meltzoff, 2007). Later we will encounter evidence that young infants are remarkably adept at coordinating information across sensory systems.

Indeed, scientists have identified specialized cells in many areas of the cerebral cortex of primates—called **mirror neurons**—that underlie these capacities. Mirror neurons fire identically when a primate hears or sees an action and when it carries out that action on its own (Rizzolatti & Craighero, 2004). Brain-imaging studies confirm that human adults have especially elaborate systems of mirror neurons, which enable us to observe another person's behavior (such as smiling or throwing a ball) while simulating the behavior in our own brain. Mirror neurons are believed to be the biological basis of a variety of interrelated, complex social abilities, including imitation, empathic sharing of emotions, and understanding others' intentions (Iacoboni, 2009; Schulte-Ruther et al., 2007).

Brain-imaging findings support a functioning mirror-neuron system as early as 6 months of age. Using NIRS, researchers found that the same motor areas of the cerebral cortex were activated in 6-month-olds and in adults when they observed a model engage in a behavior that could be imitated (tapping a box to make a toy pop out) as when they themselves engaged in a motor action (Shimada & Hiraki, 2006). In contrast, when infants and adults observed an object that appeared to move on its own, without human intervention (a ball hanging from the ceiling on a string, swinging like a pendulum), motor areas were not activated.

Still, Meltzoff's view of newborn imitation as a flexible, voluntary capacity remains controversial. Mirror neurons, though possibly functional at birth, undergo an extended period of development (Bertenthal & Longo, 2007; Lepage & Théoret, 2007). Similarly, as we will see in Chapter 6, the capacity to imitate expands greatly over the first two years. But however limited it is at birth, imitation is a powerful means of learning—far faster than individual trial-and-error and discovery (Meltzoff et al., 2009). Using imitation, young infants explore their social world, not only learning from other people but getting to know them by matching their behavioral states. As babies notice similarities between their own and others' actions, they experience other people as "like me" and, thus, learn about themselves (Meltzoff, 2007). In this way, infant imitation may serve as the foundation for understanding others' thoughts and feelings, which we will take up in Chapters 10 and 11. Finally, caregivers take great pleasure in a baby who imitates their facial gestures and actions, which helps get the infant's relationship with parents off to a good start.

ASK YOURSELF

Review ■ Provide an example of classical conditioning, of operant conditioning, and of habituation/recovery in young infants. Why is each type of learning useful? Cite differences between operant conditioning and habituation findings on infant memory.

Connect ■ How do the diverse capacities of newborn babies contribute to their first social relationships? List as many examples as you can.

Apply ■ After a difficult birth, 2-day-old Kelly scores poorly on the NBAS. How would you address her mother's concern that Kelly might not develop normally?

Reflect ■ What is your attitude toward parent–infant cosleeping? Is it influenced by your cultural background?

Motor Development in Infancy

- How does the dynamic systems perspective explain motor development?
- Identify factors that influence gross- and fine-motor development during the first two years.

Virtually all parents eagerly await mastery of new motor skills, recording with pride when their infants first hold up their heads, reach for objects, sit by themselves, and walk alone. Parents' are understandably excited about these achievements, which allow babies to master their bodies and the environment in new ways. For example, sitting upright gives infants a new perspective on the world. Reaching permits babies to find out about objects by acting on them. And when infants can move on their own, their opportunities for exploration multiply.

Babies' motor achievements have a powerful effect on their social relationships. Once infants can crawl, parents start to restrict their activities by saying "no" and expressing mild impatience. Walking often brings the first "testing of wills" (Biringen et al., 1995). Despite her parents' warnings, one newly walking 12-month-old continued to pull items from shelves that were off limits. "I said, 'Don't do that!'" her mother would repeat firmly, taking her toddler's hand and redirecting her attention.

At the same time, newly walking babies more actively attend to and initiate social interaction—seeking out parents for greetings, hugs, or a gleeful game of hide-and-seek, and reaching for, pointing at, and carrying objects of interest to adults (Clearfield, Osborne, & Mullen, 2008; Karasik et al., 2011). Parents, in turn, increase their use of language, playful activities, and expressions of affection. Certain motor skills, such as reaching and pointing, enable infants to communicate more effectively. And when babies encounter risky situations, such as sloping walkways or dangerous objects, parents intervene, combining emotional warnings with rich verbal and gestural information that help infants notice critical features of their surroundings, regulate motor actions, and acquire language (Campos et al., 2000; Karasik et al., 2008). Finally, babies' delight—laughing, smiling, and babbling—as they work on new motor skills triggers pleasurable reactions in others, which encourage infants' efforts further (Mayes & Zigler, 1992). Motor, social, cognitive, and language competencies develop together and support one another.

The Sequence of Motor Development

Gross-motor development refers to control over actions that help infants get around in the environment, such as crawling, standing, and walking. *Fine-motor development* has to do with smaller movements, such as reaching and grasping. The Milestones table on page 148 shows the average age at which U.S. infants and toddlers achieve a variety of gross- and fine-motor skills. It also presents the age range during which most babies accomplish each skill, indicating large individual differences in *rate* of motor progress. Also, a baby who is a late reacher will not necessarily be a late crawler or walker. We would be concerned about a child's development only if many motor skills were seriously delayed.

Historically, researchers assumed that motor skills were separate, innate abilities that emerged in a fixed sequence governed by a built-in maturational timetable. This view has long been discredited. Rather, motor skills are interrelated. Each is a product of earlier motor attainments and a contributor to new ones. And children acquire motor skills in highly individual ways. For example, most Western babies crawl before they pull to a stand and walk. Yet one infant I know, who disliked being placed on her tummy but enjoyed sitting and being held upright, pulled to a stand and walked before she crawled! Babies display such skills as rolling, sitting, crawling, and walking in diverse orders rather than in the sequence implied by motor norms (Adolph, Karasik, & Tamis-LeMonda, 2010).

Many influences—both internal and external to the child—join together to influence the vast transformations in motor competencies of the first two years. The *dynamic systems perspective,* introduced in Chapter 1 (see page 30), helps us understand how motor development takes place.

Milestones

Some Gross- and Fine-Motor Attainments of the First Two Years

MOTOR SKILL	AVERAGE AGE ACHIEVED	AGE RANGE IN WHICH 90 PERCENT OF INFANTS ACHIEVE THE SKILL
When held upright, holds head erect and steady	6 weeks	3 weeks–4 months
When prone, lifts self by arms	2 months	3 weeks–4 months
Rolls from side to back	2 months	3 weeks–5 months
Grasps cube	3 months, 3 weeks	2–7 months
Rolls from back to side	4½ months	2–7 months
Sits alone	7 months	5–9 months
Crawls	7 months	5–11 months
Pulls to stand	8 months	5–12 months
Plays pat-a-cake	9 months, 3 weeks	7–15 months
Stands alone	11 months	9–16 months
Walks alone	11 months, 3 weeks	9–17 months
Builds tower of two cubes	11 months, 3 weeks	10–19 months
Scribbles vigorously	14 months	10–21 months
Walks up stairs with help	16 months	12–23 months
Jumps in place	23 months, 2 weeks	17–30 months
Walks on tiptoe	25 months	16–30 months

Note: These milestones represent overall age trends. Individual differences exist in the precise age at which each milestone is attained.

Motor Skills as Dynamic Systems

According to **dynamic systems theory of motor development,** mastery of motor skills involves acquiring increasingly complex *systems of action*. When motor skills work as a system, separate abilities blend together, each cooperating with others to produce more effective ways of exploring and controlling the environment. For example, control of the head and upper chest combine into sitting with support. Kicking, rocking on all fours, and reaching combine to become crawling. Then crawling, standing, and stepping are united into walking (Adolph & Berger, 2006; Thelen, 1989).

Each new skill is a joint product of the following factors: (1) central nervous system development, (2) the body's movement capacities, (3) the goals the child has in mind, and (4) environmental supports for the skill. Change in any element makes the system less stable, and the child starts to explore and select new, more effective motor patterns. The factors that induce change vary with age. In the early weeks of life, brain and body growth are especially important as infants achieve control over the head, shoulders, and upper torso. Later, the baby's goals (getting a toy or crossing the room) and environmental supports (parental encouragement, objects in the infant's everyday setting) play a greater role.

The broader physical environment also profoundly influences motor skills. Infants with stairs in their home learn to crawl up stairs at an earlier age and also more readily master a back-descent strategy—the safest but also the most challenging position because the baby must turn around at the top, give up visual guidance of her goal, and crawl backward (Berger, Theuring, & Adolph, 2007). And if children were reared on the moon, with its reduced gravity, they would prefer jumping to walking or running!

When a skill is first acquired, infants must refine it. For example, one baby, just starting to crawl, often collapsed on her tummy and moved backward instead of forward. Soon she figured out how to propel herself forward by alternately pulling with her arms and pushing with her feet, "belly-crawling" in various ways for several weeks (Vereijken & Adolph, 1999). As they attempt a new skill, most babies move back and forth between its presence and absence: An infant might roll over, sit, crawl, or take a few steps on Monday but not do so again until Friday, and then not again until the following week. And related, previously mastered skills often become less secure. As the novice walker experiments with balancing the body vertically over two small moving feet, balance during sitting may become temporarily less stable (Adolph & Berger, 2006; Chen et al., 2007). This variability is evidence of loss of stability in the system—in dynamic systems theory, a necessary transition between a less mature and a more mature, stable state.

© GERI ENGBERG/THE IMAGE WORKS

This baby scales a staircase purposefully, determined to reach the top. Still a novice stair climber, she is likely to repeat the ascent many times, experimenting with the skill until her speed and coordination improve.

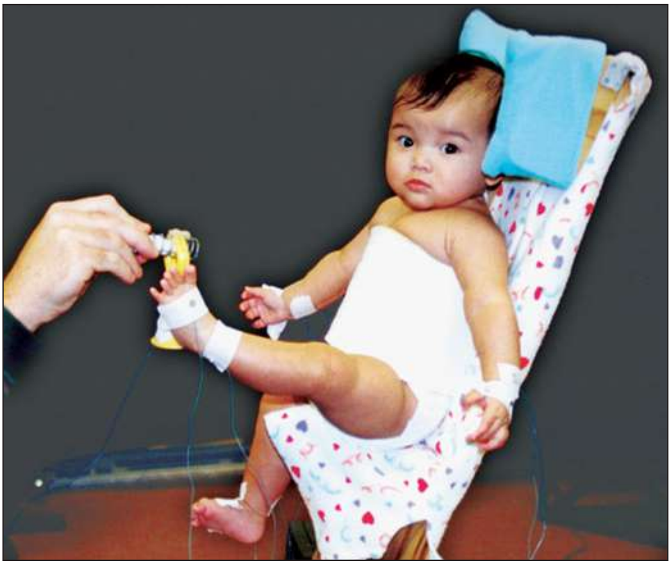
Furthermore, motor mastery involves intense practice. In learning to walk, toddlers practice six or more hours a day, traveling the length of 29 football fields! Gradually their small, unsteady steps change to a longer stride, their feet move closer together, their toes point to the front, and their legs become symmetrically coordinated (Adolph, Vereijken, & Shrout, 2003). As movements are repeated thousands of times, they promote new connections in the brain that govern motor patterns.

Dynamic systems theory shows us why motor development cannot be genetically determined. Because it is motivated by exploration and the desire to master new tasks, heredity can map it out only at a general level. Rather than being *hardwired* into the nervous system, behaviors are *softly assembled,* allowing for different paths to the same motor skill (Adolph, 2008; Thelen & Smith, 2006).

Dynamic Motor Systems in Action

To find out how infants acquire motor capacities, researchers conduct *microgenetic studies* (see Chapter 2, page 64), following babies from their first attempts at a skill until it becomes smooth and effortless. Using this research strategy, James Galloway and Esther Thelen (2004) held sounding toys alternately in front of infants' hands and feet, from the time they first showed interest until they engaged in well-coordinated reaching and grasping. As Figure 4.7 shows, the infants violated the normative sequence of arm and hand control preceding leg and foot control, shown in the Milestones table on page 148. They first explored the toys with their feet—as early as 8 weeks of age, at least a month before reaching with their hands!

Why did babies reach "feet first"? Because the hip joint constrains the legs to move less freely than the shoulder constrains the arms, infants could more easily control their leg movements. Consequently, foot reaching required far less practice than hand reaching. As these findings confirm, rather than following a strict, predetermined cephalocaudal pattern, the order in which motor skills develop depends on the anatomy of the body part being used, the surrounding environment, and the baby's efforts.



© DEXTER GORMLEY/COURTESY OF COLE GALLOWAY, PH.D.

FIGURE 4.7 **Reaching "feet first."** When sounding toys were held in front of babies' hands and feet, they reached with their feet as early as 8 weeks of age, a month or more before they reached with their hands—a clear violation of the cephalocaudal pattern. Reduced freedom of movement in the hip joint makes leg movements easier to control than arm movements. This 2½-month-old skillfully explores an object with her foot.

Cultural Variations in Motor Development Cross-cultural research further illustrates how early movement opportunities and a stimulating environment contribute to motor development. Half a century ago, Wayne Dennis (1960) observed infants in Iranian orphanages who were deprived of the tantalizing surroundings that induce infants to acquire motor skills. These babies spent their days lying on their backs in cribs, without toys to play with. As a result, most did not move on their own until after 2 years of age. When they finally did move, the constant experience of lying on their backs led them to scoot in a sitting position rather than crawl on their hands and knees. Because babies who scoot come up against objects such as furniture with their feet, not their hands, they are far less likely to pull themselves to a standing position in preparation for walking. Indeed, by 3 to 4 years of age, only 15 percent of the Iranian orphans were walking alone.

LOOK and LISTEN

Spend an hour observing a newly crawling or walking baby. Note the goals that motivate the baby to move, along with the baby's effort and motor experimentation. Describe parenting behaviors and features of the environment that promote mastery of the skill.

Cultural variations in infant-rearing practices affect motor development. **TAKE A MOMENT...** Take a quick survey of several parents you know, asking this question: Should sitting, crawling, and walking be deliberately encouraged? Answers vary widely from culture to culture. Japanese mothers, for example, believe such efforts are unnecessary because children "just learn" (Seymour, 1999). Among the Zinacanteco Indians of southern Mexico and Gusii of Kenya, rapid motor progress is actively discouraged. Babies who walk before they know enough to keep away from cooking fires and weaving looms are viewed as dangerous to themselves and disruptive to others (Greenfield, 1992).

In contrast, among the Kipsigis of Kenya and the West Indians of Jamaica, babies hold their heads up, sit alone, and walk considerably earlier than North American infants. In both societies, parents emphasize early motor maturity, practicing formal exercises to stimulate particular skills (Adolph, Karasik, & Tamis-LeMonda, 2010). In the first few months, babies are seated in holes dug in the ground, with rolled blankets to keep them upright. Walking is promoted by frequently standing babies in adults' laps, bouncing them on their feet, and exercising the stepping reflex (see page 130) (Hopkins & Westra, 1988; Super, 1981). As parents in these cultures support babies in upright postures and rarely put them down on the floor, their infants usually skip crawling—a motor skill regarded as crucial in Western nations!

© DON DESPAIR/WWW.REKINDLEPHOTO.COM/ALAMY

This West Indian mother of Jamaica "walks" her baby up her body in a deliberate effort to promote early mastery of walking.

Finally, because it decreases exposure to "tummy time," the current Western practice of having babies sleep on their backs to protect them from SIDS (see page 136) delays gross-motor milestones of rolling, sitting, and crawling (Majnemer & Barr, 2005; Scrutton, 2005). To prevent these delays, caregivers can regularly expose babies to the tummy-lying position during waking hours.

Fine-Motor Development: Reaching and Grasping

Of all motor skills, reaching may play the greatest role in infant cognitive development. By grasping things, turning them over, and seeing what happens when they are released, infants learn a great deal about the sights, sounds, and feel of objects.

Reaching and grasping, like many other motor skills, start out as gross, diffuse activity and move toward mastery of fine movements. Figure 4.8 illustrates some milestones of reaching over the first nine months. Newborns will actively work to bring their hands into their field of vision: In a dimly lit room, they keep their hand within a narrow beam of light, moving the hand when the light beam moves (van der Meer, 1997). Newborns also make poorly coordinated swipes, called **prereaching,** toward an object in front of them, but because of poor arm and hand control they rarely contact the object. Like newborn reflexes, prereaching drops out around 7 weeks of age, when babies improve in eye movements involved in tracking and fixating on objects, which are essential for accurate reaching. Yet these early behaviors suggest that infants are biologically prepared to coordinate hand with eye in the act of exploring (Rosander & von Hofsten, 2002; von Hofsten, 2004).

FIGURE 4.8 **Some milestones of reaching and grasping.** The average age at which each skill is attained is given. (Ages from Bayley, 1969; Rochat, 1989.)

Development of Reaching and Grasping

At about 3 to 4 months, as infants develop the necessary eye, head, and shoulder control, reaching reappears as purposeful, forward arm movements in the presence of a nearby toy and gradually improves in accuracy (Bhat, Heathcock, & Galloway, 2005; Spencer et al., 2000). By 5 to 6 months, infants reach for an object in a room that has been darkened during the reach by switching off the lights—a skill that improves over the next few months (Clifton et al., 1994; McCarty & Ashmead, 1999). This indicates that the baby does not need to use vision to guide the arms and hands in reaching. Rather, reaching is largely controlled by *proprioception*—our sense of movement and location in space, arising from stimuli within the body. When vision is freed from the basic act of reaching, it can focus on more complex adjustments, such as fine-tuning actions to fit the distance and shape of objects.

Reaching improves as depth perception advances and as infants gain greater control of body posture and arm and hand movements. Four-month-olds aim their reaches ahead of a moving object so they can catch it (von Hofsten, 1993). Around 5 months, babies reduce their efforts when an object is moved beyond their reach (Robin, Berthier, & Clifton, 1996). By 7 months, the arms become more independent: Infants reach for an object by extending one arm, rather than both (Fagard & Pezé, 1997). During the next few months, infants become more efficient at reaching for moving objects—ones that spin, change direction, and move sideways, closer, or farther away (Fagard, Spelke, & von Hofsten, 2009; Wentworth, Benson, & Haith, 2000).

Once infants can reach, they modify their grasp. The newborn's grasp reflex is replaced by the **ulnar grasp,** a clumsy motion in which the baby's fingers close against the palm. Still, even 4-month-olds adjust their grasp to the size and shape of an object—a capacity that improves over the first year as infants orient the hand more precisely and do so in advance of contacting the object (Barrett, Traupman, & Needham, 2008; Witherington, 2005). Around 4 to 5 months, when infants begin to sit up, both hands become coordinated in exploring objects. Babies of this age can hold an object in one hand while the other scans it with the tips of the fingers, and they frequently transfer objects from hand to hand (Rochat & Goubet, 1995). By the end of the first year, infants use the thumb and index finger in a well-coordinated **pincer grasp.** Then the ability to manipulate objects greatly expands. The 1-year-old can pick up raisins and blades of grass, turn knobs, and open and close small boxes.

Between 8 and 11 months, reaching and grasping are well-practiced. As a result, attention is released from the motor skill to events that occur before and after obtaining the object. For example, 10-month-olds easily modify their reach to anticipate their next action. They reach for a ball faster when they intend to throw it than when they intend to drop it carefully through a narrow tube (Claxton, Keen, & McCarty, 2003). Around this time, too, infants begin to solve simple problems that involve reaching, such as searching for and finding a hidden toy.

Finally, the capacity to reach for and manipulate an object increases infants' attention to the way an adult reaches for and plays with that same object (Hauf, Aschersleben, & Prinz, 2007). Perhaps with the aid of mirror neurons (see page 146), babies match their own active experience of reaching to their perception of others' actions. As a result, they broaden their understanding of others' behaviors and—as they watch what others do—of the range of actions that can be performed on various objects.

Early Experience and Reaching Like other motor milestones, early experience affects reaching. In cultures where mothers carry their infants on their hips or in slings for most of the day, babies have rich opportunities to explore with their hands. Among the !Kung of Botswana, Africa, infants grasp their mothers' colorful, beaded necklaces to steady themselves while breastfeeding as the mother moves. While riding along, they also frequently swipe at and manipulate their mother's jewelry and other dangling objects (Konner, 1977). As a result, !Kung infants are advanced in development of reaching and grasping. And because babies of Mali and Uganda spend half or more of their day held in sitting or standing positions, which facilitate reaching, they, too, develop manual skills earlier than Western infants, who spend much of their day lying down (Adolph, Karasik, & Tamis-LeMonda, 2010).

Babies' visual surroundings are also influential. In a well-known study, institutionalized infants given a moderate amount of visual stimulation—at first, simple designs and, later, a mobile hung over their crib—reached for objects six weeks earlier than infants given nothing to look at. A third group given massive stimulation—patterned crib bumpers and mobiles at an early age—also reached sooner than unstimulated babies. But this heavy enrichment took a toll: These infants looked away and cried a great deal, and they were less advanced in reaching than the moderately stimulated group (White & Held, 1966). These findings remind us that more stimulation is not necessarily better. Trying to push infants beyond their current readiness to handle stimulation can undermine the development of important motor skills. We will return to this theme at the end of this chapter, and in Chapter 5, where we consider brain development.

ASK YOURSELF

Review ■ Cite evidence that motor development is a joint product of biological, psychological, and environmental factors.

Connect ■ Provide several examples of how motor development supports infants' attainment of cognitive and social competencies.

Apply ■ List everyday experiences that promote infants' mastery of reaching, grasping, sitting, and crawling. Why should caregivers place young infants in a variety of waking-time body positions?

Reflect ■ Do you favor early, systematic training of infants in motor skills such as crawling, walking, and stair climbing? Why or why not?

- Describe the newborn baby's sensitivty to touch, taste, smell, and sound, noting changes during infancy.
- Describe the development of vision in infancy, with special emphasis on depth, pattern, face, and object perception.

Perceptual Development in Infancy

TAKE A MOMENT... List research findings in previous sections that illustrate the close link between perception and action in babies' discovery of new skills. To reach for and manipulate objects, maintain balance, or move across various surfaces, infants must continually coordinate their motor behavior with perceptual information. Acting and perceiving are not separate aspects of experience. Instead, motor activity is a vital means for exploring and learning about the world, and improved perception brings about more effective motor activity. The union of perceptual and motor information is basic to our nervous systems, and each domain supports development of the other (Adolph & Berger, 2006; von Hofsten, 2004).

What can young infants perceive with their senses, and how does perception change with age? Researchers have sought answers to these questions for two reasons. First, studies of infant perception reveal in what ways babies are biologically prepared to perceive their world, and how brain development and experience expand their capacities. Second, infant perception sheds light on other aspects of development. For example, because touch, vision, and hearing enable us to interact with others, they are basic to emotional and social development. Through hearing, language is learned. And because knowledge of the world is first gathered through the senses, perception provides the foundation for cognitive development.

Studying infant perception is especially challenging because babies cannot describe their experiences. Fortunately, investigators can make use of a variety of nonverbal responses that vary with stimulation, such as looking, sucking, head turning, facial expressions, and reaching. As noted earlier, researchers also rely on operant conditioning and habituation to find out whether infants can make certain discriminations. And eye-movement tracking, in which researchers examine infants' inspection of stimuli, attention to particular features, and gaze-shifting as stimuli move along various trajectories, has revealed much about infant visual capacities. Neurobiological measures—such as stimulus-induced changes in respiration, heart rate, and brain activity (using ERPs and NIRS)—are also used. We will see examples of these methods as we explore the baby's sensitivity to touch, taste, smell, sound, and visual stimulation.

- ▶ Describe how intermodal perception develops during infancy.
- ▶ How does differentiation theory explain perceptual development?

Touch

Touch is a fundamental means of interaction between parents and babies. Within the first few days, mothers can recognize their own newborn by stroking the infant's cheek or hand (Kaitz et al., 1993). Touch helps stimulate early physical growth (see Chapter 3), and it is vital for emotional development. Therefore, it is not surprising that sensitivity to touch is well-developed at birth.

The reflexes listed in Table 4.1 on page 130 reveal that the newborn baby responds to touch, especially around the mouth, on the palms, and on the soles of the feet. During the prenatal period, these areas, along with the genitals, are the first to become sensitive to touch (Humphrey, 1978; Streri, 2005).

At birth, infants are quite sensitive to pain. If male newborns are circumcised, anesthetic is sometimes not used because of the risk of giving drugs to a very young infant. Babies often respond to pain with a high-pitched, stressful cry and a dramatic rise in heart rate, blood pressure, palm sweating, pupil dilation, and muscle tension (Lehr et al., 2007; Warnock & Sandrin, 2004). Measures of brain activity during painful medical procedures, using ERP and NIRS, reveal that preterm and male babies show intense activation of sensorimotor areas in the cerebral cortex (Bartocci et al., 2006; Slater et al., 2010). Because of central nervous system immaturity, these infants seem to feel pain especially intensely.

Recent research establishing the safety of certain local anesthetics for newborns promises to ease the pain of medical procedures. Offering a nipple that delivers a sugar solution is also helpful; it quickly reduces crying and discomfort in young babies, preterm and full-term alike. Breast milk may be especially effective: Even the smell of the milk of the baby's mother reduces infant distress to a routine blood-test heelstick more effectively than the odor of another mother's milk or of formula (Nishitani et al., 2009). And combining sweet liquid with gentle holding by the parent lessens pain even more. Research on infant mammals indicates that physical touch releases *endorphins*—painkilling chemicals in the brain (Axelin, Salanterä, & Lehtonen, 2006; Gormally et al., 2001).

Allowing a baby to endure severe pain overwhelms the nervous system with stress hormones, which can disrupt the child's developing capacity to handle common, everyday stressors. The result is heightened pain sensitivity, sleep disturbances, feeding problems, and difficulty calming down when upset (Mitchell & Boss, 2002).

© LAURA DWIGHT PHOTOGRAPHY

This 6-month-old uses touch to investigate an object, turning the ball between her palms and examining its unusual texture with her fingertips while staring at it intently.

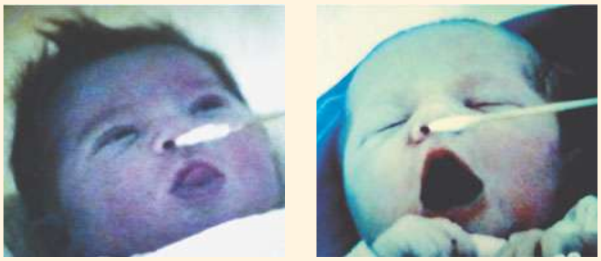
Gentle touching, in contrast, enhances babies' positive responsiveness to their physical and social surroundings. An adult's soft caresses induce infants to smile and become more attentive to the adult's face (Stack & Muir, 1992). And parents vary their style of touching, depending on whether the goal of their interaction is to comfort, convey affection, or induce smiling, attention, or play in their baby (Jean & Stack, 2009; Stack 2010).

Even newborns use touch to investigate their world. Using their palms, they can distinguish the shapes (prism versus cylinder) and textures (smooth versus rough) of small objects, as indicated by their tendency to hold on longer to an object with an unfamiliar shape or texture than to a familiar object (Sann & Streri, 2008; Streri, Lhote, & Dutilleul, 2000). As reaching develops, babies frequently run their lips and tongue over the surface of novel objects, then remove the object to look at it. This exploratory mouthing peaks in the middle of the first year as hand–mouth contact becomes more accurate (Lew & Butterworth, 1997). Then it declines in favor of more elaborate touching with the hands, in which infants turn, poke, and feel the surface of things while looking at them intently (Ruff et al., 1992).

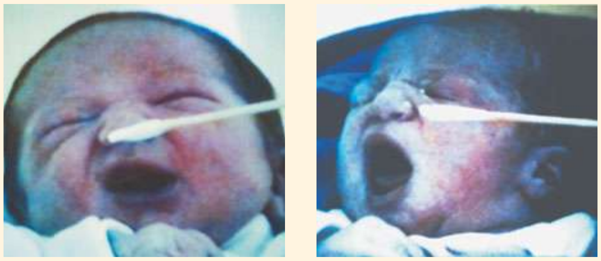
Taste and Smell

Facial expressions reveal that newborns can distinguish several basic tastes. Like adults, they relax their facial muscles in response to sweetness, purse their lips when the taste is sour, and show a distinct archlike mouth opening when it is bitter (Steiner, 1979; Steiner et al., 2001). These reactions are important for survival: The food that best supports the infant's early growth is the sweet-tasting milk of the mother's breast. Not until 4 months do babies prefer a salty taste to plain water, a change that may prepare them to accept solid foods (Mennella & Beauchamp, 1998).

Nevertheless, newborns can readily learn to like a taste that at first evoked either a neutral or a negative response. For example, babies allergic to cow's-milk formula who are given a soy- or other vegetable-based substitute (typically very strong and bitter-tasting) soon prefer it to regular formula. A taste previously disliked can come to be preferred when it is paired with relief of hunger (Harris, 1997).



(a) Responses by newborns of anise-consuming mothers



(b) Responses by newborns of non-anise-consuming mothers

FIGURE 4.9 **Examples of facial expressions of newborns exposed to the odor of anise whose mothers' diets differed in anise-flavored foods during late pregnancy.** (a) Babies of anise-consuming mothers spent more time turning toward the odor and sucking, licking, and chewing. (b) Babies of non-anise-consuming mothers more often turned away with a negative facial expression. (From B. Schaal, L. Marlier, & R. Soussignan, 2000, "Human Foetuses Learn Odours from Their Pregnant Mother's Diet," *Chemical Senses, 25,* p. 731. © Oxford University Press 2000. Reprinted by permission of Oxford University Press.)

As with taste, certain odor preferences are present at birth. For example, the smell of bananas or chocolate causes a relaxed, pleasant facial expression, whereas the odor of rotten eggs makes the infant frown (Steiner, 1979). During pregnancy, the amniotic fluid is rich in tastes and smells that vary with the mother's diet—early experiences that influence newborns' preferences. In a study carried out in the Alsatian region of France, where anise is frequently used to flavor foods, researchers tested newborns for their reaction to the anise odor (Schaal, Marlier, & Soussignan, 2000). The mothers of some babies had regularly consumed anise during the last two weeks of pregnancy; the other mothers had never consumed it. When presented with the anise odor on the day of birth, the babies of the anise-consuming mothers spent more time turning toward the odor. In contrast, infants of non-anise-consuming mothers were far more likely to turn away with a negative facial expression (see Figure 4.9). These different reactions were still apparent four days later, even though all mothers had refrained from consuming anise during this time.

In many mammals, the sense of smell plays an important role in protecting the young from predators by helping mothers and babies identify each other. Although smell is less well-developed in humans, traces of its survival value remain.

Immediately after birth, infants placed face down between their mother's breasts spontaneously latch on to a nipple and begin sucking within an hour. If one breast is washed to remove its natural scent, most newborns move toward the unwashed breast, indicating that they are guided by smell (Varendi & Porter, 2001). At 4 days of age, breastfed babies prefer the smell of their own mother's breast to that of an unfamiliar lactating woman (Cernoch & Porter, 1985). And both breast- and bottle-fed 3- to 4-day-olds orient more and display more mouthing to the smell of unfamiliar human milk than to formula milk, indicating that (even without postnatal exposure) the odor of human milk is more attractive to newborns (Marlier & Schaal, 2005). Newborns' dual attraction to the odors of their mother and of breast milk helps them locate an appropriate food source and, in the process, distinguish their caregiver from other people.

Hearing

Although conduction of sound through structures of the ear and transmission of auditory information to the brain are inefficient at birth, newborn infants can hear a wide variety of sounds—sensitivity that improves greatly over the first few months (Saffran, Werker, & Werner, 2006; Tharpe & Ashmead, 2001). Responsiveness to sound provides support for the young baby's exploration of the environment. Infants as young as 3 days old turn their eyes and head in the general direction of a sound. The ability to identify the precise location of a sound improves greatly over the first six months and shows further gains through the preschool years (Litovsky & Ashmead, 1997).

At birth, infants prefer complex sounds, such as noises and voices, to pure tones. And babies only a few days old can tell the difference between a variety of sound patterns: a series of tones arranged in ascending versus descending order; tone sequences with a rhythmic downbeat (as in music) versus those without; utterances with two versus three syllables; the stress patterns of words, such as "*ma*-ma" versus "ma-*ma*"; and even two languages spoken by the same bilingual speaker, as long as those languages differ in their rhythmic features—for example, French versus Russian (Mastropieri & Turkewitz, 1999; Ramus, 2002; Sansavini, Bertoncini, & Giovanelli, 1997; Trehub, 2001; Winkler et al., 2009).

Over the first year, infants organize sounds into increasingly elaborate patterns. Around 2 to 4 months, they can distinguish changes in tempo—the same tone sequence played slightly faster (Baruch & Drake, 1997). Between 4 and 7 months, they show a sense of musical phrasing. They prefer Mozart minuets with pauses between phrases to those with awkward breaks (Krumhansl & Jusczyk, 1990). Around 6 to 7 months, they can distinguish musical tunes on the basis of variations in rhythmic patterns, including beat structure (duple or triple) and accent structure (emphasis on the first note of every beat unit or at other positions) (Hannon & Johnson, 2004). And by the end of the first year, infants recognize the same melody when it is played in different keys (Trehub, 2001). As we will see shortly, 6- to 12-month-olds make comparable discriminations in human speech: They readily detect sound regularities that will facilitate later language learning.

Speech Perception

Young infants listen longer to human speech than to structurally similar nonspeech sounds (Vouloumanos, 2010). And they can detect the sounds of any human language. Newborns make fine-grained distinctions among many speech sounds. For example, when given a nipple that turns on the "*ba*" sound, babies suck vigorously for a while and then habituate. When the sound switches to "*ga,*" sucking picks up, indicating that infants detect this subtle difference. Using this method, researchers have found only a few speech sounds that newborns cannot discriminate. Their ability to perceive sounds not found in their own language is more precise than an adult's (Aldridge, Stillman, & Bower, 2001; Jusczyk & Luce, 2002).

TAKE A MOMENT... Listen carefully to yourself the next time you talk to a young baby. You will probably speak in ways that highlight important parts of the speech stream—use a slow, clear, high-pitched, expressive voice with a rising tone at the end of phrases and sentences and a pause before continuing. Adults probably communicate this way because they notice that infants are more attentive when they do so. Indeed, newborns prefer speech with these characteristics, in part because it eases their perceptual learning (Saffran, Werker, & Werner, 2006). In addition, they will suck more on a nipple to hear a recording of their own mother's voice than that of an unfamiliar woman and to hear their native language as opposed

BIOLOGY and ENVIRONMENT

"Tuning In" to Familiar Speech, Faces, and Music: A Sensitive Period for Culture-Specific Learning

To share experiences with members of their family and community, babies must become skilled at making perceptual discriminations that are meaningful in their culture. As we have seen, at first babies are sensitive to virtually all speech sounds, but around 6 months, they narrow their focus, limiting the distinctions they make to the language they hear and will soon learn to speak.

The ability to perceive faces shows a similar **perceptual narrowing effect**—perceptual sensitivity that becomes increasingly attuned with age to information most often encountered. After habituating to one member of each pair of faces in Figure 4.10, 6-month-olds were shown the familiar and novel faces side by side. For both pairs, they recovered to (looked longer at) the novel face, indicating that they could discriminate individual faces of both humans and monkeys equally well (Pascalis, de Haan, & Nelson, 2002). But at 9 months, infants no longer showed a novelty preference when viewing the monkey pair. Like adults, they could distinguish only the human faces.

The perceptual narrowing effect appears again in musical rhythm perception. Western adults are accustomed to the even-beat pattern of Western music—repetition of the same rhythmic structure in every measure of a tune—and easily notice rhythmic changes that disrupt this familiar beat. But present them with music that does not follow this typical Western rhythmic form—Baltic folk tunes, for example—and they fail to pick up on rhythmic-pattern deviations. Six-month-olds, however, can detect such disruptions in both Western and non-Western melodies. But by 12 months, after added exposure to Western music, babies are no longer aware of deviations in foreign musical rhythms, although their sensitivity to Western rhythmic structure remains unchanged (Hannon & Trehub, 2005b).

Several weeks of regular interaction with a foreign-language speaker and of daily opportunities to listen to non-Western music fully restore 12-month-olds' sensitivity to wide-ranging speech sounds and music rhythms (Hannon & Trehub, 2005a; Kuhl, Tsao, & Liu, 2003). Similarly, 6-month-olds given three months of training in discriminating individual monkey faces, in which each image is labeled with a distinct name ("Carlos," "Iona") instead of the generic label "monkey," retain their ability to discriminate monkey faces at 9 months (Scott & Monesson, 2009). Adults given similar extensive experiences, by contrast, show little improvement in perceptual sensitivity.

Taken together, these findings suggest a heightened capacity—or sensitive period—in the second half of the first year, when babies are biologically prepared to "zero in" on socially meaningful perceptual distinctions. Notice how, between 6 and 12 months, learning is especially rapid across several domains (speech, faces, and music) and is easily modified by experience. This suggests a broad neurological change—perhaps a special time of brain development in which babies analyze everyday stimulation of all kinds similarly, in ways that prepare them to participate in their cultural community.

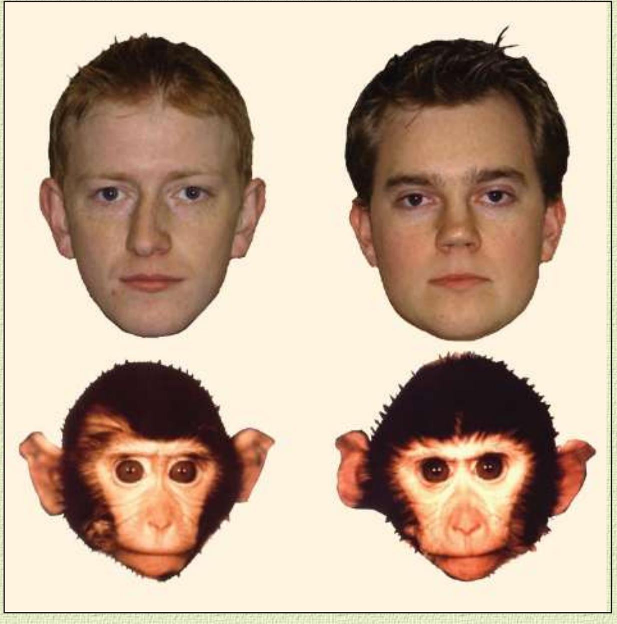


FIGURE 4.10 **Discrimination of human and monkey faces.** Which of these pairs is easiest for you to tell apart? After habituating to one of the photos in each pair, infants were shown the familiar and the novel face side-by-side. For both pairs, 6-month-olds recovered to (looked longer at) the novel face, indicating that they could discriminate human and monkey faces equally well. By 12 months, babies lost their ability to distinguish the monkey faces. Like adults, they showed a novelty preference only to human stimuli. (From O. Pascalis et al., 2002, "Is Face Processing Species-Specific During the First Year of Life?" *Science, 296,* p. 1322. Copyright © 2002 by AAAS. Reprinted with permission from AAAS.)

to a foreign language (Moon, Cooper, & Fifer, 1993; Spence & DeCasper, 1987). These preferences may have developed from hearing the muffled sounds of the mother's voice before birth.

Over the first year, infants learn much about the organization of sounds in their native language. As they listen to people talking, they learn to focus on meaningful sound variations. ERP brain-wave recordings reveal that around 5 months, babies become sensitive to syllable stress patterns in their own language (Weber et al., 2004). Between 6 and 8 months, they start to "screen out" sounds not used in their native tongue (Anderson, Morgan, & White, 2003; Polka & Werker, 1994). As the Biology and Environment box above explains, this increased responsiveness to native-language sounds is part of a general "tuning" process in the second half of the first year—a possible sensitive period in which babies acquire a range of perceptual skills for picking up socially important information.

Soon after, infants focus on larger speech units that are critical to figuring out meaning. They recognize familiar words in spoken passages and listen longer to speech with clear clause and phrase boundaries (Johnson & Seidl, 2008; Jusczyk & Hohne, 1997; Soderstrom et al., 2003). Around 7 to 9 months, infants extend this sensitivity to speech structure to individual words. They begin to divide the speech stream into wordlike units (Jusczyk, 2002; Saffran, Werker, & Werner, 2006).

Analyzing the Speech Stream How do infants make such rapid progress in perceiving the structure of language? Research shows that they have an impressive **statistical learning capacity.** By analyzing the speech stream for patterns—repeatedly occurring sequences of sounds—they acquire a stock of speech structures for which they will later learn meanings, long before they start to talk around age 12 months.

In one set of studies, researchers had 8- and 9-month-olds listen to a continuous sequence of nonsense syllables. Then they gave the babies brief, new syllable sequences; some conformed to the syllable patterns in the original sequence, while others did not. The babies quickly inferred syllable structure: They preferred to listen to new speech that preserved the original syllable patterns. In other words, they listened for statistical regularities, discriminating syllables that often occur together (indicating that they belong to the same word) from syllables that seldom occur together (indicating a word boundary). To cite an English example, consider the word sequence *pretty#baby.* After listening to the speech stream for just one minute (about 60 words), babies can distinguish a word-internal syllable pair *(pretty)* from a word-external syllable pair *(ty#ba)* (Saffran, Aslin, & Newport, 1996; Saffran & Thiessen, 2003).

Once infants locate words, they focus on the words and (as we will see in Chapter 9) detect syllable-stress regularities—for example, in English and Dutch, that the onset of a strong syllable (*hap*-py, *rab*-bit) often signals a new word (Swingley, 2005; Thiessen & Saffran, 2007). By 10 months, infants can detect words that start with weak syllables, such as "sur*prise,*" by listening for sound regularities before and after the words (Jusczyk, 2001; Kooijman, Hagoort, & Cutler, 2009).

Infants also attend to regularities in word sequences. In a study using nonsense words, 7-month-olds distinguished the ABA structure of *"ga ti ga"* and *"li na li"* from the ABB structure of *"wo fe fe"* and *"ta la la"* (Marcus et al., 1999). They seemed to detect simple word-order rules—a capacity that may help them figure out basic grammar. After extracting these rules, babies generalize them to nonspeech sounds. Seven-month-olds who were exposed to regularities in sequences of nonsense words could identify similar patterns in strings of musical tones and animal sounds. But when presented alone, these stimuli yielded no rule learning (Marcus, Fernandes, & Johnson, 2007). Analyzing speech seems to help babies structure other aspects of their auditory world.

Clearly, babies have a powerful ability to extract regularities from complex, continuous speech. Some researchers believe infants are innately equipped with a general statistical learning capacity for detecting structure in the environment, which they also apply to visual stimulation (Kirkham, Slemmer, & Johnson, 2002). Indeed, because communication is often multisensory (simultaneously verbal, visual, and tactile), infants receive much support from other senses in analyzing speech. When mothers speak to 5- to 8-month-olds, they often provide temporal synchrony between words, object motions, and touch—for example, saying "doll" while moving a doll and, sometimes, having the doll touch the infant (Gogate, Bahrick, & Watson, 2000). In doing so, they create a supportive learning environment: In two studies, 7-month-olds remembered associations between sounds and objects only when they heard the sound and saw the object move simultaneously (Gogate & Bahrick, 1998, 2001).

Finally, infants' special responsiveness to speech encourages parents to talk to their baby. Doing so strengthens infants' language

© FRANK AND HELENA/CULTURA/CORBIS

Parents often name a toy or other object—for example, saying "bear"—while moving the toy and, sometimes, having it touch the infant. This multisensory communication helps babies associate words with objects.

Milestones

Development of Touch, Taste, Smell, and Hearing

AGE	TOUCH	TASTE AND SMELL	HEARING
Birth	- Responds to touch and pain. - Distinguishes shape of object placed in palm. 	- Distinguishes sweet, sour, and bitter tastes; prefers sweetness. - Distinguishes odors; prefers those of sweet-tasting foods. - Prefers smell of own mother's amniotic fluid and the lactating breast.	- Prefers complex sounds to pure tones. - Distinguishes some sound patterns. - Prefers listening to own mother's voice over unfamiliar woman's voice, and to native language as opposed to foreign language. - Makes subtle distinctions between almost all speech sounds, including sounds not found in own language. - Turns eyes and head in the general direction of a sound.
1–6 months	- Frequently engages in exploratory mouthing of objects. 	- Prefers a salty taste to plain water. - Readily changes taste preferences through experience. 	- Prefers listening to human speech over structurally similar nonspeech sounds. - Organizes sounds into increasingly elaborate patterns, such as musical phrases. - Identifies location of a sound more precisely. - By the end of this period, becomes sensitive to syllable stress patterns in own language.
7–12 months			- Recognizes the same melody played in different keys. - "Screens out" sounds not used in native language. - Detects speech units crucial to understanding meaning, including familiar words and regularities in sound and word sequences.

Note: These milestones represent overall age trends. Individual differences exist in the precise age at which each milestone is attained.

processing. The opportunity to view an adult's face while she says two similar native-language sounds facilitates 6-month-olds' sound discrimination (Teinonen et al., 2008). Similarly, at first, infants depend on the union of auditory and visual stimuli to pick up emotional information in speech. Three- and 4-month-olds can distinguish happy- from sad-sounding speech, but only while looking at people's faces. Later, babies can discriminate positive from negative emotion in each sensory modality—first voices, then faces (Walker-Andrews, 1997).

Before we turn to visual development, consult the Milestones table above for a summary of the perceptual capacities we have just considered.

Vision

For exploring the environment, humans depend on vision more than any other sense. At birth, however, vision is the least developed of the senses. Visual structures in both the eye and the brain are not yet fully formed. For example, cells in the *retina,* the membrane lining

FIGURE 4.11 View of the human face by the newborn and the adult. The newborn baby's limited focusing ability and poor visual acuity lead the mother's face, even when viewed from close up, to look more like the fuzzy image in (a) than the clear image in (b). Also, newborn infants have some color vision, although they have difficulty discriminating colors. Researchers speculate that colors probably appear similar, but less intense, to newborns than they do to older infants and adults. (From Kellman & Arterberry, 2006; Slater et al., 2010.)

the inside of the eye that captures light and transforms it into messages that are sent to the brain, are not as mature or densely packed as they will be in several months. The optic nerve that relays these messages, and visual centers in the brain that receive them, will not be adultlike for several years. And the muscles of the *lens,* which permit us to adjust our focus to varying distances, are weak (Kellman & Arterberry, 2006).

As a result, newborns cannot focus their eyes well, and their **visual acuity,** or fineness of discrimination, is limited. At birth, infants perceive objects at a distance of 20 feet about as clearly as adults do at 600 feet (Slater et al., 2010). In addition, unlike adults (who see nearby objects most clearly), newborn babies see unclearly across a wide range of distances (Banks, 1980; Hainline, 1998). As a result, images such as the parent's face, even close up, look like the blurry image in Figure 4.11. And despite their preference for colored over gray stimuli, newborn babies are not yet good at discriminating colors (Kellman & Arterberry, 2006).

The visual system develops rapidly over the first few months. Around 2 months, infants can focus on objects about as well as adults; by 4 months, color discrimination is adultlike (Kellman & Arterberry, 2006). Visual acuity improves rapidly, reaching 20/80 by 6 months and an adult level of about 20/20 by 4 years (Slater et al., 2010).

Although they cannot yet see well, newborns actively explore their environment by scanning it for interesting sights and tracking moving objects. However, their eye movements are slow and inaccurate. Scanning and tracking improve over the first half-year as infants see more clearly and better control their eye movements. In addition, as young infants build an organized perceptual world, they scan more thoroughly and systematically, strategically picking up important information and anticipating with their eye movements what they expect to happen next in a series of events (Haith, 1994; Johnson, Slemmer, & Amso, 2004; von Hofsten et al., 1998). Consequently, scanning enhances perception, and—in bidirectional fashion—perception also enhances scanning.

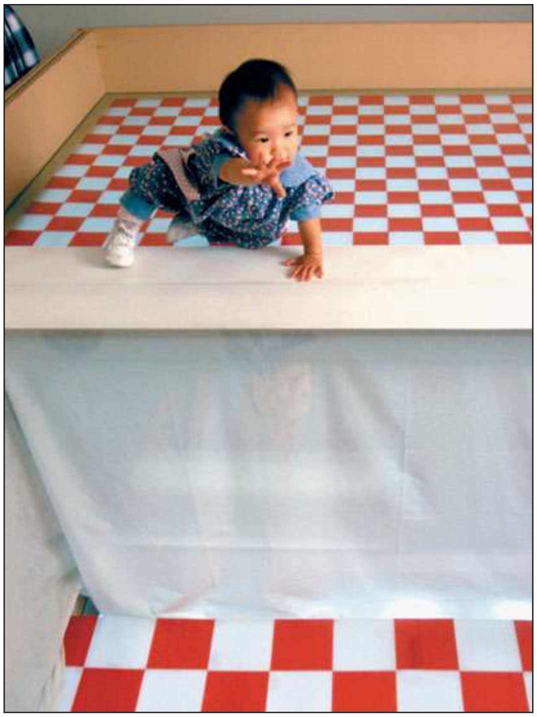
As infants explore their visual field, they figure out the characteristics of objects and how they are arranged in space. To understand how they do so, let's examine the development of three aspects of vision: depth, pattern, and object perception.

Depth Perception

Depth perception is the ability to judge the distance of objects from one another and from ourselves. It is important for understanding the layout of the environment and for guiding motor activity.

Figure 4.12 shows the well-known **visual cliff,** designed by Eleanor Gibson and Richard Walk (1960) and used in the earliest studies of depth perception. It consists of a Plexiglas-covered table with a platform at the center, a "shallow" side with a checkerboard pattern just under the glass, and a "deep" side with a checkerboard several feet below the glass. The researchers found that crawling babies readily crossed the shallow side, but

FIGURE 4.12 The visual cliff. Plexiglas covers the deep and shallow sides. By refusing to cross the deep side and showing a preference for the shallow side, this infant demonstrates the ability to perceive depth.



© MARK RICHARDS/PHOTOEDIT

most avoided the deep side. They concluded that around the time that infants crawl, most distinguish deep from shallow surfaces and avoid drop-offs.

The visual cliff shows that crawling and avoidance of drop-offs are linked, but not how they are related or when depth perception first appears. Recent research has looked at babies' ability to detect specific depth cues, using methods that do not require that they crawl.

Emergence of Depth Perception. How do we know when an object is near rather than far away? **TAKE A MOMENT...** Try these exercises to find out: Pick up a small object (such as your cup), and move it toward and then away from your face. Did its image grow larger as it approached and smaller as it receded? Next time you take a bike or car ride, notice that nearby objects move past your field of vision more quickly than those far away.

Motion is the first depth cue to which infants are sensitive. Babies 3 to 4 weeks old blink their eyes defensively when an object moves toward their face as if it is going to hit (Nánez & Yonas, 1994). As they are carried about and as people and things turn and move before their eyes, infants learn more about depth. By the time they are 3 months old, motion has helped babies figure out that objects are not flat but three-dimensional (Arterberry, Craton, & Yonas, 1993).

Binocular depth cues arise because our two eyes have slightly different views of the visual field. In a process called *stereopsis,* the brain blends these two images, resulting in perception of depth. Research in which two overlapping images are projected before the baby, who wears special goggles to ensure that each eye receives only one image, reveals that sensitivity to binocular cues emerges between 2 and 3 months and improves rapidly over the first year (Birch, 1993; Brown & Miracle, 2003). Infants soon make use of binocular cues in their reaching, adjusting arm and hand movements to match the distance of objects from the eyes.

Last to develop are *pictorial depth cues,* the ones artists use to make a painting look three-dimensional. Examples include receding and overlapping lines and line junctions (as in the drawing of a cube) that create the illusion of perspective, changes in texture (nearby textures are more detailed than faraway ones), overlapping objects (an object partially hidden by another object is perceived to be more distant), height-in-the-picture-plane (objects closer to the horizon appear farther away), and shadows cast on surfaces (indicating a separation in space between the object and the surface). Habituation research indicates that 3- to 4-month-olds are sensitive to cues of overlapping lines and line junctions. For example, 4-month-olds discriminate between the structurally "possible" and "impossible" drawings of a cube in Figure 4.13; they look much longer at the impossible alternative, as if puzzled by it (Bertin & Bhatt, 2006; Shuwairi, Albert, & Johnson, 2007). Studies in which researchers observe whether babies reach toward closer-appearing parts of images containing pictorial cues reveal that pictorial sensitivity improves considerably between 5 and 7 months (Arterberry, 2008; Kavsek, Granrud, & Yonas, 2009).

Why does perception of depth cues emerge in the order just described? Researchers speculate that motor development is involved. For example, control of the head during the early weeks of life may help babies notice motion and binocular cues. Around the middle of the first year, the ability to turn, poke, and feel the surface of objects promotes sensitivity to pictorial cues as infants pick up information about size, texture, and three-dimensional shape (Bushnell & Boudreau, 1993; Soska, Adolph, & Johnson, 2010). And as we will see next, research shows that another aspect of motor progress—independent movement—plays a vital role in refinement of depth perception.

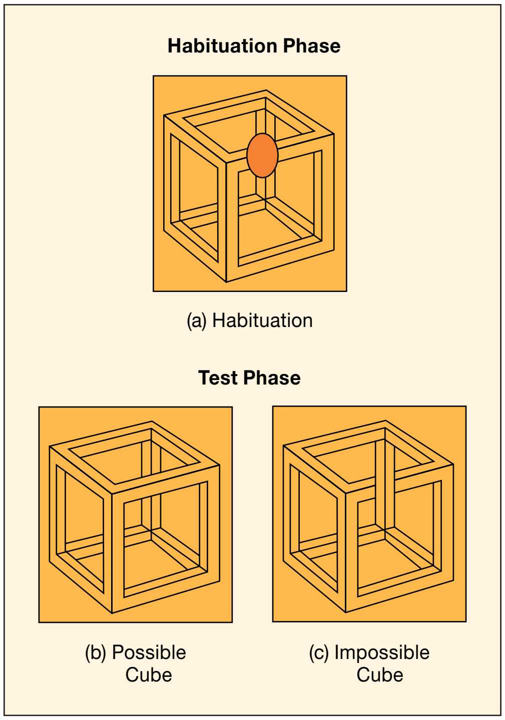


FIGURE 4.13 Testing infants' responsiveness to pictorial depth cues—overlapping lines and line junctions. (a) Infants were habituated to a line drawing of a cube made to look three-dimensional with overlapping-line and line-junction cues, but with a critical section covered, so looking preference for the makeup of that section could be tested. Next, the infants were shown two test displays in alternation: (b) a structurally "possible" cube and (c) a cube made to look structurally "impossible" by altering the coherence of pictorial cues. Four-month-olds spent much more time looking at the impossible cube, as if puzzled by it—a preference suggesting pictorial-cue sensitivity. (From S. M. Shuwairi, M. K. Albert, & S. P. Johnson, 2007, "Discrimination of Possible and Impossible Objects in Infancy," *Psychological Science, Vol. 18, No. 4,* p. 304, copyright © 2007, Association of Psychological Science. Reprinted by Permission of SAGE Publications.

Independent Movement and Depth Perception. A mother I know described her newly crawling 9-month-old as a "fearless daredevil." "If I put April down in the middle of our bed, she crawls right over the edge," the mother exclaimed. "The same thing's happened by the stairs." Will April become wary of the side of the bed and the staircase as she becomes a more experienced crawler? Research suggests that she will. Infants with more crawling experience (regardless of when they started to crawl) are far more likely to refuse to cross the deep side of the visual cliff (Campos et al., 2000).

From extensive everyday experience, babies gradually figure out how to use depth cues to detect the danger of falling. But because the loss of postural control that leads to falling differs greatly for each body position, babies must undergo this learning separately for each posture. In one study, 9-month-olds, who were experienced sitters but novice crawlers, were placed on the edge of a shallow drop-off that could be widened (Adolph, 2002, 2008). While in the familiar sitting position, infants avoided leaning out for an attractive toy at distances likely to result in falling. But in the unfamiliar crawling posture, they headed over the edge, even when the distance was extremely wide! And newly walking babies, while avoiding sharp drop-offs, careen down slopes and over uneven surfaces without making the necessary postural adjustments, even when their mothers discourage them from proceeding! Thus, they fall frequently (Adolph et al., 2008; Joh & Adolph, 2006). As infants discover how to avoid falling in various postures and situations, their understanding of depth expands.

Crawling experience promotes other aspects of three-dimensional understanding. For example, seasoned crawlers are better than their inexperienced agemates at remembering object locations and finding hidden objects (Bai & Bertenthal, 1992; Campos et al., 2000). Why does crawling make such a difference? **TAKE A MOMENT...** Compare your own experience of the environment when you are driven from one place to another with what you experience when you walk or drive yourself. When you move on your own, you are much more aware of landmarks and routes of travel, and you take more careful note of what things look like from different points of view. The same is true for infants.

In fact, crawling promotes a new level of brain organization, as indicated by more organized EEG brain-wave activity in the cerebral cortex (Bell & Fox, 1996). Perhaps crawling strengthens certain neural connections, especially those involved in vision and understanding of space. As the Social Issues: Education box on page 162 reveals, the link between independent movement and spatial knowledge is also evident in a population with very different perceptual experience: infants with severe visual impairments.

© LAURA DWIGHT PHOTOGRAPHY

As this 8-month-old becomes adept at crawling, his experience fosters other aspects of three-dimensional understanding—for example, remembering object locations and how objects appear from different viewpoints.

Pattern Perception

Even newborns prefer to look at patterned rather than plain stimuli (Fantz, 1961). As they get older, infants prefer more complex patterns. For example, 3-week-olds look longest at black-and-white checkerboards with a few large squares, whereas 8- and 14-week-olds prefer those with many squares (Brennan, Ames, & Moore, 1966).

Contrast Sensitivity. A general principle, called **contrast sensitivity,** explains early pattern preferences (Banks & Ginsburg, 1985). *Contrast* refers to the difference in the amount of light between adjacent regions in a pattern. If babies *are sensitive to* (can detect) the contrast in two or more patterns, they prefer the one with more contrast. To understand this idea, look at the checkerboards in the top row of Figure 4.14. To us, the one with many small squares has more contrasting elements. Now look at the bottom row, which shows how these checkerboards appear to infants in the first few weeks of life. Because of their poor vision, very young babies cannot resolve the small features in more complex patterns, so they prefer to look at the large, bold checkerboard. Around 2 months, when detection of fine-grained detail has

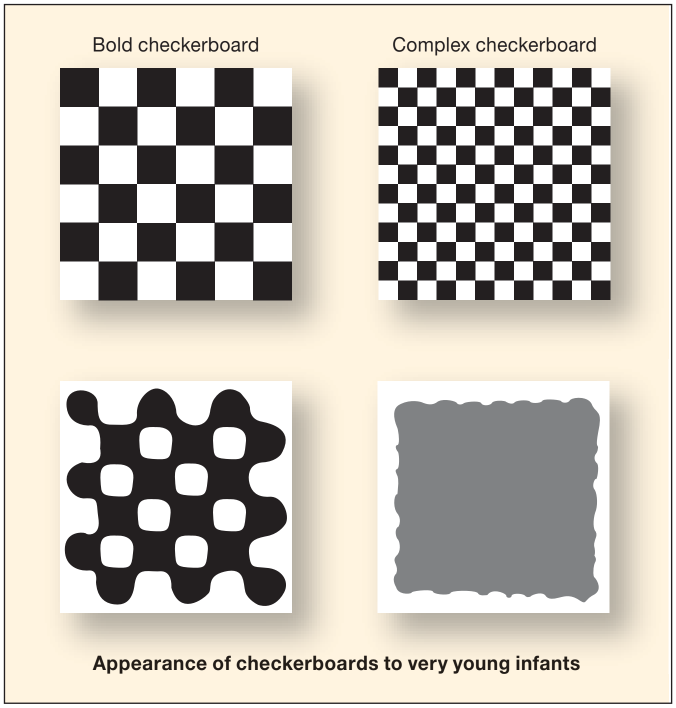

FIGURE 4.14 **The way two checkerboards differing in complexity look to infants in the first few weeks of life.** Because of their poor vision, very young infants cannot resolve the fine detail in the *complex checkerboard*. It appears blurred, like a gray field. The large, *bold checkerboard* appears to have more contrast, so babies prefer to look at it. (Adapted from M. S. Banks & P. Salapatek, 1983, "Infant Visual Perception," in M. M. Haith & J. J. Campos [Eds.], *Handbook of Child Psychology: Vol. 2. Infancy and Developmental Psychobiology* [4th ed.], New York: John Wiley & Sons, p. 504. Reprinted with permission from John Wiley & Sons, Inc.)

SOCIAL ISSUES: EDUCATION

Development of Infants with Severe Visual Impairments

Research on infants who can see little or nothing at all dramatically illustrates the interdependence of vision, motor exploration, social interaction, and understanding of the world. In a longitudinal study, infants with a visual acuity of 20/800 or worse—that is, they had only dim light perception or were blind—were followed through the preschool years. Compared to agemates with less severe visual impairments, they showed serious delays in all aspects of development. Motor and cognitive functioning suffered the most; with age, performance in both domains became increasingly distant from that of other children (Hatton et al., 1997).

What explains these profound developmental delays? Minimal or absent vision can alter the child's experiences in at least two crucial, interrelated ways.

Impact on Motor Exploration and Spatial Understanding

Infants with severe visual impairments attain gross- and fine-motor milestones many months later than their sighted counterparts (Levtzion-Korach et al., 2000). For example, on average, blind infants do not reach for and manipulate objects until 12 months, crawl until 13 months, or walk until 19 months (compare these averages to the norms in the Milestones table on page 148). Why is this so?

Infants with severe visual impairments must rely on sound to identify the whereabouts of objects. But sound does not function as a precise clue to object location until much later than vision—around the middle of the first year (Litovsky & Ashmead, 1997). And because infants who cannot see have difficulty engaging their caregivers, adults may not provide them with rich early exposure to sounding objects. As a result, the baby comes to understand relatively late that there is a world of interesting objects to explore.

Until "reaching on sound" is achieved, infants with severe visual impairments are not motivated to move independently. Because of their own uncertainty coupled with their parents' protectiveness and restraint to prevent injury, blind infants are typically tentative in their movements. These factors delay motor development further.

Motor and cognitive development are closely linked, especially for infants with little or no vision. These babies build an understanding of the location and arrangement of objects in space only after reaching and crawling (Bigelow, 1992). Inability to imitate the motor actions of others presents additional challenges as these children get older, contributing to declines in motor and cognitive progress relative to peers with better vision (Hatton et al., 1997).

Impact on the Caregiver–Infant Relationship

Infants who see poorly have great difficulty evoking stimulating caregiver interaction. They cannot make eye contact, imitate, or pick up nonverbal social cues. Their emotional expressions are muted; for example, their smile is fleeting and unpredictable. And because they cannot gaze in the same direction as a partner, they are greatly delayed in establishing a shared focus of attention on objects as the basis for play (Bigelow, 2003). Consequently, these infants may receive little adult attention and other stimulation vital for all aspects of development.

When a visually impaired child does not learn how to participate in social interaction during infancy, communication is compromised in early childhood. In an observational study of blind children enrolled in preschools with sighted agemates, the blind children seldom initiated contact with peers and teachers. When they did interact, they had trouble interpreting the meaning of others' reactions and responding appropriately (Preisler, 1991, 1993).

COURTESY OF PERKINS SCHOOL FOR THE BLIND, WATERTOWN, MA

This 3-year-old was born with severe visual impairment caused by brain damage. Using manipulative play that combines touch and sound, his caregiver helps him make sense of his physical and social environment.

Interventions

Parents, teachers, and caregivers can help infants with minimal vision overcome early developmental delays through stimulating, responsive interaction. Until a close emotional bond with an adult is forged, babies with visual impairments cannot establish vital links with their environments.

Techniques that help infants become aware of their physical and social surroundings include heightened sensory input through combining sound and touch (holding, touching, or bringing the baby's hands to the adult's face while talking or singing), engaging in many repetitions, and consistently reinforcing the infant's efforts to make contact. Manipulative play with objects that make sounds is also vital.

Finally, rich language stimulation can compensate for visual loss (Conti-Ramsden & Pérez-Pereira, 1999). It gives young children a ready means of finding out about objects, events, and behaviors they cannot see. Once language emerges, many children with limited or no vision show impressive rebounds. Some acquire a unique capacity for abstract thinking, and most master social and practical skills that enable them to lead productive, independent lives.

improved, infants become sensitive to the greater contrast in complex patterns and spend more time looking at them. Contrast sensitivity continues to improve during infancy and childhood (Gwiazda & Birch, 2001).

Combining Pattern Elements. In the early weeks of life, infants respond to the separate parts of a pattern. They stare at single, high-contrast features and have difficulty shifting their gaze away toward other interesting stimuli (Hunnius & Geuze, 2004a, 2004b). In exploring drawings of human faces, for example, 1-month-olds often limit themselves to the edges of the stimulus and focus on the hairline or chin. At 2 to 3 months, when scanning ability and contrast sensitivity improve, they thoroughly explore a pattern's internal features, pausing briefly to look at each salient part (Bronson, 1994). (Recall from page 145 that some babies continue to focus on small features and, therefore, take in less information.)

Babies' scanning also varies with pattern characteristics. When exposed to dynamic stimuli, such as the mother's nodding, smiling face, 6-week-olds fixate more on internal features (the mouth and eyes) than on edges. But when stimuli are dynamic, thorough inspection of the entire stimulus is delayed, occurring only after 4 months (Hunnius & Geuze, 2004b). And when presented with complex stimuli, such as a still frame or a video clip from the TV program *Sesame Street,* babies increase their inspection time over the second half-year as they try to make sense of the image (Courage, Reynolds, & Richards, 2006). Exploring complex patterns, especially those with moving stimuli, is more demanding than exploring simple stationary patterns—a difference we must keep in mind as we examine research on pattern perception, which is based largely on static stimuli.

Once babies take in all aspects of a pattern, they integrate the parts into a unified whole. Around 4 months, they are so good at detecting pattern organization that they perceive subjective boundaries that are not really present. For example, they perceive a square in the center of Figure 4.15a, just as you do (Ghim, 1990). Older infants carry this responsiveness to subjective form further, applying it to complex, moving stimuli. For example, 9-month-olds look much longer at an organized series of moving lights that resembles a human being walking than at upside-down or scrambled versions (Bertenthal, 1993). At 12 months, infants detect familiar objects represented by incomplete drawings, even when as much as two-thirds of the drawing is missing (see Figure 4.15b) (Rose, Jankowski, & Senior, 1997). As these findings reveal, infants' increasing knowledge of objects and actions supports pattern perception.

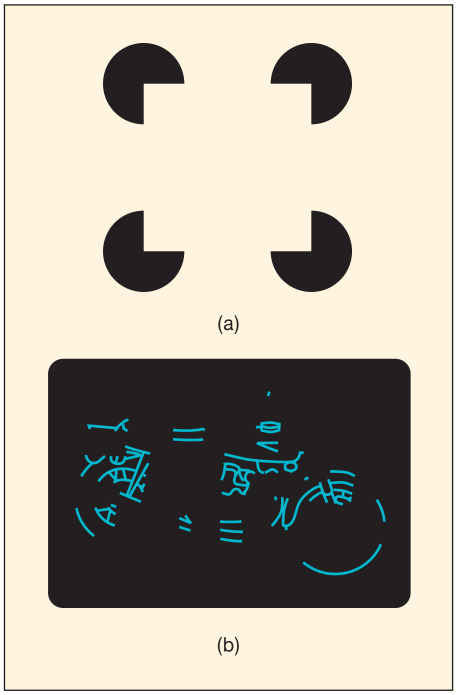

FIGURE 4.15 Subjective boundaries in visual patterns. (a) Do you perceive a square in the middle of the top figure? By 4 months of age, infants do, too. (b) What does the image on the bottom, missing two-thirds of its outline, look like to you? By 12 months, infants detect a motorcycle. After habituating to the incomplete motorcycle image, they were shown an intact motorcycle figure paired with a novel form. Twelve-month-olds recovered to (looked longer at) the novel figure, indicating that they recognized the motorcycle pattern on the basis of very little visual information. (Adapted from Ghim, 1990; Rose, Jankowski, & Senior, 1997.)

Face Perception

Infants' tendency to search for structure in a patterned stimulus applies to face perception. Newborns prefer to look at photos and simplified drawings of faces with features arranged naturally (upright) rather than unnaturally (upside down or sideways) (see Figure 4.16a and b on page 164) (Cassia, Turati, & Simion, 2004; Mondloch et al., 1999). They also track a facelike pattern moving across their visual field farther than they track other stimuli (Johnson, 1999). And although their ability to distinguish real faces on the basis of inner features is limited, newborns prefer photos of faces with eyes open and a direct gaze (Farroni et al., 2002; Turati et al., 2006). Yet another amazing capacity is their tendency to look longer at faces judged by adults as attractive (Slater et al., 2000). At least in early infancy, this attractiveness preference extends beyond human faces to nonhuman animal faces, such as domestic cats and wild tigers (Quinn et al., 2008). It may be the origin of the widespread social bias favoring physically attractive people.

Some researchers claim that these behaviors reflect a built-in capacity to orient toward members of one's own species, just as many newborn animals do (Johnson, 2001; Slater & Quinn, 2001). In support of this view, the upright face preference occurs only when newborns view stimuli in the periphery of their visual field—an area of the retina governed by primitive brain centers (Cassia, Simion, & Umiltá, 2001). Others assert that newborns simply prefer any stimulus in which the most salient elements are arranged horizontally in the upper part of a pattern—like the "eyes" in Figure 4.16b. Indeed, newborns do prefer nonfacial patterns with these characteristics over other nonfacial arrangements (Cassia, Turati, & Simion, 2004;

Simion et al., 2001). But a bias favoring the facial pattern possibly promotes such preferences. Still other researchers argue that newborns are exposed to faces more often than to other stimuli—early experiences that could quickly "wire" the brain to detect faces and prefer attractive ones (Nelson, 2001).

Although newborns respond to facelike structures, they cannot discriminate a complex, static image of the human face from other, equally complex configurations (see Figure 4.16c). But from repeated exposures to their mother's face, they quickly learn to prefer her face to that of an unfamiliar woman, although they are sensitive only to its broad outlines, not its fine-grained features. Babies quickly apply their tendency to search for pattern to face perception. Around 2 months, when they can scan an entire stimulus and combine pattern elements into an organized whole, they recognize and prefer their mother's detailed facial features to those of another woman (Bartrip, Morton, & de Schonen, 2001). And they prefer a complex drawing of the human face to other equally complex stimulus arrangements (Dannemiller & Stephens, 1988).

Around 3 months, infants make fine distinctions among the features of different faces—for example, between photographs of two strangers, even when the faces are moderately similar (Farroni et al., 2007). At 5 months—and strengthening over the second half-year—infants perceive emotional expressions as organized wholes. They treat positive faces (happy or surprised) as different from negative ones (sad or fearful) (Bornstein & Arterberry, 2003; Ludemann, 1991). Around this time, babies rely increasingly on relational information to process faces. When researchers slightly alter the distance among the eyes and mouth in a photo of a face, 5-month-olds detect that the face has changed (Hayden et al., 2007).

Experience influences face processing, leading babies to form group biases at a tender age. As early as 3 months, infants prefer and more easily discriminate among female faces than among male faces (Quinn et al., 2002; Ramsey-Rennels & Langlois, 2006). The greater time infants spend with female adults explains this effect, since babies with a male primary caregiver prefer male faces. Furthermore, 3- to 6-month-olds exposed mostly to members of their own race prefer to look at the faces of members of that race and more easily detect differences among those faces (Bar-Haim et al., 2006; Kelly et al., 2007a, 2007b). This own-race face preference is absent in babies who have frequent contact with members of other races, and it can be reversed through exposure to racial diversity (Sangrigoli et al., 2005). **TAKE A MOMENT...** Notice how early experience promotes *perceptual narrowing* with respect to gender and racial information in faces, as occurs for species information, discussed in the Biology and Environment box on page 156.

Clearly, extensive face-to-face interaction with caregivers contributes to infants' refinement of face perception. As we will see in Chapter 10, babies' developing sensitivity to the human face supports their earliest social relationships and helps regulate exploration of the environment in adaptive ways.

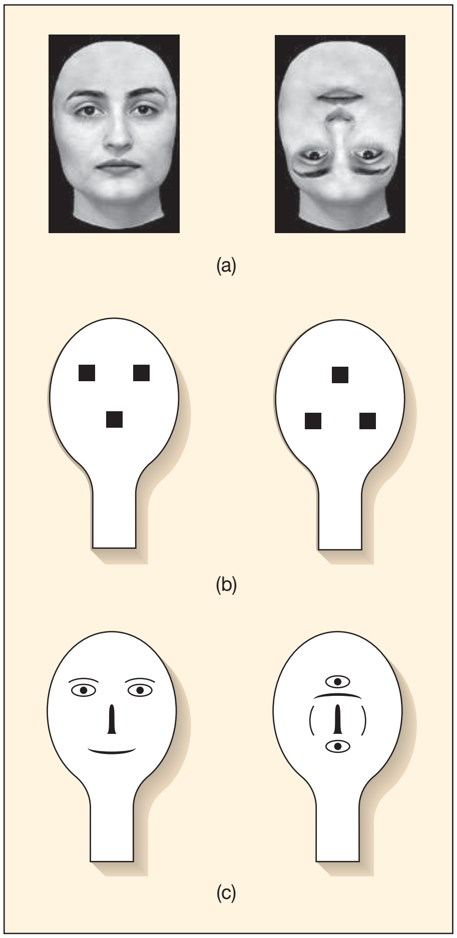

FIGURE 4.16 **Early face perception.** Newborns prefer to look at the photo of a face (a) and the simple pattern resembling a face (b) over the upside-down versions. (c) When the complex drawing of a face on the left and the equally complex, scrambled version on the right are moved across newborns' visual field, they follow the face longer. But if the two stimuli are stationary, infants show no preference for the face until around 2 months of age. (From Cassia, Turati, & Simion, 2004; Johnson, 1999; Mondloch et al., 1999.)

Object Perception

Research on pattern perception involves only two-dimensional stimuli, but our environment is made up of stable, three-dimensional objects. Do young infants perceive a world of independently existing objects—knowledge essential for distinguishing the self, other people, and things?

Size and Shape Constancy. As we move around the environment, the images that objects cast on our retina constantly change in size and shape. To perceive objects as stable and unchanging, we must translate these varying retinal images into a single representation.

Size constancy—perception of an object's size as the same, despite changes in the size of its retinal image—is evident in the first week of life. To test for it, researchers habituated infants to a small cube at varying distances from the eye, in an effort to desensitize them to changes in the cube's retinal image size and direct their attention to the object's actual size. When the small cube was presented together with a new, large cube—but at different distances so that they cast retinal images of the same size—all babies recovered to (looked longer at) the novel large cube, indicating that they distinguished objects on the basis of actual size, not retinal image size (Slater et al., 2010).

Perception of an object's shape as stable, despite changes in the shape projected on the retina, is called **shape constancy.** Habituation research reveals that it, too, is present within the first week of life, long before babies can actively rotate objects with their hands and view them from different angles (Slater & Johnson, 1999).

In sum, both size and shape constancy seem to be built-in capacities that help babies detect a coherent world of objects. Yet they provide only a partial picture of young infants' object perception.

Perception of Object Identity. At first, infants rely heavily on motion and spatial arrangement to identify objects (Jusczyk et al., 1999; Spelke & Hermer, 1996). When two objects are touching and either move in unison or stand still, babies younger than 4 months cannot distinguish between them. Infants, as we saw earlier in this chapter, are fascinated by moving objects. While observing objects' motions, they pick up additional information about objects' boundaries, such as shape, color, and texture.

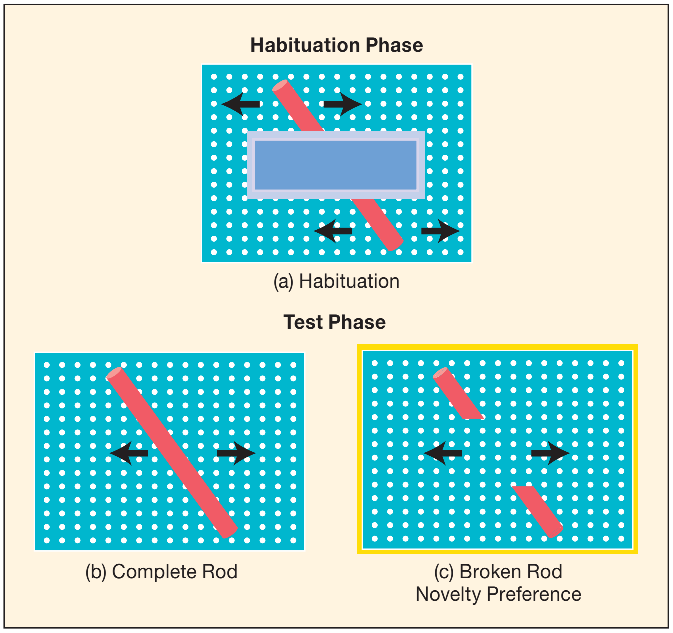

FIGURE 4.17 **Testing infants' ability to perceive object unity.** (a) Infants were habituated to a rod moving back and forth behind a box against a textured background. Next, they were shown two test displays in alternation: (b) a complete rod and (c) a broken rod with a gap corresponding to the location of the box. Each stimulus was moved back and forth against the textured background, in the same way as the habituation stimulus. Infants 2 months of age and older typically recovered to (looked longer at) the broken rod than the complete rod. Their novelty preference suggests that they perceive the rod behind the box in the first display as a single unit. (Adapted from Johnson, 1997.)

For example, as Figure 4.17 reveals, around 2 months, babies first realize that a moving rod whose center is hidden behind a box is a complete rod rather than two rod pieces. Motion, a textured background, and a small box (so most of the rod is visible) are necessary for young infants to infer object unity. They need all these cues to heighten the distinction between objects in the display because their ability to scan for salient information is still immature (Amso & Johnson, 2006; Johnson et al., 2002).

As infants become familiar with many objects and can integrate each object's diverse features into a unified whole, they rely more on shape, color, and pattern and less on motion (Slater et al., 2010). Babies as young as 4½ months can discriminate two touching objects on the basis of their features in simple, easy-to-process situations. And prior exposure to one of the test objects enhances 4½-month-olds' ability to discern the boundary between two touching objects—a finding that highlights the role of experience (Dueker, Modi, & Needham, 2003; Needham, 2001).

In everyday life, objects frequently move in and out of sight, so infants must keep track of their disappearance and reappearance to perceive their identity. Habituation research, in which a ball moves back and forth behind a screen, reveals that at age 4 months, infants first perceive the ball's path as continuous (see Figure 4.18) (Johnson et al., 2003). Between 4 and 5 months, infants can monitor increasingly intricate paths of objects. As indicated by their future-oriented eye movements (looking ahead to where they expect an object to appear from behind a barrier), 5-month-olds even keep track of an object that travels on a curvilinear course at varying speeds (Rosander & von Hofsten, 2004). Again, experience—the opportunity to track a moving object along a fully visible path of movement just before testing—enhances young infants' predictive eye tracking (Johnson & Shuwairi, 2009).

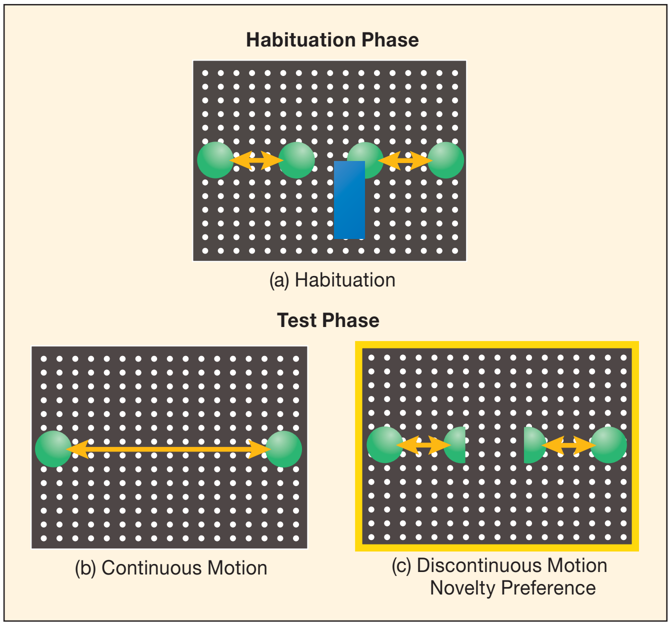

FIGURE 4.18 **Testing infants' ability to perceive an object's path of movement.** (a) Infants were habituated to a ball moving back and forth behind a screen. Next, they were shown two test displays in alternation: (b) a ball undergoing continuous back-and-forth motion, with its full trajectory visible, and (c) a ball undergoing discontinuous motion, out of and back into view just as in the habituation stimulus, but without moving behind a visible screen. As long as the ball was out of sight only briefly in the habituation display, 4-month-olds typically recovered to (looked longer at) the discontinuous motion than the continuous motion. Their novelty preference suggests that they perceive the motion of the ball behind the screen in the first display as continuous. (From S. P. Johnson et al., 2003, "Infants' Perception of Object Trajectories," *Child Development, 74,* pp. 98, 101. © 2003 The Society for Research in Child Development, Inc. Reprinted by permission of Blackwell Publishing Ltd.)

From 4 to 11 months, infants increasingly rely on featural information to detect the identity of an object traveling behind a screen—at first, form (size and shape) and later in the first year, surface features (pattern and then color) (Wilcox & Woods, 2009). And as before, experience—in particular, physically manipulating the object—boosts older infants' attention to its surface features.

In sum, perception of object identity is mastered gradually over the first year. We will consider a related attainment—infants' understanding of object permanence—awareness that an object still exists when hidden—in Chapter 6.

The Milestones table on the following page provides an overview of the vast changes in visual perception during the first year. Up to this point, we have considered the sensory systems one by one. Now let's examine their coordination.

Intermodal Perception

Our world provides rich, continuous *intermodal stimulation*—simultaneous input from more than one modality, or sensory system. In **intermodal perception,** we make sense of these running streams of light, sound, tactile, odor, and taste information, perceiving them as integrated wholes. We know, for example, that an object's shape is the same whether we see it or touch it, that lip movements are closely coordinated with the sound of a voice, and that dropping a rigid object on a hard surface will cause a sharp, banging sound.

Recall that newborns turn in the general direction of a sound and reach for objects in a primitive way. These behaviors suggest that infants expect sight, sound, and touch to go together. Research reveals that babies perceive input from different sensory systems in a unified way by detecting **amodal sensory properties**—information that is not specific to a single modality but that overlaps two or more sensory systems, such as rate, rhythm, duration, intensity, temporal synchrony (for vision and hearing), and texture and shape (for vision and touch). Consider, for example, the sight and sound of a bouncing ball or the face and voice of a speaking person. In each event, visual and auditory information are conveyed simultaneously and with the same rate, rhythm, duration, and intensity.

© DAVID YOUNG-WOLFF/PHOTOEDIT

Within the first half-year, infants master a remarkable range of intermodal relationships. This baby picks up associations between the sight, sound, and feel of his father's guitar.

Even newborns are impressive perceivers of amodal properties. After touching an object (such as a cylinder) placed in their palms, they recognize it visually, distinguishing it from a different-shaped object (Sann & Streri, 2007). And they require just one exposure to learn the association between the sight and sound of a toy, such as a rhythmically jangling rattle (Morrongiello, Fenwick, & Chance, 1998).

Within the first half-year, infants master a remarkable range of intermodal relationships. Three- to 4-month-olds can match faces with voices on the basis of lip–voice synchrony, emotional expression, and even age and gender of the speaker: On hearing a voice, they look longer at an appropriate face than at an inappropriate one (Bahrick, Netto, & Hernandez-Reif, 1998). Between 4 and 6 months, infants can perceive and remember the unique face–voice pairings of unfamiliar adults (Bahrick, Hernandez-Reif, & Flom, 2005).

How does intermodal perception develop so quickly? Young infants seem biologically primed to focus on amodal information. Their detection of amodal relations—for example, the common tempo and rhythm in sights and sounds—precedes and seems to provide the basis for detecting more specific intermodal matches, such as the relation between a particular person's face and the sound of her voice or between an object and its verbal label (Bahrick, Hernandez-Reif, & Flom, 2005).

Intermodal sensitivity is crucial for perceptual development. In the early months, infants detect amodal properties only when exposed to intermodal stimulation. For example, 3-month-olds discriminated a change in the rhythm of a toy hammer tapping from an audiovisual display but not from a purely auditory presentation (just hearing the tapping) or a purely visual presentation (just seeing the hammer move) (Bahrick, Flom, & Lickliter, 2003). Intermodal stimulation makes amodal properties (such as rhythm) stand out. As a result, inexperienced

Milestones

Visual Development in Infancy

AGE	ACUITY, COLOR PERCEPTION, FOCUSING, AND EXPLORATION	DEPTH PERCEPTION	PATTERN PERCEPTION	OBJECT PERCEPTION
Birth–1 month	• Visual acuity is 20/600. • Scans the visual field and tracks moving objects.	• Responds to motion, blinking defensively when an object moves toward the face.	• Prefers large, bold patterns. • Responds to separate parts of a pattern, focusing on single, high-contrast features. • Prefers to look at simplified drawings of facelike patterns and at photos of faces with eyes open and a direct gaze. • Shows preference for attractive faces over less attractive ones.	• Displays size and shape constancy.
2–3 months	• Has adultlike focusing ability. • Scans more thoroughly and systematically. 	• Responds to binocular depth cues.	• Prefers patterns with finer details. • Thoroughly scans internal pattern features. • Begins to perceive overall pattern structure. • Prefers complex drawings of human face to other, equally complex stimulus arrangements. • Prefers and more easily discriminates among female than male faces. • Recognizes and prefers mother's face and distinguishes among faces of strangers.	• Uses motion and spatial arrangement to identify objects.
4–5 months	• Color discrimination is adultlike. 	• Sensitivity to binocular depth cues improves. • Begins to respond to pictorial depth cues.	• Perceives subjective boundaries in simple patterns. • Increasingly relies on relational information (such as distance among features) to differentiate faces. • Distinguishes emotionally positive from emotionally negative facial expressions.	• Uses shape, color, and texture to identify objects. • Perceives an object's path of movement as continuous without seeing the entire path.
6–9 months	• Visual acuity improves to near 20/20. • Scans the visual field and tracks moving objects more efficiently.	• Responsiveness to pictorial depth cues improves.	• Improves at detecting subjective form in complex patterns. • Increasingly perceives facial expressions of emotion as organized wholes.	
10–12 months			• Continues to improve at detecting subjective form: Detects familiar objects represented by incomplete drawings.	

Note: These milestones represent overall age trends. Individual differences exist in the precise age at which each milestone is attained.

perceivers notice a unitary event (the hammer's intricate tapping) and are not distracted by momentarily irrelevant aspects of the situation, such as the hammer's color or orientation.

In contrast, young infants notice changes in purely visual properties, such as color, orientation, and pattern, only when exposed to purely visual information (Bahrick, Lickliter, & Flom, 2004). With experience, perceptual capacities become more flexible. In the second half of the first year, infants can discriminate amodal properties in both intermodal and unimodal (sights or sounds alone) stimulation. But early on, when much input is unfamiliar and confusing, intermodal stimulation helps babies selectively attend to and make sense of their surroundings.

In addition to easing infants' perception of the physical world, intermodal perception facilitates social and language processing, as evidence reviewed earlier in this chapter illustrates. Recall that an adult's gentle touch induces infants to attend to her face (see page 154). And as infants gaze at an adult's face, they initially require both vocal and visual input to distinguish positive from negative emotional expressions. Furthermore, in their earliest efforts to make sense of language, infants profit from temporal synchrony between a speech sound and the motion of an object (see page 157). Similarly, sound–movement temporal synchrony facilitates perception of rhythm and beat in music (Trainor, 2007). When 7-month-olds were bounced while listening to an unaccented musical rhythm, some infants on every second beat (duple rhythm) and others on every third beat (triple rhythm), the babies later preferred the accented version of the music they had experienced intermodally (Phillips-Silver & Trainor, 2005).

In sum, intermodal perception is a fundamental ability that fosters all aspects of psychological development. When caregivers provide many concurrent sights, sounds, touches, and smells, babies process more information, learn faster, and show better memory (Bahrick, 2010). Intermodal perception is yet another fundamental capacity that assists infants in their active efforts to build an orderly, predictable world.

LOOK and LISTEN

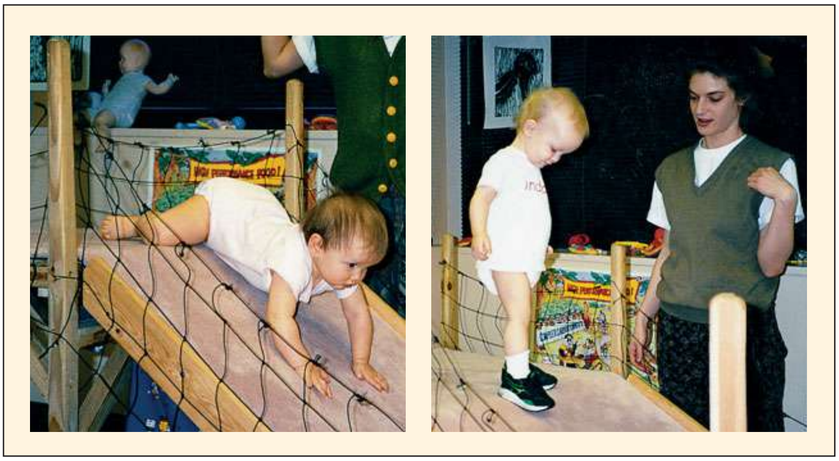
While watching a parent and infant playing, list instances of parental intermodal stimulation and communication. What is the baby likely learning about people, objects, or language from each intermodal experience?

Understanding Perceptual Development

Now that we have reviewed the development of infant perceptual capacities, how can we put together this diverse array of amazing achievements? Widely accepted answers come from the work of Eleanor and James Gibson. According to the Gibsons' **differentiation theory,** infants actively search for **invariant features** of the environment—those that remain stable—in a constantly changing perceptual world. In pattern perception, for example, young babies search for features that stand out and orient toward faces. Soon they explore internal features and notice *stable relationships* among them. As a result, they detect patterns, such as complex designs and individual faces. Similarly, babies analyze the speech stream for regularities, detecting words, word-order sequences, and—within words—consistent syllable-stress patterns. The development of intermodal perception also reflects this principle. Infants seek out invariant relationships—first, amodal properties, such as common rate and rhythm, in a voice and face; later, more detailed associations, such as unique voice–face matches.

The Gibsons described their theory as *differentiation* (where *differentiate* means "analyze" or "break down") because over time the baby detects finer and finer invariant features among stimuli. In addition to pattern perception and intermodal perception, differentiation applies to depth and object perception: Recall how in each, sensitivity to motion precedes detection of fine-grained features. So one way of understanding perceptual development is to think of it as a built-in tendency to seek order and consistency—a capacity that becomes increasingly fine-tuned with age (Gibson, 1970; Gibson, 1979).

Acting on the environment is vital in perceptual differentiation. According to the Gibsons, perception is guided by the discovery of **affordances**—the action possibilities that a situation offers an organism with certain motor capabilities (Gibson, 2000, 2003). By moving about and exploring the environment, babies figure out which objects can be grasped, squeezed, bounced, or stroked and whether a surface is safe to cross or presents the possibility of falling. Sensitivity to these affordances means that we spend far less time correcting ineffective actions than we would otherwise. It makes our actions future-oriented and largely successful rather than reactive and blundering.



COURTESY OF KAREN ADOLPH, NEW YORK UNIVERSITY

FIGURE 4.19 Acting on the environment plays a major role in perceptual differentiation. Crawling and walking change the way babies perceive a sloping surface. The newly crawling infant on the left plunges headlong down the slope. He has not yet learned that it affords the possibility of falling. The toddler on the right, who has been walking for more than a month, approaches the slope cautiously. Experience in trying to remain upright but frequently tumbling over has made him more aware of the consequences of his movements. He perceives the incline differently than he did at a younger age.

To illustrate, recall how infants' changing capabilities for independent movement affect their perception. When babies crawl, and again when they walk, they gradually realize that a steeply sloping surface *affords the possibility* of falling (see Figure 4.19). With added weeks of practicing each skill, they become hesitant to crawl or walk down a risky incline. Experience in trying to keep their balance on various surfaces makes crawlers and walkers more aware of the consequences of their movements. Crawlers come to detect when surface slant places so much body weight on their arms that they will fall forward, and walkers come to sense when an incline shifts body weight so their legs and feet can no longer hold them upright. Learning is gradual and effortful because newly crawling and walking babies traverse many types of surfaces in their homes each day (Adolph, 2008; Adolph & Joh, 2009). As they experiment with balance and postural adjustments to accommodate each, they perceive surfaces in new ways that guide their movements. As a result, they act more competently. **TAKE A MOMENT...** Can you think of other links between motor action and perceptual development described in this chapter?

Some researchers believe that babies do more than make sense of experience by searching for invariant features and discovering affordances: They also *impose meaning* on what they perceive, constructing categories of objects and events in the surrounding environment. We have seen the glimmerings of this *cognitive* point of view in this chapter. For example, older babies *interpret* a familiar face as a source of pleasure and affection and a pattern of blinking lights as a moving human being. We will save our discussion of infant cognition for later chapters, acknowledging that this cognitive perspective also offers insight into the achievements of infancy. In fact, many researchers combine these two positions, regarding infant development as proceeding from a perceptual to a cognitive emphasis over the first year of life.

ASK YOURSELF

Review ■ Using examples, explain why intermodal stimulation is vital for infants' developing understanding of their physical and social worlds.

Connect ■ According to differentiation theory, perceptual development reflects infants' active search for invariant features. Provide examples from research on hearing, pattern perception, and intermodal perception.

Apply ■ After several weeks of crawling, Ben learned to avoid going headfirst down a steep incline. Now he has started to walk. Can his mother trust him not to try walking down a steep surface? Explain, using the concept of affordances.

Reflect ■ Are young infants more competent than you thought they were before you read this chapter? List the capacities that most surprised you.

Early Deprivation and Enrichment: Is Infancy a Sensitive Period of Development?

- How does research on early deprivation and enrichment shed light on the question of whether infancy is a sensitive period of development?

Throughout this chapter, we have considered how a variety of early experiences affect the development of motor and perceptual skills. In view of the findings already reviewed, it is not surprising that many investigations have reported that stimulating physical surroundings and warm caregiving that is responsive to infants' self-initiated efforts promote active exploration of the environment and earlier attainment of developmental milestones (see, for example, Belsky & Fearon, 2002; Bendersky & Lewis, 1994).

The powerful effect of early experience is dramatically apparent in infants who lack the rich, varied stimulation of normal homes. Babies reared in severely deprived family situations or in institutions remain substantially below average in physical and psychological development and display emotional and behavior problems throughout childhood and adolescence (Rutter et al., 2010). These findings indicate that early experience has a profound impact, but they do not tell us whether infancy is a *sensitive period.* That is, if babies do not experience appropriate stimulation of their senses in the first year or two of life, can they fully recover? This question is controversial. Recall from Chapter 1 that some theorists argue that early experience leaves a lasting imprint on the child's competence. Others believe that most developmental delays resulting from events in the early years of life can be overcome.

Studies of animals exposed to extreme forms of sensory deprivation provide ample evidence that sensitive periods exist. For example, early, varied visual experiences must occur for the brain's visual centers to develop normally. If a 1-month-old kitten is deprived of light for just three or four days, these areas of the brain degenerate. If the kitten is kept in the dark during the fourth week of life and beyond, the damage is severe and permanent (Crair, Gillespie, & Stryker, 1998). And the general quality of the early environment affects overall brain growth. When animals reared from birth in physically and socially stimulating surroundings are compared with those reared in isolation, the brains of the stimulated animals are larger (Greenough & Black, 1992).

For ethical reasons, we cannot deliberately deprive some infants of normal rearing experiences and observe the impact on their brains and competencies. Instead, we must turn to natural experiments, in which children were victims of deprived early environments that were later rectified. Such studies have revealed some parallels with the animal evidence just described.

For example, when babies are born with cataracts (clouded lenses, preventing clear visual images) in both eyes, those who have corrective surgery within 4 to 6 months show rapid improvement in vision, except for subtle aspects of face perception, which require early visual input to the cerebral cortex to develop (Le Grand et al., 2003; Maurer, Mondloch, & Lewis, 2007). The longer cataract surgery is postponed beyond infancy, the less complete the recovery in visual skills. And if surgery is delayed until adulthood, vision is severely and permanently impaired (Lewis & Maurer, 2005).

Studies of infants placed in orphanages who were later exposed to family rearing confirm the importance of a generally stimulating physical and social environment for psychological development. In one investigation, researchers followed the progress of a large sample of children transferred between birth and 3½ years from Romanian orphanages to adoptive families in Great Britain (Beckett et al., 2006; O'Connor et al., 2000; Rutter et al., 1998, 2004, 2010). On arrival, most were impaired in all domains of development. By the preschool years, catch-up in physical size was dramatic. Cognitive catch-up was impressive for children adopted before age 6 months, who consistently attained average mental test scores in childhood and adolescence, performing as well as a comparison group of early-adopted British-born children.

These children in an orphanage in Romania receive little adult contact or stimulation. The longer they remain in this barren environment, the more likely they are to display profound impairment in all domains of development.

© ANDREW HOLBROOKE/CORBIS

But Romanian children who had been institutionalized for more than the first six months showed serious intellectual deficits (see Figure 4.20). Although they improved in mental test scores during middle childhood (perhaps as a result of added time in their adoptive homes and special services at school), they remained substantially below average. And most displayed at least three serious mental health problems, such as inattention, overactivity, unruly behavior, and autistic-like symptoms (social disinterest, stereotyped behavior) (Kreppner et al., 2007, 2010). A major correlate of both time spent in the institution and poor cognitive and emotional functioning was below-average head size, suggesting that early lack of stimulation permanently damaged the brain (Sonuga-Barke, Schlotz, & Kreppner, 2010).

Neurobiological findings indicate that early, prolonged institutionalization leads to a generalized reduction in activity in the cerebral cortex, especially the prefrontal cortex, which (as we will see in

Chapter 5) governs complex cognition and impulse control. Neural fibers connecting the prefrontal cortex with other brain structures involved in control of emotion are also reduced (Eluvathingal et al., 2006; Nelson, 2007). Consequently, as Chapter 10 will reveal, by the second half of the first year, institutionalized infants have difficulty discriminating others' emotional expressions—a persistent deficiency that contributes to their emotional and social adjustment problems.

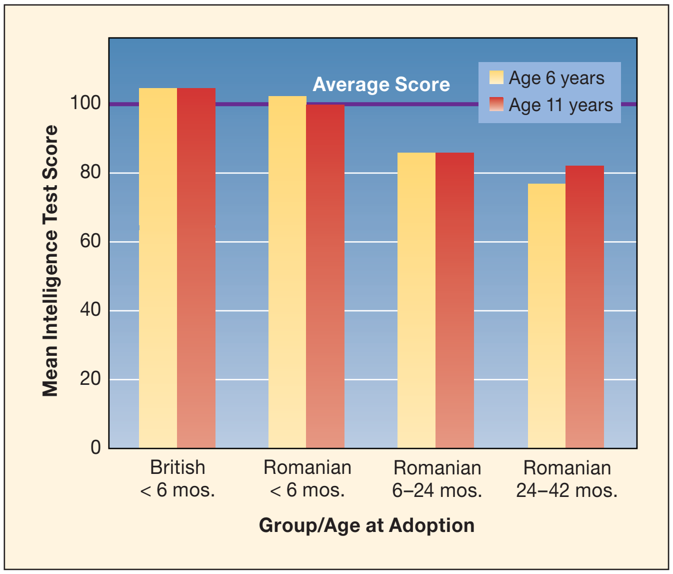


FIGURE 4.20 Relationship of age at adoption to mental test scores at ages 6 and 11 among British and Romanian adoptees. Children transferred from Romanian orphanages to British adoptive homes in the first six months of life attained average scores and fared as well as British early-adopted children, suggesting that they had fully recovered from extreme early deprivation. Romanian children adopted after 6 months of age performed well below average. And although those adopted after age 2 improved between ages 6 and 11, they continued to show serious intellectual deficits. (Adapted from Beckett et al., 2006.)

Among institutionalized infants, abnormal development in one domain often impedes progress in others. For example, adoptive parents of children from orphanages often report visual impairments. A frequent problem is *strabismus* ("crossed eyes"), in which the eyes, because of muscle weakness, do not converge on the same point in space. Untreated infants, for whom strabismus persists longer than a few months, show abnormalities in the brain's visual structures and permanent deficits in visual acuity, depth perception, tracking of moving objects, and perception of the spatial layout of the environment (Tychsen, 2001). Also, the bland, colorless rooms where orphanage infants spend their days, rarely touched or spoken to, lead to deficits in intermodal perception (Cermak & Daunhauer, 1997). Children who have trouble integrating information across modalities tend to be overwhelmed by stimulation, reacting to it with disorganized behavior or withdrawal—a circumstance that impedes all domains of development.

Unfortunately, many infants reared in underprivileged environments—whether homes or institutions—continue to be affected by disadvantaged conditions during their childhood years. Interventions that break this pattern with warm, stimulating caregiver interaction and environmental enrichment can have lasting cognitive and social benefits. In the Bucharest Early Intervention Project, about 200 institutionalized Romanian babies were randomized into conditions of either care as usual or transfer to high-quality foster families between ages 5 and 30 months. Specially trained social workers provided foster parents with counseling and support in managing children's diverse developmental problems. Follow-ups between 2½ and 4 years revealed that the foster-care group exceeded the institutional-care group in intelligence test scores, language skills, perception of emotional expressions, emotional responsiveness, and EEG and ERP assessments of brain activity. On all measures, the earlier the foster placement, the better the outcome (Nelson et al., 2007; Smyke et al., 2009). Yet consistent with an early sensitive period, the foster-care group remained behind never-institutionalized agemates living with Bucharest families. In sum, to be maximally effective, intensive intervention must begin early.

Finally, in addition to impoverished environments, ones that overwhelm children with expectations beyond their current capacities also undermine development. In recent years, expensive early learning centers have sprung up, in which infants are trained with letter and number flash cards, and slightly older toddlers are given a full curriculum of reading, math, science, art, gym, and more. There is no evidence that these programs yield smarter, better "superbabies" (Hirsh-Pasek & Golinkoff, 2003). To the contrary, trying to prime infants with stimulation for which they are not ready can cause them to withdraw, threatening their spontaneous interest and pleasure in learning and creating conditions much like those of stimulus deprivation! We will return to this theme when we take up brain development in Chapter 5.

ASK YOURSELF

Review ■ Explain why either too much stimulation or too little stimulation over an extended time negatively disrupts early development.

Connect ■ What implications do findings on children from Eastern European orphanages have for the controversy over the lasting impact of early experiences on development (see Chapter 1, page 9)?

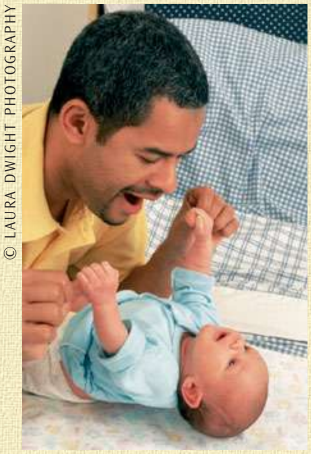
Reflect ■ Do you think infancy is a sensitive period? Explain, using research evidence.

SUMMARY

The Organized Infant (p. 129)

Explain the functions of newborn reflexes, and describe changing states of arousal during infancy, emphasizing sleep and crying.

- **Reflexes** are the newborn baby's most obvious organized patterns of behavior. Some have survival value, others help parents and infants establish gratifying interaction, and still others provide the foundation for voluntary motor skills.



© LAURA DWIGHT PHOTOGRAPHY

- Although newborns move in and out of five **states of arousal,** they spend most of their time asleep. Sleep includes at least two states: **rapid-eye-movement (REM)** and **non-rapid-eye-movement (NREM) sleep.** Newborns spend about 50 percent of their sleep time in REM sleep, far more than they ever will again. REM sleep provides stimulation essential for central nervous system development. Individual and cultural differences in sleep–wake patterns are evident in early infancy. Disturbed REM–NREM cycles are a sign of central nervous system abnormalities, which may lead to sudden infant death syndrome (SIDS).
- A crying baby stimulates strong feelings of discomfort in nearby adults. The intensity of the cry and experiences leading up to it help parents identify what is wrong. Once feeding and diaper changing have been tried, a highly effective soothing technique is lifting the baby to the shoulder and rocking or walking. Ethological research indicates that parental responsiveness to infant crying leads to less crying over time.

Why is neonatal behavioral assessment useful?

- The most widely used instrument for assessing the organized functioning of newborn infants, Brazelton's **Neonatal Behavioral Assessment Scale (NBAS),** helps researchers understand individual and cultural differences in newborn behavior. Sometimes it is used to teach parents about their baby's capacities.

Describe infant learning capacities, the conditions under which they occur, and the unique value of each.

- **Classical conditioning** helps infants to associate events that usually occur together in the everyday world. Infants can be classically conditioned most easily when the pairing of an **unconditioned stimulus (UCS)** and a **conditioned stimulus (CS)** has survival value—for example, learning which stimuli regularly accompany feeding.
- In **operant conditioning,** infants act on their environment, and their behavior is followed by either **reinforcers,** which increase the occurrence of a preceding behavior, or **punishment,** which either removes a desirable stimulus or presents an unpleasant one to decrease the occurrence of a response. Retention of operant responses increases dramatically over the first 18 months. In young infants, interesting sights and sounds and pleasurable caregiver interaction serve as effective reinforcers.
- **Habituation** and **recovery** reveal that at birth, babies are attracted to novelty. With age, infants habituate and recover more quickly. Novelty preference assesses infants' recent memory, whereas familiarity preference assesses their remote memory. Habituation research shows that young infants are especially attracted to motion and remember the movements of objects and people for weeks to months. Habituation and recovery are effective early predictors of intelligence because they assess memory and quickness and flexibility of thinking.
- Newborns have a primitive ability to imitate adults' facial expressions and gestures. **Imitation** is a powerful means of learning that may serve as the foundation for understanding others' thoughts and feelings. Scientists have identified specialized cells called **mirror neurons** that underlie these capacities. However, whether newborn imitation is a voluntary capacity remains controversial.

Motor Development in Infancy (p. 147)

How does the dynamic systems perspective explain motor development?

- According to **dynamic systems theory of motor development,** children acquire new motor skills by combining existing skills into increasingly complex systems of action. Each new skill is a joint product of central nervous system development, the body's movement possibilities, the child's goals, and environmental supports for the skill.

Identify factors that influence gross- and fine-motor development during the first two years.

- Movement opportunities and a stimulating environment profoundly affect motor development, as shown by research on infants reared in deprived institutions. Cultural values and child-rearing customs also contribute to motor development.
- During the first year, infants master reaching and grasping. The poorly coordinated **prereaching** of newborns drops out. Gradually, reaching becomes more flexible and accurate, and the clumsy **ulnar grasp** becomes the well-coordinated **pincer grasp.**

Perceptual Development in Infancy (p. 152)

Describe the newborn baby's sensitivity to touch, taste, smell, and sound, noting changes during infancy.

- The senses of touch, taste, smell, and hearing are well-developed at birth. Newborns use their palms to distinguish the shapes of small objects. They are also highly sensitive to pain and prefer sweet tastes. Around 4 months, liking for the salty taste emerges and probably supports acceptance of solid foods. Newborns orient toward the odor of their own mother's amniotic fluid and that of the lactating breast—responses that help them identify their caregiver and locate an appropriate food source.

- Newborns can distinguish a few sound patterns, as well as nearly all speech sounds. Over the first year, infants organize sounds into increasingly elaborate patterns.

- Newborns can distinguish almost all speech sounds. They prefer listening to slow, clear, high-pitched expressive voices, to their own mother's voice, and to speech in their native language. Around the middle of the first year, they start to "screen out" sounds not used in their own language.
- Infants' impressive **statistical learning capacity** enables them to detect speech patterns for which they will later learn meanings. In the second half-year, babies detect word boundaries and, soon after, syllable-stress regularities within words. They also detect simple word-order rules that may help them figure out the basic grammar of their language. Multisensory communication, such as mothers' tendency to label an object while demonstrating, supports infants' language learning.

© FRANK AND HELENA/CULTURA/CORBIS

Describe the development of vision in infancy, with special emphasis on depth, pattern, face, and object perception.

- Vision is the least developed of the newborn's senses. As the eye and visual centers in the brain develop during the first few months, focusing ability, **visual acuity,** scanning, tracking, and color perception improve rapidly.
- Research on depth perception reveals that responsiveness to motion develops first, followed by sensitivity to binocular and then to pictorial depth cues. Experience in crawling enhances depth perception and other aspects of three-dimensional understanding, but babies must learn to avoid drop-offs for each body position.
- **Contrast sensitivity** accounts for early pattern preferences. At first, babies stare at single, high-contrast features. At 2 to 3 months, they explore a pattern's internal features and, over time, discriminate increasingly complex, meaningful patterns.
- Newborns prefer to look at photos and simplified drawings of faces, but researchers disagree on whether they have a built-in tendency to orient toward human faces. Around 2 months, infants recognize and prefer their mother's facial features, and at 3 months, they distinguish the features of different faces. From 5 months on, they perceive emotional expressions as organized wholes. Experience promotes a **perceptual narrowing effect,** leading babies to form group biases—for example, a preference for female and own-race faces.
- At birth, **size** and **shape constancy** help infants construct a coherent world of objects. Initially, infants depend on motion and spatial arrangement to identify objects. After 4 months, they rely increasingly on object features, such as distinct shape, color, and pattern. Around this time, they first perceive the path of a ball moving back and forth behind a screen as continuous. Soon they can monitor increasingly intricate paths of objects, as they look for featural information to detect the identity of a moving object.

Describe how intermodal perception develops during infancy.

- Infants' remarkable capacity to engage in **intermodal perception** enables them to combine information across sensory modalities. Detection of **amodal sensory properties,** such as rate, rhythm, duration, intensity, temporal synchrony, and texture and shape, seems to provide the basis for detecting more specific intermodal relationships. Intermodal perception is a fundamental ability that fosters all aspects of psychological development, including perception of the physical world and social and language processing.

How does differentiation theory explain perceptual development?

- According to **differentiation theory,** perceptual development is a matter of detecting increasingly fine-grained **invariant features** in a constantly changing perceptual world. Perceptual differentiation is guided by discovery of **affordances**—the action possibilities that a situation offers the individual.

Early Deprivation and Enrichment: Is Infancy a Sensitive Period of Development? (p. 169)

How does research on early deprivation and enrichment shed light on the question of whether infancy is a sensitive period of development?

- Evidence that infancy is a sensitive period comes from natural experiments, such as babies placed in orphanages who were later adopted into families. Prolonged early deprivation can disrupt brain growth and result in persistent intellectual impairments and mental health problems. To be maximally effective, intensive intervention aimed at breaking the pattern of disadvantaged conditions must begin early. Environments that overwhelm infants with stimulation beyond their current capacities also undermine development.

CHAPTER 5

"Rhythmic Gymnast"

Deanna Hodgson
12 years, United Kingdom

The dramatic gains in strength and coordination of adolescence are evident in this young dancer's grace and expressiveness. Her exuberant leap radiates self-confidence and pleasure in her expanding physical capacities.

Physical Growth

On Sabrina's eleventh birthday, her friend Joyce gave her a surprise party, but Sabrina seemed somber during the celebration. Although Sabrina and Joyce had been close friends since third grade, their relationship was faltering. Sabrina was a head taller and some 20 pounds heavier than most girls in her sixth-grade class. Her breasts were well-developed, her hips and thighs had broadened, and she had begun to menstruate. In contrast, Joyce still had the short, lean, flat-chested body of a school-age child.

Ducking into the bathroom while Joyce and the other girls put candles on the cake, Sabrina frowned at her image in the mirror. "I'm so big and heavy," she whispered. At church youth group on Sunday evenings, Sabrina broke away from Joyce and joined the eighth-grade girls. Around them, she didn't feel so large and awkward.

Once a month, parents gathered at Sabrina's and Joyce's school to discuss child-rearing concerns. Sabrina's parents, Franca and Antonio, attended whenever they could. "How you know they are becoming teenagers is this," volunteered Antonio. "The bedroom door is closed, and they want to be alone. Also, they contradict and disagree. Anything I say to Sabrina, she gives me an argument."

"All our children were early developers," Franca added. "But it was easier for the boys—being tall made them feel big and important. Sabrina is moody, she avoids her old friends, and she thinks about boys instead of her studies. As a little girl, she was skinny, but now she says she is too fat and needs to diet. I try to be patient with her," reflected Franca sympathetically.

During the first two decades of life, the human body changes continuously and dramatically. The average individual's height multiplies more than threefold, and weight increases as much as 15- to 20-fold. The top-heavy, chubby infant, whose head represents a quarter of the body's total length, gradually becomes the better-proportioned child and eventually the taller, broader, more muscular teenager. This chapter traces the course of human growth, along with biological and environmental factors that regulate and influence it.

As Sabrina's behavior indicates, physical and psychological development are closely linked. But just how the child's transforming body is related to cognitive, emotional, and social changes has puzzled philosophers and scientists for centuries. In particular, they have pondered this question with respect to *puberty*. **TAKE A MOMENT...** Ask several parents of young children what they expect their sons and daughters to be like as teenagers. You will probably get answers like these: "Rebellious and reckless," "Full of rages and tempers" (Buchanan & Holmbeck, 1998). This widespread view dates back to eighteenth-century philosopher Jean-Jacques Rousseau (see Chapter 1), who believed that the biological upheaval of puberty triggered heightened emotionality, conflict, and defiance of adults.

In the early twentieth century, major theorists picked up this storm-and-stress perspective. The most influential, G. Stanley Hall, described adolescence as a cascade of instinctual passions, a period so turbulent that it resembled the era in which humans evolved from savages into civilized beings.

Were Rousseau and Hall correct in seeing adolescence as a period of biologically engendered storm and stress? Or do social and cultural factors combine with biology to influence psychological development? In our discussion, we will see what contemporary research says about this issue. ■

- Describe the course of physical growth, including changes in body size, proportions, muscle–fat makeup, and skeleton, and their relationship to gains in gross-motor skills.
- Describe hormonal influences on physical growth.
- Discuss factors that contribute to worldwide variations and secular trends in physical growth.

The Course of Physical Growth

Compared with other animals, primates (including humans) experience a prolonged period of physical growth. Mice and rats develop from birth to puberty in just a few weeks—about 2 percent of the lifespan. By contrast, in chimpanzees, the species most similar to humans genetically, growth takes about seven years, or 16 percent of the lifespan. Physical immaturity is even more exaggerated in humans, who devote about 20 percent of their total years to growing. This prolonged physical immaturity is adaptive (Konner, 2010). By ensuring that children remain dependent on adults, it gives them added time to acquire the knowledge and skills essential for life in a complex social world.

Changes in Body Size

The most obvious signs of physical growth are changes in overall body size. During infancy, these changes are rapid—faster than at any other time after birth. By the end of the first year, a typical infant's height is 50 percent greater than at birth; by 2 years, it is 75 percent greater. Similarly, birth weight typically doubles by age 5 months, triples by 1 year, and quadruples by age 2. If children kept growing at this rate, by age 10 they would be 10 feet tall and weigh over 200 pounds! Fortunately, growth slows in early and middle childhood, when children add about 2 to 3 inches in height and 5 pounds in weight each year. Then, puberty brings a sharp acceleration. On average, adolescents gain 10 to 11 inches in height and about 50 to 75 pounds in weight.

Two types of growth curves are used to track overall changes in body size. The first, shown in Figure 5.1a, is a **distance curve,** which plots the average size of a sample of children at each age, indicating typical yearly progress toward maturity. The figure shows gains in height; weight gain follows a similar trend. Notice how during infancy and childhood the two sexes are similar, with the typical girl just slightly shorter (and lighter) than the typical boy. Around age 10 to 11, the typical North American and European girl becomes taller (and heavier) for a time because her pubertal growth spurt takes place two years earlier than the boy's (Archibald, Graber, & Brooks-Gunn, 2006; Bogin, 2001). At age 14, however, she is surpassed by the typical boy, whose growth spurt has now started, whereas hers is almost finished. Growth in height is complete for most North American and European girls by age 16, for boys by age 17½.

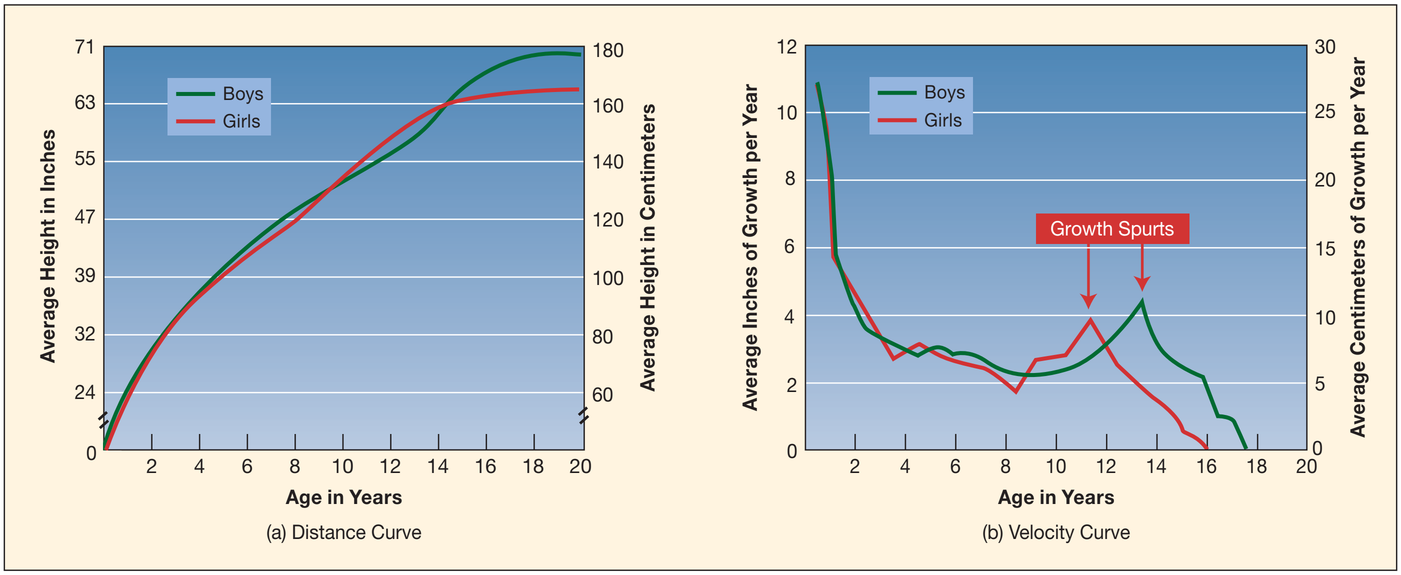
© BARBARA PEACOCK/CORBIS

The dramatic rate of body growth in the first two years is evident when we look at a 4-month-old side by side with a 2-year-old. Height increases by 75 percent, and weight quadruples.

Figure 5.1b shows a second type of growth curve, the **velocity curve,** which plots the average amount of growth at each yearly interval, revealing the exact timing of growth spurts. Note the rapid but decelerating growth in infancy; a slower, constant rate during early and middle childhood; and a sharp increase in early adolescence, followed by a swift decrease as the body approaches its adult size.

Changes in Body Proportions

As the child's overall size increases, parts of the body grow at different rates. Two growth patterns describe these changes. The first is the **cephalocaudal trend**—from the Latin for "head to tail." Recall from Chapter 3 that during the prenatal period, the head develops first from the primitive embryonic disk, followed by the lower part of the body. After birth, the head and chest continue to have a growth advantage, but the trunk and legs gradually pick up speed. In the second pattern, the **proximodistal trend,** growth proceeds, literally, from "near to far"—from the center of the body



(a) Distance Curve

(b) Velocity Curve

FIGURE 5.1 **Distance and velocity curves for height.** (a) The *distance curve* plots average size at each age and shows typical yearly progress toward maturity. (b) The *velocity curve* plots average amount of growth at each yearly interval and reveals the timing of growth spurts. The curves are based on cross-sectional height measurements taken on thousands of U.S. children. (U.S. Department of Health and Human Services, 2000.)

outward. In the prenatal period, the head, chest, and trunk grow first, then the arms and legs, finally the hands and feet. During infancy and childhood, the arms and legs continue to grow somewhat ahead of the hands and feet.

During puberty, growth proceeds in the reverse direction. The hands, legs, and feet accelerate first, followed by the torso, which accounts for most of the adolescent height gain (Sheehy et al., 1999). This pattern helps explain why young adolescents often appear awkward and out of proportion—long-legged, with giant feet and hands.

In infancy and childhood, girls and boys have similar body proportions. During adolescence, however, large differences appear, caused by the action of sex hormones on the skeleton. Boys' shoulders broaden relative to the hips, whereas girls' hips broaden relative to the shoulders and waist. Of course, boys also end up considerably larger than girls, and their legs are longer in relation to the rest of the body. The major reason is that boys have two extra years of preadolescent growth, when the legs are growing the fastest.

LOOK and LISTEN

Observe 10- to 14-year-olds on school grounds or at another gathering place, noting changes in body size and proportions, along with sex differences in timing of the growth spurt.

Changes in Muscle–Fat Makeup

Body fat (most of which lies just beneath the skin) increases in the last few weeks of prenatal life and continues to do so after birth, reaching a peak at about 9 months of age. This early rise in "baby fat" helps the infant keep a constant body temperature. Starting in the second year and continuing into middle childhood, most toddlers slim down (Fomon & Nelson, 2002). At birth, girls have slightly more body fat than boys, a difference that persists into the early school years and then magnifies. Around age 8, girls start to add more fat on their arms, legs, and trunk; they continue to do so throughout puberty, while the arm and leg fat of adolescent boys decreases (Siervogel et al., 2000).

Muscle accumulates slowly throughout infancy and childhood, with a dramatic rise at adolescence. Both sexes gain muscle at puberty, but this increase is 150 percent greater in boys, who develop larger skeletal muscles, hearts, and lung capacity (Rogol, Roemmich, & Clark, 2002). Also, the number of red blood cells—and therefore the ability to carry oxygen from the lungs to the muscles—increases in boys but not in girls. Altogether, boys gain far more muscle strength than girls, contributing to their superior athletic performance during the teenage years (Ramos et al., 1998).

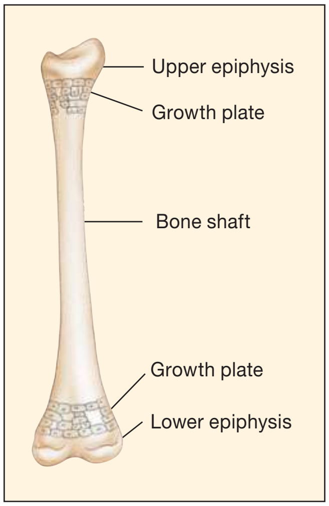


FIGURE 5.2 Diagram of a long bone showing upper and lower epiphyses. Cartilage cells are produced at the growth plates of the epiphyses and gradually harden into bone.

Skeletal Growth

Because children of the same age differ in *rate* of physical growth, researchers have devised methods for measuring progress toward physical maturity that are useful for studying the causes and consequences of these individual differences. The best estimate of a child's physical maturity is **skeletal age**—a measure of development of the bones of the body. The embryonic skeleton is first formed out of soft, pliable tissue called *cartilage.* In the sixth week of pregnancy, cartilage cells begin to harden into bone, a gradual process that continues throughout childhood and adolescence (Moore & Persaud, 2008).

Just before birth, special growth centers, called **epiphyses,** appear at the two extreme ends of each of the long bones of the body (see Figure 5.2). Cartilage cells continue to be produced at the growth plates of these epiphyses, which increase in number throughout childhood and then, as growth continues, get thinner and disappear. After that, no further growth in bone length is possible. As Figure 5.3 shows, skeletal age can be estimated by X-raying the bones to determine the number of epiphyses and the extent to which they are fused.

African-American children tend to be slightly ahead of Caucasian-American children in skeletal age. And girls are considerably ahead of boys—a gap of about four to six weeks at birth, which widens over infancy and childhood (Tanner, Healy, & Cameron, 2001). Girls are advanced in development of other organs as well. This greater physical maturity may contribute to girls' greater resistance to harmful environmental influences. As noted in Chapter 3, girls experience fewer developmental problems than boys and have lower infant and childhood mortality rates.

Gains in Gross-Motor Skills

Changes in size, proportions, and muscle strength support an explosion of new gross-motor skills. As the body becomes more streamlined and less top-heavy, the center of gravity shifts downward, toward the trunk. The resulting improvement in balance paves the way for new motor skills involving large muscles.

Advances in Early and Middle Childhood

By age 2, preschoolers' gaits become smooth and rhythmic—secure enough that they soon leave the ground, first by running and jumping and then, between 3 and 6 years, by hopping, galloping, and skipping. Eventually, upper and lower body skills combine into more effective actions (Haywood & Getchell, 2005). Whereas 2- and 3-year-olds throw a ball rigidly, using only the arms, 4- and 5-year-olds use a smooth, flexible motion, involving the shoulders, torso, trunk, and legs, that makes the ball travel faster and farther.

During the school years, improved balance, strength, agility, and flexibility support refinements in running, jumping, hopping, and ball skills. Children sprint across the playground, play hopscotch in intricate patterns, kick and dribble soccer balls, and swing bats at pitched balls. The Milestones table on the following page summarizes gross-motor achievements in early and middle childhood. At adolescence, increased body size and muscle bring continued motor gains.

The same principle that governs motor development during the first two years continues to operate in childhood and adolescence. Children integrate previously acquired skills into more complex, *dynamic systems of action.* (Return to Chapter 4, page 148, to review this concept.) Then they revise each skill as their bodies grow larger and stronger, their central nervous systems become better developed, their interests and goals become clearer, and their

Milestones

Gross-Motor Development in Early and Middle Childhood

AGE	GROSS-MOTOR SKILLS
2–3 years	• Walks more rhythmically; hurried walk changes to run • Jumps, hops, throws, and catches with rigid upper body • Pushes riding toy with feet; little steering
3–4 years	• Walks up stairs, alternating feet, and down stairs, leading with one foot • Jumps and hops, flexing upper body • Throws and catches with slight involvement of upper body; still catches by trapping ball against chest • Pedals and steers tricycle
4–5 years	• Walks down stairs, alternating feet • Runs more smoothly • Gallops and skips with one foot • Throws ball with increased body rotation and transfer of weight on feet; catches ball with hands • Rides tricycle rapidly; steers smoothly
5–6 years	• Increases running speed to 12 feet per second • Gallops more smoothly; engages in true skipping and sideways stepping • Displays mature, whole-body throwing and catching pattern; increases throwing speed • Rides bicycle with training wheels
7–12 years	• Increases running speed to more than 18 feet per second • Displays continuous, fluid skipping and sideways stepping • Increases vertical jump from 4 to 12 inches and broad jump from 3 to over 5 feet; accurately jumps and hops from square to square • Increases throwing and kicking speed, distance, and accuracy • Increases ability to catch small balls thrown over greater distances • Involves the whole body in batting a ball; batting increases in speed and accuracy • Hand dribbling changes from awkward slapping of the ball to continuous, relaxed, even stroking

Note: These milestones represent overall age trends. Individual differences exist in the precise age at which each milestone is attained.

environments present new challenges. Sex differences in motor skills, already present in the preschool years, illustrate these multiple influences. Size and strength contribute to boys' superior athletic performance in adolescence but cannot fully account for their childhood advantage. As the Social Issues: Education box on page 180 reveals, the social environment plays a prominent role.

Organized Youth Sports Partly because of parents' concerns about safety and the availability and attractions of TV, computer and video games, and the Internet, today's school-age children and adolescents devote less time to outdoor, informal physical play than children in

SOCIAL ISSUES: EDUCATION

Sex Differences in Gross-Motor Development

Sex differences in gross-motor development are present as early as the preschool years, increase during middle childhood, and are large at adolescence. What underlies this expanding gender gap, and how can we ensure that both boys and girls have opportunities that optimize skill and enjoyment of athletics?

Early and Middle Childhood

In early childhood, boys are advanced over girls in abilities that emphasize force and power. By age 5, they can broad-jump slightly farther, run slightly faster, and throw a ball about 5 feet farther. During middle childhood, these differences intensify. For example, on average, a 12-year-old boy can throw a ball 43 feet farther than a 12-year-old girl. Boys are also more adept at batting, kicking, dribbling, and catching. Their slightly greater muscle mass and, in the case of throwing, slightly longer forearms contribute to their skill advantages. And partly because of greater overall physical maturity, girls have an edge in fine-motor skills of handwriting and drawing and in gross-motor capacities that depend on balance and agility, such as hopping and skipping (Fischman, Moore, & Steele, 1992; Haywood & Getchell, 2005).

Sex differences in motor skills increase with age. However, differences in physical capacity remain small throughout childhood, suggesting that social pressures for boys, more than girls, to be active and physically skilled exaggerate small genetically based sex differences. In support of this view, boys can throw a ball much farther than girls only when using their dominant hand. Practice—such as fathers more often playing catch with sons than with daughters—seems to be largely responsible for this advantage. When boys use their nondominant hand, the sex difference is minimal (Williams, Haywood, & Painter, 1996).

Research confirms that parents hold higher expectations for boys' athletic performance—a social message that children absorb at an early age. From first through twelfth grade, girls are less positive than boys about the value of sports and their own sports ability—differences explained in part by parental beliefs (Fredricks & Eccles, 2002). The stronger girls' belief that females are incompetent at sports (such as hockey or soccer), the lower girls judge their own ability and the poorer their actual performance (Belcher et al., 2003; Chalabaev, Sarrazin, & Fontayne, 2009). Girls have few opportunities in school to reverse these gender-based appraisals. To devote more time to academic instruction, U.S. schools have cut back on physical education. Currently, only 15 percent of U.S. elementary and middle schools provide a physical education class at least three days a week, and just 6 percent provide a daily class (Lee et al., 2007).

Adolescence

Not until puberty do sharp sex differences in physical size and muscle strength account for large differences in athletic ability. During adolescence, girls' gains in gross-motor performance are slow and gradual, leveling off by age 14. In contrast, boys show a dramatic spurt in strength, speed, and endurance that continues through the teenage years, widening the gender gap. By midadolescence, few girls perform as well as the average boy in running speed, broad jump, or throwing distance. And practically no boys score as low as the average girl (Haywood & Getchell, 2005; Malina & Bouchard, 1991).

In 1972, the U.S. federal government required schools receiving public funds to provide equal opportunities for males and females in all educational programs, including athletics. Since then, girls' high school extracurricular sports participation has increased, although it still falls far short of boys. In a recent survey of all 50 U.S. state high school athletic associations, 41 percent of sports participants were girls, 59 percent boys (National Federation of State High School Associations, 2009).

By high school, only 58 percent of U.S. boys and 55 percent of girls take any physical education, and daily physical education classes are offered in just 2 percent of U.S. high schools (Centers for Disease Control and Prevention, 2007; U.S. Department of Health and Human Services, 2010g). For both sexes, physical activity declines during adolescence, a trend that parallels school cutbacks (typically to conserve costs) in required physical education. The drop is sharper for girls, two-thirds of whom (compared with just half of boys) take no physical education during their senior year.

Interventions

Besides improving motor performance, sports and exercise influence cognitive and social development. Interschool and intramural athletics provide important lessons in teamwork, problem solving, assertiveness, and competition. And regular, sustained physical activity is associated with healthier dietary habits, enhanced functioning of the immune and cardiovascular systems, better sleep quality, and favorable psychological well-being, as indicated by better academic performance and reduced alcohol and drug use in adolescence (Brand et al., 2010; Castelli et al., 2007; Pate et al., 2000).

Special steps must be taken to raise girls' confidence that they can do well at athletics. Educating parents about the minimal differences between school-age boys' and girls' physical capacities and sensitizing them to unfair biases against promotion of athletic ability among girls may prove helpful. Greater emphasis on skill training for girls, along with increased attention to their athletic achievements, is also likely to improve their participation and performance.

Finally, daily physical education in school, emphasizing enjoyable games and individual exercise rather than competition, is particularly motivating for girls and is associated with lasting positive consequences (Weinberg et al., 2000). In a longitudinal study, participating in team or individual sports at age 14 predicted high rates of physical activity at age 31. Endurance sports such as running and cycling—activities that can easily be performed on one's own time, without expensive equipment or special facilities—were especially likely to carry over into adulthood (Tammelin et al., 2003). The stamina these activities require fosters high *physical self-efficacy*—belief in one's ability to sustain an exercise program (Motl et al., 2002; Telama et al., 2005).

IMAGES-USA/ALAMY

Parental encouragement of girls' involvement in sports is a vital factor in reducing the gender gap in athletic participation, skill, and enjoyment.

previous generations. At the same time, organized sports, such as Little League baseball and soccer and hockey leagues, have expanded tremendously, filling many hours that children used to spend gathering spontaneously for physical play on sidewalks and playgrounds. About half of U.S. youngsters—60 percent of boys and 37 percent of girls—participate in organized sports outside of school hours at some time between ages 5 and 18 (National Council of Youth Sports, 2008).

For most children, joining community athletic teams is associated with increased self-esteem and social skills (Daniels & Leaper, 2006; Fletcher, Nickerson, & Wright, 2003). Among shy children, sports participation seems to play a protective role, fostering self-confidence and a decline in social anxiety, perhaps because it provides a sense of group belonging and a basis for communicating with peers (Findlay & Coplan, 2008). And children who view themselves as good at sports are more likely to continue playing on teams in adolescence, which predicts greater participation in sports and other physical fitness activities in early adulthood (Kjonniksen, Anderssen, & Wold, 2009; Marsh et al., 2007).

In some cases, though, the arguments of critics—that youth sports overemphasize competition and substitute adult control for children's natural experimentation with rules and strategies—are valid. Children who join teams so early that the necessary skills are beyond their abilities soon lose interest. Coaches and parents who criticize rather than encourage can prompt intense anxiety in some children. Rather than promoting elite performance, high parental pressure to excel at sports and frequent, intense practice are linked to children's emotional difficulties and early athletic dropout (Tofler, Knapp, & Drell, 1998; Wall & Côté, 2007).

© STEVE SKJOLD/ALAMY

When coaches emphasize effort, teamwork, and skills over competition, school-age children benefit both physically and socially from playing team sports and are more likely to remain active in adolescence.

In most organized sports, health and safety rules help ensure that injuries are infrequent and mild. The exception is football, which has a high rate of serious injury (Radelet et al., 2002). But frequent, intense practice in any sport can lead to painful "overuse" injuries and, in extreme cases, to stress-related fractures resulting in premature closure of the epiphyses of the long bones (Frank et al., 2007).

When parents and coaches emphasize effort, improvement, participation, and teamwork, young athletes enjoy sports more, exert greater effort to improve their skills, and perceive themselves as more competent at their chosen sport (Ullrich-French & Smith, 2006). This positive emphasis helps promote physical activity, an important factor at a time when inactivity is pervasive among U.S. children and adolescents. Only 49 percent of school-age boys and 35 percent of girls are active enough for good health—that is, engage in at least moderate-intensity exercise for one hour or more per day. As children move into adolescence, these rates drop sharply, to just 25 percent of boys and 11 percent of girls (Troiano et al., 2007; U.S. Department of Health and Human Services, 2010g).

LOOK and LISTEN

Observe a youth athletic league game, such as soccer, baseball, or hockey. Do coaches and parents encourage children's effort and skill gains, or are they overly focused on winning? Cite examples of adult and child behaviors.

Hormonal Influences on Physical Growth

The endocrine glands control the vast physical changes of childhood and adolescence. They manufacture *hormones,* chemical substances secreted by specialized cells in one part of the body that pass to and influence cells in another.

The most important hormones for human growth are released by the **pituitary gland,** located at the base of the brain near the **hypothalamus,** a structure that initiates and regulates pituitary secretions (see Figure 5.4). Once pituitary

FIGURE 5.5 **Hormonal influences on postnatal growth.** The hypothalamus stimulates the pituitary gland to release hormones that either induce growth directly or stimulate other endocrine glands to release growth-inducing hormones (red lines). A highly sensitive feedback loop exists in which the hypothalamus detects hormone levels in the bloodstream and instructs the pituitary gland to increase or decrease the amount of each hormone accordingly (blue lines).

hormones enter the bloodstream, they act directly on body tissues to induce growth, or they stimulate the release of other hormones from endocrine glands located elsewhere in the body. The hypothalamus contains special receptors that detect hormone levels in the bloodstream. Through a highly sensitive feedback loop, it instructs the pituitary gland to increase or decrease the amount of each hormone. In this way, growth is carefully controlled. You may find it useful to refer to Figure 5.5 as we review major hormonal influences.

Growth hormone (GH), the only pituitary secretion produced continuously throughout life, affects development of all tissues except the central nervous system and the genitals. GH production doubles during puberty, contributing to tremendous gains in body size, and then decreases after final adult height is reached. GH acts directly on the body and also stimulates the liver and epiphyses of the skeleton to release another hormone, *insulin-like growth factor 1 (IGF-1),* which triggers cell duplication throughout the body, especially the skeleton, muscles, nerves, bone marrow (origin of blood cells), liver, kidney, skin, and lungs.

Although GH does not seem to affect prenatal growth, it is necessary for physical development from birth on. About 2 percent of children suffer from inherited conditions that cause either GH deficiency or IGF-1 deficiency (in which GH fails to stimulate IGF-1). Without medical intervention, such children reach an average mature height of only 4 to 4½ feet. When treated early with injections of GH or IGF-1 (depending on the disorder), these children show catch-up growth and then grow at a normal rate, becoming much taller than they would have without treatment (Bright, Mendoza, & Rosenfeld, 2009; Saenger, 2003).

A second pituitary hormone, **thyroid-stimulating hormone (TSH),** prompts the thyroid gland in the neck to release *thyroxine*, which is necessary for brain development and for GH to have its full impact on body size. Infants born with a deficiency of thyroxine must receive it at once, or they will be mentally retarded. Once the most rapid period of brain development is complete, thyroxine deficiency no longer affects the central nervous system but still causes children to grow more slowly than average. With prompt treatment, however, they eventually reach normal size (Salerno et al., 2001).

Sexual maturation is controlled by pituitary secretions that stimulate the release of sex hormones. Although we think of **estrogens** as female hormones and **androgens** as male hormones, both types are present in each sex, but in different amounts. The boy's testes release large quantities of the androgen *testosterone,* which leads to muscle growth, body and facial hair, and other male sex characteristics. Androgens (especially testosterone for boys) exert a GH-enhancing effect, contributing greatly to gains in body size. The testes also secrete small amounts of estrogen—the reason that 50 percent of boys experience temporary breast enlargement. In both sexes, estrogens also increase GH secretion, adding to the growth spurt and, in combination with androgens, stimulating gains in bone density, which continue into early adulthood (Cooper, Sayer, & Dennison, 2006; Styne, 2003).

Estrogens released by girls' ovaries cause the breasts, uterus, and vagina to mature, the body to take on feminine proportions, and fat to accumulate. Estrogens also contribute to regulation of the menstrual cycle. *Adrenal androgens,* released from the adrenal glands located on top of each kidney, influence girls' height spurt and stimulate growth of underarm and pubic hair. They have little impact on boys, whose physical characteristics are influenced mainly by androgen and estrogen secretions from the testes.

Worldwide Variations in Body Size

TAKE A MOMENT... Glance into almost any school classroom, and notice the wide individual differences in body growth. Diversity in physical size is especially apparent when we travel to different nations. Worldwide, a 9-inch gap exists between the smallest and the largest 8-year-olds. The shortest children, found in South America, Asia, the Pacific Islands, and parts of Africa, include such ethnic groups as Colombian, Burmese, Thai, Vietnamese, Ethiopian, and Bantu. The tallest children—living in Australia, northern and central Europe, Canada, and the United States, come from Czech, Dutch, Latvian, Norwegian, Swiss, and African populations (Meredith, 1978; Ruff, 2002).

Ethnic variations in growth rate are also common: African-American and Asian children tend to mature faster than Caucasian-American children, who are slightly ahead of European children (Eveleth & Tanner, 1990; Komlos & Breitfelder, 2008). These findings remind us that *growth norms* (age-related averages for height and weight) must be applied cautiously, especially in countries with high immigration rates and many ethnic minorities.

Both heredity and environment contribute to these differences. Body size sometimes reflects evolutionary adaptations to a particular climate. Long, lean physiques are typical in hot, tropical regions and short, stocky ones in cold, Arctic areas (Katzmarzyk & Leonard, 1998). Also, children who grow tallest usually live in developed countries, where food is plentiful and infectious diseases are largely controlled. Physically small children tend to live in less-developed regions, where poverty, hunger, and disease are common (Bogin, 2001). When families move from poor to wealthy nations, their children not only grow taller but also change to a longer-legged body shape. (Recall that during childhood, the legs are growing fastest.) For example, U.S.-born school-age children of immigrant Guatemalan Mayan parents are, on average, 4½ inches taller, with legs nearly 3 inches longer, than their agemates in Guatemalan Mayan villages (Bogin et al., 2002; Varela-Silva et al., 2007).

© ZUTE LIGHTFOOT/IMPACT/HIP/THE IMAGE WORKS

Body size is often the result of evolutionary adaptations to a particular climate. These boys of Tanzania, who live on the hot African plains, have long, lean physiques that permit their bodies to cool easily.

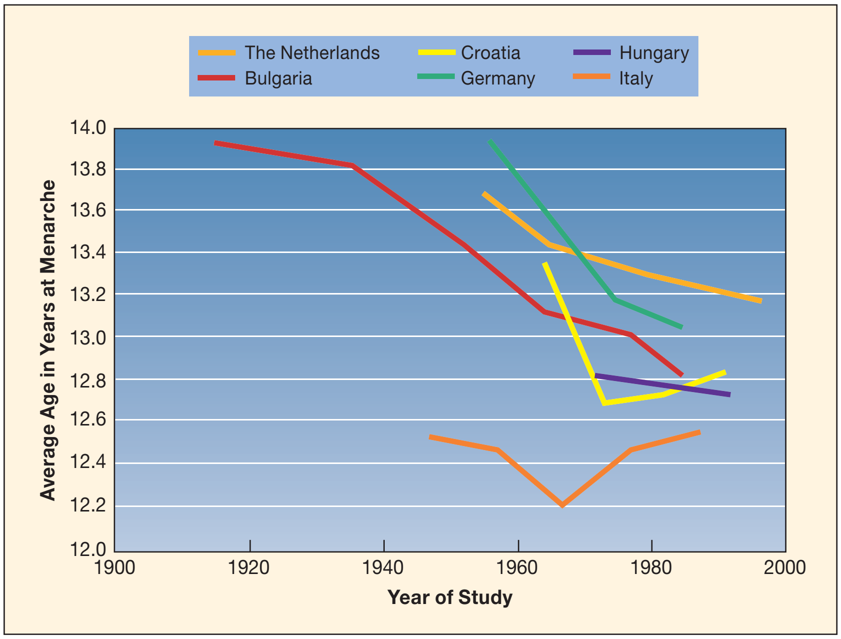

FIGURE 5.6 **Secular trend in age at menarche in six industrialized nations.** Age of menarche declined from 1900 to 1970. Thereafter, a few countries showed a modest, continuing decline due to rising rates of overweight and obesity. Others leveled off or underwent a slight reversal. (From S. M. P. F. de Muinck Keizer-Schrama & D. Mul, 2001, "Trends in Pubertal Development in Europe," *Human Reproduction Update,* 7, p. 289. © European Society of Human Reproduction and Embryology. Secular Trends

Over the past 150 years, **secular trends in physical growth**—changes in body size from one generation to the next—have occurred in industrialized nations. In Australia, Canada, Japan, New Zealand, the United States, and nearly all European countries, most children today are taller and heavier than their parents and grandparents were as children (Ong, Ahmed, & Dunger, 2006). The secular gain appears early in life, increases over childhood and early adolescence, and then declines as mature body size is reached. This pattern suggests that the larger size of today's children is mostly due to a faster rate of physical development. Consistent with this view, age of first menstruation declined steadily from 1900 to 1970, by about 3 to 4 months per decade. Although evidence on boys is sparse, they, too, show signs of having reached puberty earlier in recent decades (Euling et al., 2008).

Improved health and nutrition are largely responsible. As developing nations make socioeconomic progress, they also show secular gains (Ji & Chen, 2008). Secular trends are smaller for low-income children, who have poorer diets and are more likely to suffer from growth-stunting illnesses. And in regions with widespread poverty, famine, and disease, either no secular change or a secular decrease in body size has occurred (Barnes-Josiah & Augustin, 1995; Cole, 2000).

In most industrialized nations, the secular gain in height has slowed, and—as Figure 5.6 illustrates—the trend toward earlier first menstruation has stopped or undergone a slight reversal. But in the United States and a few European countries, soaring rates of overweight and obesity are responsible for a modest, continuing trend toward earlier menarche (Kaplowitz, 2008; Parent et al., 2003).

ASK YOURSELF

Review ■ What aspects of physical growth account for the long-legged appearance of many 8- to 12-year-olds?

Connect ■ Relate secular trends in physical growth to the concept of cohort effects, discussed on page 62 in Chapter 2.

Apply ■ Nine-year-old Allison dislikes physical education and thinks she isn't good at sports. What strategies can be used to improve her involvement and pleasure in physical activity?

Reflect ■ How does your height compare with that of your parents and grandparents when they were your age? Do your observations illustrate secular trends?

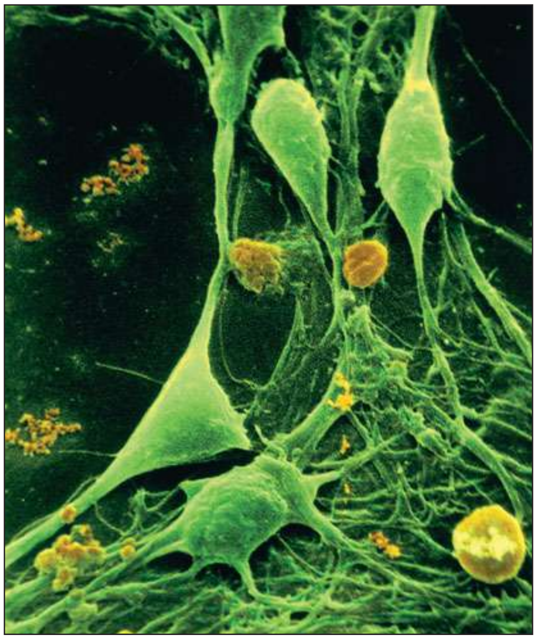
- Describe changes in other brain structures and in the adolescent brain, and discuss evidence on sensitive periods in brain development.

Brain Development

The human brain is the most elaborate and effective living structure on earth today. Despite its complexity, it reaches its adult size earlier than any other organ. We can best understand brain growth by looking at it from two vantage points: (1) the microscopic level of individual brain cells and (2) the larger level of the cerebral cortex, the most complex brain structure and the one responsible for the highly developed intelligence of our species.

Development of Neurons

The human brain has 100 to 200 billion **neurons,** or nerve cells, that store and transmit information, many of which have thousands of direct connections with other neurons. Unlike other body cells, neurons are not tightly packed together. Between them are tiny gaps, or **synapses,** where fibers from different neurons come close together but do not touch (see Figure 5.7). Neurons send messages to one another by releasing chemicals called **neurotransmitters,** which cross synapses.



© ASAP/CNRI/SCIENCE SOURCE/PHOTO RESEARCHERS, INC.

FIGURE 5.7 **Neurons and their connective fibers.** This photograph of several neurons, taken with the aid of a powerful microscope, shows the elaborate synaptic connections that form with neighboring cells.

The basic story of brain growth concerns how neurons develop and form this elaborate communication system. Figure 5.8 summarizes major milestones of brain development. In the prenatal period, neurons are produced in the embryo's primitive neural tube. From there, they migrate to form the major parts of the brain (see Chapter 3, page 91). Once neurons are in place, they differentiate, establishing their unique functions by extending their fibers to form synaptic connections with neighboring cells. During infancy and early childhood, neural fibers increase at an astounding pace (Huttenlocher, 2002; Moore & Persaud, 2008). A surprising aspect of brain growth is **programmed cell death,** which makes space for these connective structures: As synapses form, many surrounding neurons die—20 to 80 percent, depending on the brain region (de Haan & Johnson, 2003; Stiles, 2008). Fortunately, during the prenatal period, the neural tube produces far more neurons than the brain will ever need.

As neurons form connections, *stimulation* becomes vital to their survival. Neurons that are stimulated by input from the surrounding environment continue to establish synapses, forming increasingly elaborate systems of communication that support more complex abilities. At first, stimulation results in massive overabundance of synapses, many of which serve identical functions, thereby ensuring that the child will acquire the motor, cognitive, and social skills that our species needs to survive. Neurons that are seldom stimulated soon lose their synapses, in a process called **synaptic pruning** that returns neurons not needed at the moment to an uncommitted state so they can

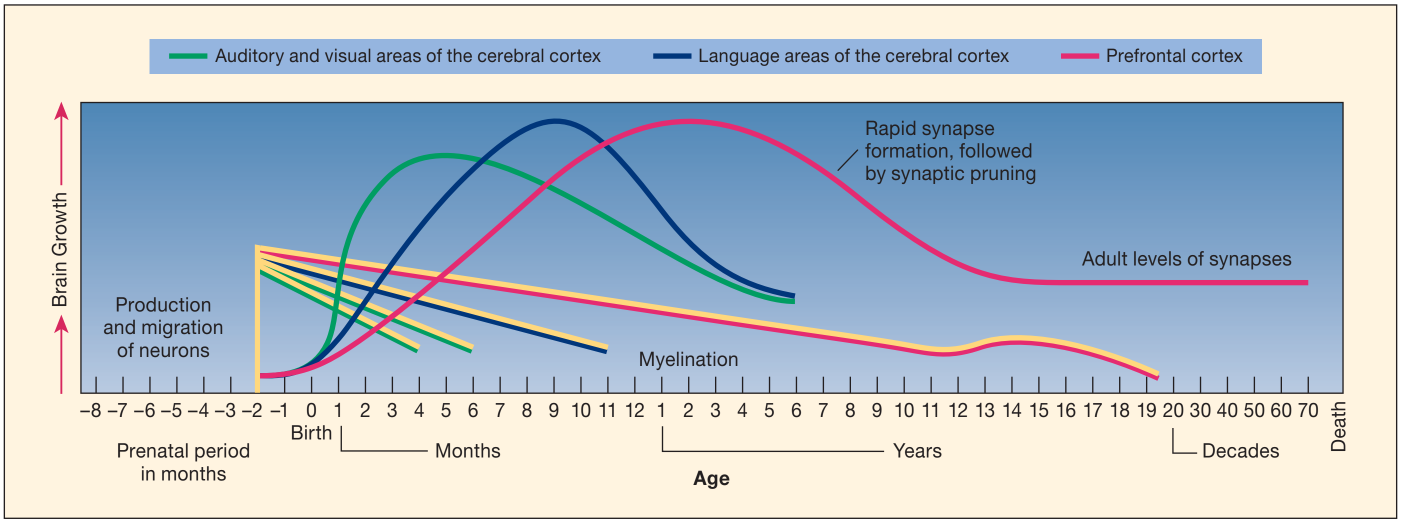


FIGURE 5.8 **Major milestones of brain development.** Formation of synapses is rapid during the first two years, especially in the auditory, visual, and language areas of the cerebral cortex. The prefrontal cortex undergoes more extended synaptic growth. In each area, overproduction of synapses is followed by synaptic pruning. The prefrontal cortex is among the last regions to attain adult levels of synaptic connections—in mid- to late adolescence. Myelination occurs at a dramatic pace during the first two years, more slowly through childhood, followed by an acceleration at adolescence. The multiple yellow lines indicate that the timing of myelination varies among different brain areas. For example, neural fibers continue to myelinate over a longer period in the language areas, and especially in the prefrontal cortex, than in the visual and auditory areas. (Adapted from Thompson & Nelson, 2001.)

support future development. In all, about 40 percent of synapses are pruned during childhood and adolescence (Webb, Monk, & Nelson, 2001). For this process to go forward, appropriate stimulation of the child's brain is vital during periods in which the formation of synapses is at its peak (Nelson, Thomas, & de Haan, 2006).

If few new neurons are produced after the prenatal period, what causes the dramatic increase in brain size during infancy and early childhood? About half the brain's volume is made up of **glial cells,** which are responsible for **myelination,** the coating of neural fibers with an insulating fatty sheath (called *myelin*) that improves the efficiency of message transfer. Glial cells multiply rapidly from the fourth month of pregnancy through the second year of life—a process that continues at a slower pace through middle childhood and accelerates again in adolescence. Gains in neural fibers and myelination are responsible for the extraordinary increase in overall size of the brain—from nearly 30 percent of its adult weight at birth to 70 percent by age 2 and 90 percent at age 6 (Johnson, 2005; Knickmeyer et al., 2008).

Brain development can be compared to molding a "living sculpture." First, neurons and synapses are overproduced; then, cell death and synaptic pruning sculpt away excess building material to form the mature brain—a process jointly influenced by genetically programmed events and the child's experiences. The resulting "sculpture" is a set of interconnected regions, each with specific functions—much like countries on a globe that communicate with one another (Johnston et al., 2001). This "geography" of the brain permits researchers to study its organization using neurobiological methods, such as EEG, ERP, fMRI, and NIRS (see page 48 in Chapter 2 to review). We will encounter these measures as we turn now to the development of the cerebral cortex.

Development of the Cerebral Cortex

The **cerebral cortex** surrounds the rest of the brain, resembling half of a shelled walnut. It is the largest brain structure—accounting for 85 percent of the brain's weight and containing the greatest number of neurons and synapses. Because the cerebral cortex is also the last brain structure to stop growing, it is sensitive to environmental influences for a much longer period than any other part of the brain.

Regions of the Cerebral Cortex

Figure 5.9 shows specific functions of regions of the cerebral cortex, such as receiving information from the senses, instructing the body to move, and thinking. The order in which cortical regions develop corresponds to the order in which various capacities emerge in the infant and growing child. For example, a burst of activity occurs in the auditory and visual cortexes and in areas responsible for body movement over the first year—a period of dramatic gains in auditory and visual perception and mastery of motor skills (Johnson, 2005). Language areas are especially active from late infancy through the preschool years, when language development flourishes (Pujol et al., 2006; Thompson et al., 2000).

The cortical regions with the most extended period of development are the *frontal lobes.* The **prefrontal cortex,** lying in front of areas controlling body movement, is responsible for thought—in particular, consciousness, attention, inhibition of impulses, integration of information, and use of memory, reasoning, planning, and problem-solving strategies. From age 2 months on, the prefrontal cortex functions more effectively. But it undergoes especially rapid myelination and formation and pruning of synapses during the preschool and school years, followed by another period of accelerated growth in adolescence, when it reaches an adult level of synaptic connections (Nelson, 2002; Nelson, Thomas, & de Haan, 2006; Sowell et al., 2002).

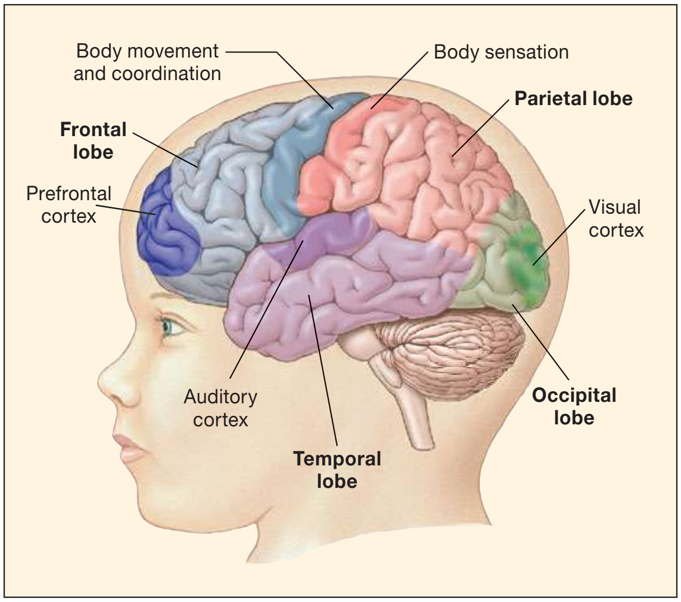

FIGURE 5.9 **The left side of the human brain, showing the cerebral cortex.** The cortex is divided into different lobes, each containing a variety of regions with specific functions. Some major regions are labeled here.

Lateralization and Plasticity of the Cerebral Cortex The cerebral cortex has two *hemispheres,* or sides, that differ in their functions. Some tasks are done mostly by the left hemisphere, others by the right. For example, each hemisphere receives sensory information from the side of the body opposite to it and controls only that side.[1] For most of us, the left hemisphere is largely responsible for verbal abilities (such as spoken and written language) and positive emotion (such as joy). The right hemisphere handles spatial abilities (judging distances, reading maps, and recognizing geometric shapes) and negative emotion (such as distress) (Banish & Heller, 1998; Nelson & Bosquet, 2000). In left-handed people, this pattern may be reversed or, more commonly, the cortex may be less clearly specialized than in right-handers.

Why does this specialization of the two hemispheres, called **lateralization,** occur? Studies using fMRI reveal that the left hemisphere is better at processing information in a sequential, analytic (piece-by-piece) way, a good approach for dealing with communicative information—both verbal (language) and emotional (a joyful smile). In contrast, the right hemisphere is specialized for processing information in a holistic, integrative manner, ideal for making sense of spatial information and regulating negative emotion. A lateralized brain may have evolved because it enabled humans to cope more successfully with changing environmental demands (Falk, 2005). It permits a wider array of functions to be carried out effectively than if both sides processed information exactly the same way.

© CHRISTINA KENNEDY/PHOTOEDIT

Because this deaf toddler is learning to communicate in sign language, a spatial skill, she will depend more on the right hemisphere of the cerebral cortex for language processing than her hearing agemates will.

Brain Plasticity. Researchers study when brain lateralization occurs to learn more about **brain plasticity.** A highly plastic cerebral cortex, in which many areas are not yet committed to specific functions, has a high capacity for learning. And if a part of the cortex is damaged, other parts can take over the tasks it would have handled. But once the hemispheres lateralize, damage to a specific region means that the abilities it controls cannot be recovered to the same extent or as easily as earlier.

At birth, the hemispheres have already begun to specialize. Most newborns favor the right side of the body in their head position and reflexive reactions (Grattan et al., 1992; Rönnqvist & Hopkins, 1998). Most also show greater activation (detected with either ERP or NIRS) in the left hemisphere while listening to speech sounds or displaying a positive state of arousal. In contrast, the right hemisphere reacts more strongly to nonspeech sounds and to stimuli (such as a sour-tasting fluid) that evoke negative emotion (Davidson, 1994; Fox & Davidson, 1986; Hespos et al., 2010).

Nevertheless, research on brain-damaged children and adults offers dramatic evidence for substantial plasticity in the young brain, summarized in the Biology and Environment box on page 188. Furthermore, early experience greatly influences the organization of the cerebral cortex. For example, deaf adults who, as infants and children, learned sign language (a spatial skill) depend more than hearing individuals on the right hemisphere for language processing (Neville & Bavelier, 2002). And toddlers who are advanced in language development show greater left-hemispheric specialization for language than their more slowly developing agemates (Mills et al., 2005). Similarly, while performing motor and cognitive tasks, children show diffuse fMRI activity in the cerebral cortex relative to adolescents and adults, for whom activity is concentrated in certain cortical areas (Casey et al., 2002; Luna et al., 2001). Apparently, the very process of acquiring motor, cognitive, and language skills promotes lateralization.

In sum, the brain is more plastic during the first few years than it will be ever again. An overabundance of synaptic connections supports brain plasticity, ensuring that young children will acquire certain capacities even if some areas are damaged. And although the cortex is programmed from the start for hemispheric specialization, experience greatly influences the rate and success of its advancing organization.

---

[1] The eyes are an exception. Messages from the right half of each retina go to the right hemisphere; messages from the left half of each retina go to the left hemisphere. Thus, visual information from *both* eyes is received by *both* hemispheres.

BIOLOGY and ENVIRONMENT

Brain Plasticity: Insights from Research on Brain-Damaged Children and Adults

In the first few years of life, the brain is highly plastic. It can reorganize areas committed to specific functions in ways that the mature brain cannot. Consistently, adults who suffered brain injuries in infancy and early childhood show fewer cognitive impairments than adults with later-occurring injuries (Holland, 2004; Huttenlocher, 2002). Nevertheless, the young brain is not totally plastic. When it is injured, its functioning is compromised. The extent of plasticity depends on several factors, including age at time of injury, site of damage, and skill area.

Brain Plasticity in Infancy and Early Childhood

In a large study of children with injuries to the cerebral cortex that occurred before birth or in the first six months of life, language and spatial skills were assessed repeatedly into adolescence (Akshoomoff et al., 2002; Stiles, 2001a; Stiles et al., 2005, 2008). All the children had experienced early brain seizures or hemorrhages. Brain-imaging techniques (fMRI and PET) revealed the precise site of damage.

Regardless of whether injury occurred in the left or right cerebral hemisphere, the children showed delays in language development that persisted until about 3½ years of age. That damage to either hemisphere affected early language competence indicates that at first, language functioning is broadly distributed in the brain. But by age 5, the children caught up in vocabulary and grammatical skills. Undamaged areas—in either the left or the right hemisphere—had taken over these language functions.

Compared with language, spatial skills were more impaired after early brain injury. When preschool through adolescent-age youngsters were asked to copy designs, those with early right-hemispheric damage had trouble with holistic processing—accurately representing the overall shape. In contrast, children with left-hemispheric damage captured the basic shape but omitted fine-grained details. Nevertheless, the children improved in drawing skills with age—gains that do not occur in brain-injured adults (Akshoomoff et al., 2002; Stiles et al., 2003, 2008).

Clearly, recovery after early brain injury is greater for language than for spatial skills. Why is this so? Researchers speculate that spatial processing is the older of the two capacities in our evolutionary history and, therefore, more lateralized at birth (Stiles, 2001b; Stiles et al., 2002, 2008). But early brain injury has far less impact than later injury on *both* language and spatial skills. In sum, the young brain is remarkably plastic.

The Price of High Plasticity in the Young Brain

Despite impressive recovery of language and (to a lesser extent) spatial skills, children with early brain injuries show deficits in a wide variety of complex mental abilities during the school years. For example, their reading and math progress is slow. And in telling stories, they produce simpler narratives than agemates without early brain injuries (although many catch up in narrative skills by early adolescence) (Reilly, Bates, & Marchman, 1998; Reilly et al., 2004). Furthermore, the more brain tissue destroyed in infancy or early childhood, the poorer children score on intelligence tests (Anderson et al., 2006).

© JIM WEST/THE IMAGE WORKS

This preschooler, who experienced brain damage in infancy, has been spared massive impairments because of early, high brain plasticity. A teacher guides his hand in drawing shapes to strengthen spatial skills, which are more impaired than language.

High brain plasticity, researchers explain, comes at a price. When healthy brain regions take over the functions of damaged areas, a "crowding effect" occurs: Multiple tasks must be done by a smaller than usual volume of brain tissue. Consequently, the brain processes information less quickly and accurately than it would if it were intact. Complex mental abilities of all kinds suffer into middle childhood, and often longer, because performing them well requires considerable space in the cerebral cortex (Huttenlocher, 2002).

Later Plasticity

Brain plasticity is not restricted to early childhood. Though far more limited, reorganization in the brain can occur later, even in adulthood. For example, adult stroke victims often display considerable recovery, especially in response to stimulation of language and motor skills. Brain-imaging techniques reveal that structures adjacent to the permanently damaged area or in the opposite cerebral hemisphere reorganize to support the impaired ability (Kalra & Ratan, 2007; Murphy & Corbett, 2009).

In infancy and childhood, the goal of brain growth is to form neural connections that ensure mastery of essential skills. Animal research reveals that plasticity is greatest while the brain is forming many new synapses; it declines during synaptic pruning (Murphy & Corbett, 2009). At older ages, specialized brain structures are in place, but after injury they can still reorganize to some degree. The adult brain can produce a small number of new neurons. And when an individual practices relevant tasks, the brain strengthens existing synapses and generates new ones (Nelson, Thomas, & de Haan, 2006).

Plasticity seems to be a basic property of the nervous system. Researchers hope to discover how experience and brain plasticity work together throughout life so they can help people of all ages—with and without brain injuries—develop at their best.

Lateralization and Handedness. Research on handedness supports the joint contribution of nature and nurture to brain lateralization. As early as the tenth prenatal week, most fetuses show a right-hand preference during thumb-sucking (Hepper, McCartney, & Shannon, 1998). And by age 6 months, infants typically reach more smoothly and efficiently with their right than their left arm. These tendencies, believed to be biologically based, may contribute to the right-handed bias of most children by the end of the first year (Hinojosa, Sheu, & Michel, 2003; Rönnqvist & Domellöf, 2006). During toddlerhood and early childhood, handedness gradually extends to a wider range of skills.

Handedness reflects the greater capacity of one side of the brain—the individual's **dominant cerebral hemisphere**—to carry out skilled motor action. Other important abilities are generally located on the dominant side as well. For right-handed people—in Western nations, 90 percent of the population—language is housed in the left hemisphere with hand control. For the left-handed 10 percent, language is occasionally located in the right hemisphere or, more often, shared between the hemispheres (Perelle & Ehrman, 2009). This indicates that the brains of left-handers tend to be less strongly lateralized than those of right-handers.

Left-handed parents show only a weak tendency to have left-handed children (Vuoksimaa et al., 2009). One genetic theory proposes that most children inherit a gene that *biases* them for right-handedness and a left-dominant cerebral hemisphere. But that bias is not strong enough to overcome experiences that might sway children toward a left-hand preference (Annett, 2002). Even prenatal events may profoundly affect handedness. Both identical and fraternal twins are more likely than ordinary siblings to differ in hand preference, probably because twins usually lie in opposite orientations in the uterus (Derom et al., 1996). The orientation of most singleton fetuses—facing toward the left—is believed to promote greater control over movements on the body's right side (Previc, 1991).

Handedness also involves practice. It is strongest for complex skills requiring extensive training, such as eating with utensils, writing, and engaging in athletic activities. And wide cultural differences exist: In Tanzania, Africa, where children are physically restrained and punished for favoring the left hand, less than 1 percent of adults are left-handed (Provins, 1997).

Although rates of left-handedness are elevated among people with mental retardation and mental illness, atypical brain lateralization is probably not responsible for these individuals' problems. Rather, early damage to the left hemisphere may have caused their disabilities while also leading to a shift in handedness. In support of this idea, left-handedness is associated with prenatal and birth difficulties that can result in brain damage, including prolonged labor, prematurity, and Rh incompatibility (Powls et al., 1996; Rodriguez & Waldenström, 2008).

Most left-handers, however, have no developmental problems—in fact, unusual lateralization may have certain advantages. Left- and mixed-handed young people are slightly advantaged in speed and flexibility of thinking, and they are more likely than their right-handed agemates to develop outstanding verbal and mathematical talents (Flannery & Liederman, 1995; Gunstad et al., 2007). More even distribution of cognitive functions across both hemispheres may be responsible.

Advances in Other Brain Structures

Besides the cerebral cortex, several other areas of the brain make strides during childhood and adolescence. All of these changes involve establishing links among parts of the brain, increasing the coordinated functioning of the central nervous system. (To see where the structures we are about to discuss are located, turn back to Figure 5.4 on page 181.)

At the rear and base of the brain is the **cerebellum,** a structure that aids in balance and control of body movement. Fibers linking the cerebellum to the cerebral cortex grow and myelinate from birth through the preschool years, contributing to dramatic gains in motor coordination: By the time they start school, children can play hopscotch, throw and catch a ball with well-coordinated movements, and print letters of the alphabet. Connections between the cerebellum and the cerebral cortex also support thinking (Diamond, 2000). Children with damage to the cerebellum usually display both motor and cognitive deficits, including problems with memory, planning, and language (Noterdaeme et al., 2002; Riva & Giorgi, 2000).

The **reticular formation,** a structure in the brain stem that maintains alertness and consciousness, generates synapses and myelinates from early childhood into adolescence. Neurons in the reticular formation send out fibers to many other areas of the brain. Many go to the prefrontal lobes of the cerebral cortex, contributing to improvements in sustained, controlled attention.

An inner-brain structure called the **hippocampus,** which plays a vital role in memory and in images of space that help us find our way, undergoes rapid synapse formation and myelination in the second half of the first year, when recall memory and independent movement emerge. Over the preschool and elementary school years, the hippocampus and surrounding areas of the cerebral cortex continue to develop swiftly, establishing connections with one another and with the prefrontal cortex (Nelson, Thomas, & de Haan, 2006). These changes make possible dramatic gains in memory (ability to use strategies to store and retrieve information) and spatial understanding (drawing and reading of maps), which we will take up in Chapters 6 and 7.

Also located in the inner brain, adjacent to the hippocampus, is the **amygdala,** a structure that plays a central role in processing emotional information. The amygdala is sensitive to facial emotional expressions, especially fear (Whalen et al., 2009). It also enhances memory for emotionally salient events, thereby ensuring that information relevant for survival—stimuli that evoke fear or signify safety—will be retrieved on future occasions. This capacity for emotional learning seems to emerge in early childhood: Damage to the amygdala in the first few years leads to loss of ability to learn about fear and safety signals and typically results in wide-ranging socially inappropriate behaviors (Shaw, Brierley, & David, 2005). Throughout childhood and adolescence, connections between the amygdala and the prefrontal cortex, which governs regulation of emotion, form and myelinate (Tottenham, Hare, & Casey, 2009).

The **corpus callosum** is a large bundle of fibers connecting the two cerebral hemispheres. Production of synapses and myelination of the corpus callosum increase at 1 year, peak between 3 and 6 years, and then continue at a slower pace through middle childhood and adolescence (Thompson et al., 2000). The corpus callosum supports smooth coordination of movements on both sides of the body and integration of perception, attention, memory, language, and problem solving. The more complex the task, the more essential is communication between the hemispheres.

© STEVE SKJOLD/ALAMY

In adolescence, changes in the brain's emotional/social network outpace development of the cognitive control network. As a result, teenagers do not yet have the capacity to control their powerful drive for new—and sometimes risky—experiences.

Brain Development in Adolescence

From middle childhood to adolescence, connectivity among distant regions of the cerebral cortex expands and attains rapid communication. As a result, the prefrontal cortex becomes a more effective "executive"—overseeing and managing the integrated functioning of various areas, yielding more complex, flexible, and adaptive thinking and behavior (Blakemore & Choudhury, 2006; Lenroot & Giedd, 2006). Consequently, adolescents gain in diverse cognitive skills, including speed of thinking, attention, memory, planning, capacity to integrate information, and regulation of cognition and emotion.

But these advances occur gradually over the teenage years. fMRI evidence reveals that adolescents recruit the prefrontal cortex's connections with other brain areas less effectively than adults do. Because the *prefrontal cognitive-control network* still requires fine-tuning, teenagers' performance on tasks requiring self-restraint, planning, and future orientation (rejecting a smaller immediate reward in favor of a larger delayed reward) is not yet fully mature (Luna et al., 2001; McClure et al., 2004; Steinberg et al., 2009).

Adding to these self-regulation difficulties are changes in the brain's *emotional/social network.* As humans and other mammals become sexually mature, neurons become more responsive to excitatory neurotransmitters. As a result, adolescents react more strongly to stressful events and experience pleasurable stimuli more intensely. But because the cognitive control network is not yet functioning optimally, most teenagers find it hard to manage these powerful influences (Casey, Getz, & Galvan, 2008; Spear, 2008; Steinberg et al., 2008). This imbalance contributes to adolescents' unchecked drive for novel experiences, including drug taking, reckless driving, unprotected sex, and delinquent activity, especially among those who are highly stressed and engage in reward seeking to counteract chronic emotional pain.

In addition, the surge in sex hormones (both estrogens and androgens) at puberty heightens sensitivity of the prefrontal cortex and inner brain structures (such as the amygdala) to the hormone *oxytocin,* secreted by the pituitary gland. In new mothers, oxytocin promotes caregiving behavior. In teenagers, it increases responsiveness to emotional and social stimuli, including feedback from others (Steinberg, 2008). Enhanced oxytocin sensitivity helps explain why adolescents, as we will we will see in Chapter 15, are so self-conscious and sensitive to others' opinions. It also contributes to teenagers' receptiveness to peer influence—a strong predictor of adolescent risk taking of all kinds (Gardner & Steinberg, 2005; Ranking et al., 2004).

Of course, not all teenagers display this rise in risk taking in the form of careless, dangerous acts: Temperament, parenting, and school and neighborhood resources (which are linked to opportunities to take risks) make a difference. Nevertheless, transformations in the adolescent brain enhance our understanding of both the cognitive advances and worrisome behaviors of this period, along with teenagers' need for adult patience, oversight, and guidance.

Sensitive Periods in Brain Development

We have seen that stimulation of the brain is vital when it is growing most rapidly. Both animal and human studies, as noted in Chapter 4, reveal that early, extreme sensory deprivation results in permanent brain damage and loss of functions—findings that verify the existence of sensitive periods in brain development. Recall, also, that research on children adopted from Romanian orphanages indicates that deprived institutional care extending beyond the first six months results in persistent intellectual impairments and mental health problems (see page 170).

Much evidence confirms that the brain is particularly spongelike during the first few years, enabling children to acquire new skills easily and quickly. How, then, can we characterize appropriate stimulation during this time? To answer this question, researchers distinguish between two types of brain development. The first, **experience-expectant brain growth,** refers to the young brain's rapidly developing organization, which depends on ordinary experiences—opportunities to interact with people, hear language and other sounds, see and touch objects, and move about and explore the environment. As a result of millions of years of evolution, the brains of all infants, toddlers, and young children *expect* to encounter these experiences and, if they do, grow normally. The second type of brain development, **experience-dependent brain growth,** occurs throughout our lives. It consists of additional growth and refinement of established brain structures as a result of specific learning experiences that vary widely across individuals and cultures (Greenough & Black, 1992). Reading and writing, playing computer games, weaving an intricate rug, and practicing the violin are examples. The brain of a violinist differs in certain ways from that of a poet because each has exercised different brain regions for a long time.

Experience-expectant brain development occurs early and naturally, as caregivers offer babies and preschoolers age-appropriate play materials and engage them in enjoyable daily routines—a shared meal, a game of peekaboo, a bath before bed, a picture book to talk about, or a song to sing. The resulting growth provides the foundation for later-occurring, experience-dependent development (Huttenlocher, 2002; Shonkoff & Phillips, 2001). In Chapter 4, we indicated that not just

Experience-expectant brain growth occurs naturally, through ordinary, stimulating experiences. As they explore spring flowers with magnifying glasses, these preschoolers engage in the type of informal activity that best promotes brain development in the early years.

understimulation but also overstimulation—overwhelming children with tasks and expectations for which they are not yet ready—can threaten their development. No evidence exists for a sensitive period in the first five or six years for mastering skills that depend on extensive training, such as reading, musical performance, or gymnastics (Bruer, 1999). To the contrary, rushing early learning harms the brain by overwhelming its neural circuits, thereby reducing the brain's sensitivity to the everyday experiences it needs for a healthy start in life.

ASK YOURSELF

Review ■ How does stimulation affect brain development? Cite evidence at the level of neurons and at the level of the cerebral cortex.

Connect ■ What stance on the nature–nurture issue does evidence on development of handedness support? Document your answer with research findings.

Apply ■ Lucia experienced damage to the left hemisphere of her cerebral cortex shortly after birth. As a first grader, she shows impressive recovery of language and spatial skills, but she lags behind her peers in academic progress. What accounts for her recovery of skills? How about her cognitive deficits?

Reflect ■ Which infant enrichment program would you choose: one that emphasizes social games and gentle talking and touching, or one that includes reading and number drills and classical music lessons? Explain.

▶ How do heredity, nutrition, infectious disease, and parental affection contribute to physical growth and health?

Factors Affecting Physical Growth

Physical growth, like other aspects of development, results from a complex interplay between genetic and environmental factors. Although heredity remains important, environmental factors continue to affect genetic expression. Good nutrition, relative freedom from disease, and emotional well-being are essential to children's healthy development, while environmental pollutants can be a threat. The Biology and Environment box on the following page considers the extent to which one of the most common pollutants, low-level lead, undermines children's mental and emotional functioning.

Heredity

Because identical twins are much more alike in body size than fraternal twins, we know that heredity contributes considerably to physical growth (Estourgie-van Burk et al., 2006). When diet and health are adequate, height and rate of physical growth (as measured by skeletal age and timing of first menstruation) are largely determined by heredity. In fact, as long as negative environmental influences, such as poor nutrition or illness, are not severe, children and adolescents typically show *catch-up growth*—a return to a genetically influenced growth path once conditions improve. Still, the brain, the heart, the digestive system, and many other internal organs may be permanently compromised (Hales & Ozanne, 2003). (Recall the consequences of inadequate prenatal nutrition for long-term health, discussed on page 104 in Chapter 3.)

Genes influence growth by controlling the body's production of and sensitivity to hormones. Mutations can disrupt this process, leading to deviations in physical size. Occasionally, a mutation becomes widespread in a population. Consider the Efe of the Republic of Congo, whose typical adult height is less than 5 feet. For genetic reasons, the impact of growth hormone (GH) is reduced in Efe children (Bailey, 1990). By age 5, the average Efe child is shorter than over 97 percent of North American agemates. The Efe's small size probably evolved because it reduces their caloric requirements in the face of food scarcity in the rain forests of Central Africa and enables them to move easily through the dense forest underbrush (Perry & Dominy, 2009).

BIOLOGY and ENVIRONMENT

Low-Level Lead Exposure and Children's Development

Lead is a highly toxic element that, at blood levels exceeding 60 µg/dL (micrograms per deciliter), causes brain swelling, hemorrhaging, disrupted functioning of neurons, and widespread cell death. Before 1980, exposure to lead resulted from use of lead-based paints for the interiors of residences (infants and young children often ate paint flakes) and from use of leaded gasoline (car exhaust resulted in a highly breathable form of lead). Laws limiting the lead content of paint and mandating lead-free gasoline led to a sharp decline in children's lead levels, from an average of 15 µg/dL in 1980 to 1.8 µg/dL today (Jones et al., 2009; Meyer et al., 2003).

But in areas near airports with significant burning of jet fuel, near industries using lead production processes, or where lead-based paint remains in older homes, children's blood levels are still markedly elevated. In some areas, water-pipe corrosion has caused lead to rise in drinking water. Contaminated soil and imported consumer products, such as toys made of leaded plastic, are additional sources of exposure (Cole & Winsler, 2010). About 15 percent of low-income children living in large central cities, and 19 percent of African-American children, have blood-level levels exceeding 10 µg/dL (the U.S. government official "level of concern"), warranting immediate efforts to reduce exposure (Jones et al., 2009). How much lead exposure is too much? Does lead contamination, even in small quantities, impair children's mental functioning? Until recently, answers were unclear. Studies reporting a negative relationship between children's current lead levels and cognitive performance had serious limitations. Researchers knew nothing about children's history of lead exposure and often failed to control for factors associated with both blood-lead levels and mental test scores (such as family income, home environmental quality, and nutrition) that might account for the findings.

© DARREN McCOLLESTER

This girl and her family of Kosovo, displaced by war, have lived for a decade on land polluted by lead. Long-term negative effects of lead exposure include learning impairments and behavior problems.

Over the past two decades, a host of longitudinal studies of the developmental consequences of lead have been conducted in multiple countries, including the United States, Australia, Mexico City, and Yugoslavia. Some focused on inner-city, economically disadvantaged minority children, others on middle- and upper-middle-class suburban children, and one on children living close to a lead smelter. Each tracked children's lead exposure over an extended time and included relevant controls.

All but one site reported negative relationships between lead exposure and children's IQs (Canfield et al., 2003; Hubbs-Tait et al., 2005; Lanphear et al., 2005). Higher blood levels were also associated with deficits in verbal and visual-motor skills and with distractibility, overactivity, poor organization, weak academic performance, and behavior problems. And an array of additional findings suggested that persistent childhood lead exposure contributes to antisocial behavior in adolescence (Needleman et al., 2002; Nevin, 2006; Stretesky & Lynch, 2004).

The investigations did not agree on an age period of greatest vulnerability. In some, relationships were strongest in toddlerhood and early childhood; in others, at the most recently studied age, suggesting cumulative effects over time. Still other studies reported similar lead-related cognitive deficits from infancy through adolescence. Overall, poorer mental test scores associated with lead exposure persisted over time and seemed to be permanent. Children given drugs to induce excretion of lead (chelation) did not improve (Dietrich et al., 2004; Rogan et al., 2001). And negative cognitive consequences were evident at all levels of lead exposure—even below 10 µg/dL (Canfield et al., 2003; Lanphear et al., 2005; Wright et al., 2008).

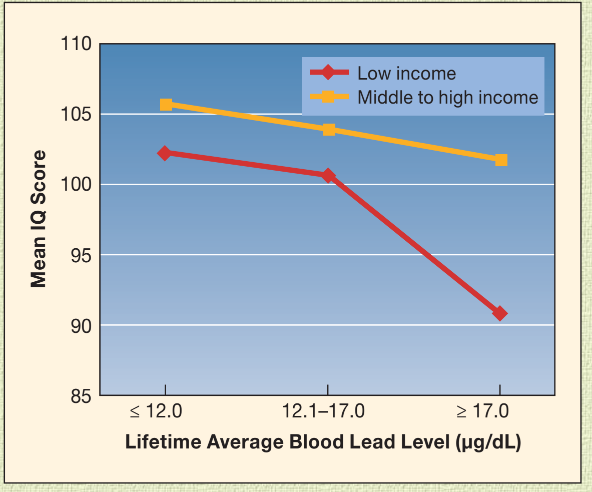

FIGURE 5.10 Relationship of lifetime average lead exposure to 11- to 13-year-olds' IQ by family economic status. In this study, conducted in the lead-smelting city of Port Pirie, Australia, blood-lead levels of 375 children were measured repeatedly from birth to age 11 to 13. The lead-exposure-related drop in IQ was much greater for children from economically disadvantaged than advantaged families. (Adapted from Tong, McMichael, & Baghurst, 2000.)

Furthermore, in several investigations, cognitive consequences were much greater for children from low-income than middle- and high-income families (see, for example, Figure 5.10) (Bellinger, Leviton, & Sloman, 1990; Ris et al., 2004; Tong, McMichael, & Baghurst, 2000). A stressed, disorganized home life seems to heighten lead-induced damage. Dietary factors can also magnify lead's toxic effects. Iron and zinc deficiencies, especially common in economically disadvantaged children, increase lead concentration in the blood (Noonan et al., 2003; Wolf, Jimenez, & Lozoff, 2003; Wright et al., 2003).

In sum, lead impairs mental development and contributes to behavior problems. Children from low-income families are more likely both to live in lead-contaminated areas and to experience additional risks that magnify lead-induced damage. Because lead is a stable element, its release into the air and soil is difficult to reverse. Therefore, in addition to laws that control lead pollution, interventions that reduce the negative impact of lead—through involved parenting, dietary enrichment, better schools, and public education about lead hazards—are vital.

Twin studies reveal that genetic makeup also affects body weight (Kinnunen, Pietilainen, & Rissanen, 2006). At the same time, environment—in particular, nutrition and eating habits—plays an especially important role.

Nutrition

Nutrition is important at any time of development, but it is especially crucial during the first two years because the baby's brain and body are growing so rapidly. Pound for pound, an infant's energy needs are twice those of an adult. Twenty-five percent of babies' total caloric intake is devoted to growth, and infants need extra calories to keep their rapidly developing organs functioning properly (Meyer, 2009).

Breastfeeding versus Bottle-Feeding Babies need not only enough food but also the right kind of food. In early infancy, breast milk is ideally suited to their needs, and bottled formulas try to imitate it. Applying What We Know on the following page summarizes major nutritional and health advantages of breast milk.

© LIBA TAYLOR/ALAMY

Midwives in India support a mother as she learns to breastfeed her infant. Breastfeeding is especially important in developing countries, where it helps protect babies against life-threatening infections and early death.

Because of these benefits, breastfed babies in poverty-stricken regions are much less likely to be malnourished and 6 to 14 times more likely to survive the first year of life. The World Health Organization recommends breastfeeding until age 2 years, with solid foods added at 6 months. These practices, if widely followed, would save the lives of more than a million infants annually (World Health Organization, 2011). Even breastfeeding for just a few weeks offers some protection against respiratory and intestinal infections, which are devastating to young children in developing countries. Also, because a nursing mother is less likely to get pregnant, breastfeeding helps increase spacing between siblings, a major factor in reducing infant and childhood deaths in nations with widespread poverty. (Note, however, that breastfeeding is not a reliable method of birth control.)

Yet many mothers in the developing world do not know about the benefits of breastfeeding. In Africa, the Middle East, and Latin America, most babies get some breastfeeding, but fewer than 40 percent are exclusively breastfed for the first 6 months, and one-fourth are fully weaned from the breast by 1 year (UNICEF, 2009). In place of breast milk, mothers give their babies commercial formula or low-grade nutrients, such as rice water or highly diluted cow or goat milk. Contamination of these foods as a result of poor sanitation is common and often leads to illness and infant death. The United Nations has encouraged all hospitals and maternity units in developing countries to promote breastfeeding as long as mothers do not have viral or bacterial infections (such as HIV or tuberculosis) that can be transmitted to the baby. Today, most developing countries have banned the practice of giving free or subsidized formula to new mothers.

Partly as a result of the natural childbirth movement, breastfeeding has become more common in industrialized nations, especially among well-educated women. Today, 75 percent of American mothers breastfeed, but more than half stop by 6 months (U.S. Centers for Disease Control and Prevention, 2010). And despite the health benefits of breast milk, only 50 percent of preterm infants are breastfed at hospital discharge. Breastfeeding a preterm baby presents special challenges, including maintaining a sufficient milk supply with artificial pumping until the baby is mature enough to suck at the breast and providing the infant with enough sucking experience to learn to feed successfully (Callen & Pinelli, 2005). Kangaroo care (see pages 115–116 in Chapter 3) and the support of health professionals are helpful.

Because breast milk is so easily digestible, a breastfed infant becomes hungry every 1½ to 2 hours, compared to every 3 or 4 hours for a bottle-fed baby. This makes breastfeeding inconvenient for many employed women. Not surprisingly, mothers who return to work sooner wean their babies from the breast earlier (Kimbro, 2006). But mothers who cannot be with their babies all the time can still combine breast- and bottle-feeding. The U.S.

APPLYING WHAT WE KNOW

Reasons to Breastfeed

NUTRITIONAL AND HEALTH ADVANTAGES	EXPLANATION
Provides the correct balance of fat and protein	Compared with the milk of other mammals, human milk is higher in fat and lower in protein. This balance, as well as the unique proteins and fats contained in human milk, is ideal for a rapidly myelinating nervous system.
Ensures nutritional completeness	A mother who breastfeeds need not add other foods to her infant's diet until the baby is 6 months old. The milks of all mammals are low in iron, but the iron contained in breast milk is much more easily absorbed by the baby's system. Consequently, bottle-fed infants need iron-fortified formula.
Helps ensure healthy physical growth	One-year-old breastfed babies are leaner (have a higher percentage of muscle to fat), a growth pattern that persists through the preschool years and that may help prevent later overweight and obesity.
Protects against many diseases	Breastfeeding transfers antibodies and other infection-fighting agents from mother to baby and enhances functioning of the immune system. Compared with bottle-fed infants, breastfed babies have far fewer allergic reactions and respiratory and intestinal illnesses. Breast milk also has anti-inflammatory effects, which reduce the severity of illness symptoms. Breastfeeding in the first four months (especially when exclusive) is linked to lower blood cholesterol levels in childhood and, thereby, may help prevent cardiovascular disease.
Protects against faulty jaw development and tooth decay	Sucking the mother's nipple instead of an artificial nipple helps avoid malocclusion, a condition in which the upper and lower jaws do not meet properly. It also protects against tooth decay due to sweet liquid remaining in the mouths of infants who fall asleep while sucking on a bottle.
Ensures digestibility	Because breastfed babies have a different kind of bacteria growing in their intestines than do bottle-fed infants, they rarely suffer from constipation or other gastrointestinal problems.
Smooths the transition to solid foods	Breastfed infants accept new solid foods more easily than do bottle-fed infants, perhaps because of their greater experience with a variety of flavors, which pass from the maternal diet into the mother's milk.

Sources: American Academy of Pediatrics, 2005a; Buescher, 2001; Michels et al., 2007; Owen et al., 2008; Rosetta & Baldi, 2008; Wayerman, Rothenbacher, & Brenner, 2006.

Department of Health and Human Services (2009a) advises exclusive breastfeeding for the first 6 months and inclusion of breast milk in the baby's diet until at least 1 year.

Women who do not breastfeed sometimes worry that they are depriving their baby of an experience essential for healthy psychological development. Yet breastfeeding mothers are not more attached to their babies, and breastfed and bottle-fed children in industrialized nations do not differ in emotional adjustment (Fergusson & Woodward, 1999; Jansen, de Weerth, & Riksen-Walraven, 2008). Some studies report a small advantage in intelligence test performance for children and adolescents who were breastfed, after controlling for many factors. Most, however, find no cognitive benefits (Der, Batty, & Deary, 2006; Holme, MacArthur, & Lancashire, 2010).

Nutrition in Childhood and Adolescence Around 1 year, infants' diets should include all the basic food groups. As children approach age 2, their appetites become unpredictable. Preschoolers eat well at one meal but barely touch their food at the next. And many become picky eaters. This decline in appetite occurs because growth has slowed. Furthermore, preschoolers' wariness of new foods is adaptive. If they stick to familiar foods, they are less likely to swallow dangerous substances when adults are not around to protect them (Birch & Fisher, 1995). Parents need not worry about variations in amount eaten from meal to meal. Over the course of a day, preschoolers compensate for eating little at one meal by eating more at a later one (Hursti, 1999).

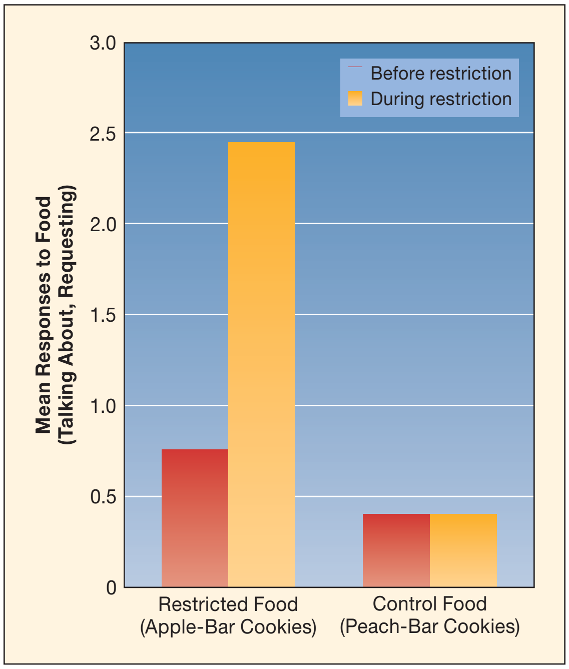

FIGURE 5.11 Children's spontaneous behavioral responses to a tasty food before and during restriction at snack times. Three- to 6-year-olds talked about, requested, and otherwise attempted to obtain a tasty food (apple-bar cookies) three times more often after they were restricted from eating it. They rarely responded this way to an equally tasty control food (peach-bar cookies) that remained unrestricted throughout the study. (Adapted from Fisher & Birch, 1999.)

Children tend to imitate the food choices and eating practices of people they admire, both adults and peers. For example, mothers who drink milk or soft drinks tend to have 5-year-old daughters with a similar beverage preference (Fisher et al., 2001). In Mexico, where children see family members delighting in the taste of peppery foods, preschoolers enthusiastically eat chili peppers, whereas most U.S. children reject them (Birch, Zimmerman, & Hind, 1980).

Repeated, unpressured exposure to a new food also increases acceptance (Fuller et al., 2005). Serving broccoli or tofu increases children's liking for these healthy foods. In contrast, offering sweet fruit or soft drinks promotes "milk avoidance" (Black et al., 2002).

Although children's healthy eating depends on a wholesome food environment, too much parental control over eating limits children's opportunities to develop self-control. When parents offer bribes ("Finish your vegetables, and you can have an extra cookie"), children tend to like the healthy food less and the treat more (Birch, Fisher, & Davison, 2003). Similarly, restricting access to tasty foods focuses children's attention on those foods and increases their desire to eat them. After caregivers in a child-care center prevented 3- to 6-year-olds from selecting apple-bar cookies at snack time by enclosing them in a transparent jar but gave them free access to peach-bar cookies (which they liked just as well), the children more often talked about and asked for the apple-bar cookies and otherwise tried to obtain them (see Figure 5.11) (Fisher & Birch, 1999). And when given access, they ate more apple-bar cookies than they had during previous, unrestricted snack times.

During puberty, rapid body growth leads to a dramatic rise in food intake. This increase in nutritional requirements comes at a time when eating habits are the poorest. Of all age groups, adolescents are the most likely to skip breakfast (a practice linked to obesity), eat on the run, and consume empty calories rather than nutrient-rich fruits and vegetables (Ritchie et al., 2007; Striegel-Moore & Franko, 2006). Fast-food restaurants, where teenagers often gather, have begun to offer some healthy menu options, but adolescents need guidance in choosing these alternatives. Eating fast food and school purchases from snack bars and vending machines is strongly associated with consumption of high-fat foods and soft drinks (Bowman et al., 2004; Kubik et al., 2003).

Frequency of family meals is a powerful predictor of healthy eating—greater intake of fruits, vegetables, grains, and milk products and reduced soft drink and fast-food consumption (Burgess-Champoux et al., 2009; Fiese & Schwartz, 2008). But compared to families with children, those with adolescents eat fewer meals together. Finding ways to arrange family meals, despite busy schedules, can greatly improve teenagers' diets.

LOOK and LISTEN

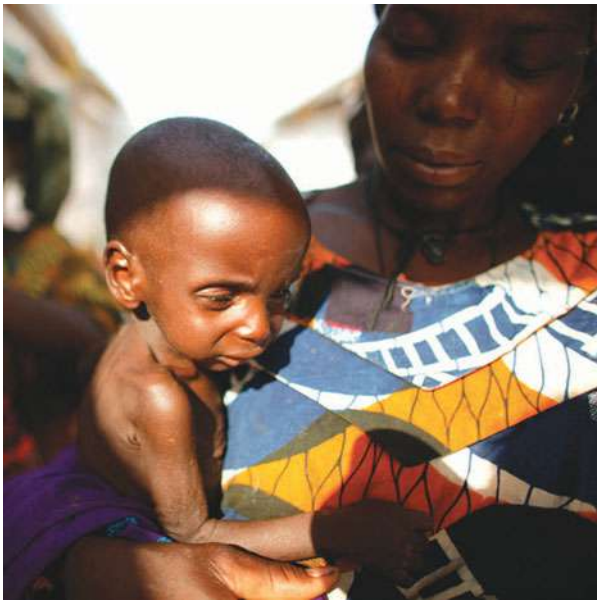
Arrange to join a family with at least one preschooler for a meal, and closely observe parental mealtime practices. Are they likely to promote healthy eating habits? Explain.

Malnutrition

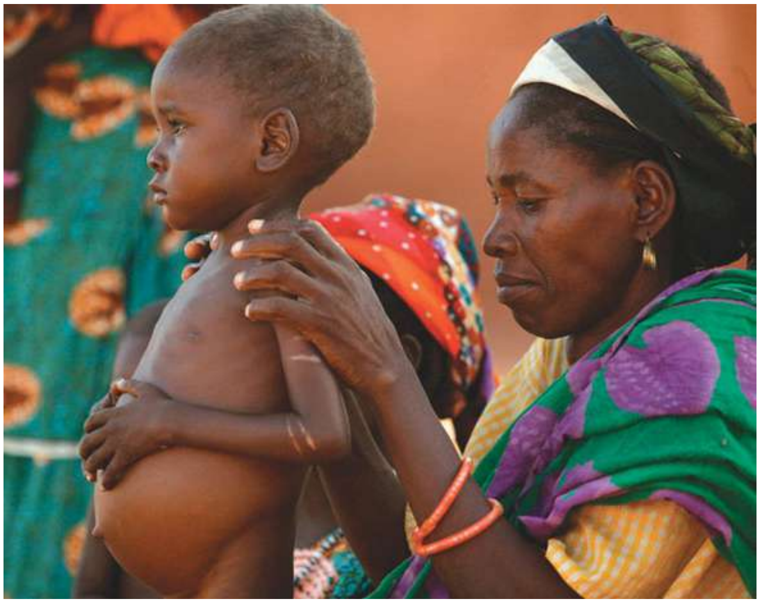
In developing countries and war-torn areas where food resources are limited, malnutrition is widespread. Recent evidence indicates that about 27 percent of the world's children suffer from malnutrition before age 5 (World Health Organization, 2010b). The 10 percent who are severely affected suffer from two dietary diseases.

Marasmus is a wasted condition of the body caused by a diet low in all essential nutrients. It usually appears in the first year of life when a baby's mother is too malnourished to produce enough breast milk and bottle-feeding is also inadequate. Her starving baby becomes painfully thin and is in danger of dying.

Kwashiorkor is caused by an unbalanced diet very low in protein. The disease usually strikes after weaning, between 1 and 3 years of age. It is common in regions where children get just enough calories from starchy foods but little protein. The child's body responds by breaking down its own protein reserves. Soon the belly enlarges, the feet swell, the hair falls out, and a skin rash appears. A once bright-eyed, curious youngster becomes irritable and listless.



© MICHAEL KAMBER/POLARIS



© MICHAEL KAMBER/POLARIS

The baby on the left, of Niger, Africa, has marasmus, a wasted condition caused by a diet low in all essential nutrients. The swollen abdomen of the toddler on the right, also of Niger, is a symptom of kwashiorkor, which results from a diet very low in protein. If these children survive, they are likely to be growth stunted and to suffer from lasting organ damage and serious cognitive and emotional impairments.

Children who survive these extreme forms of malnutrition often grow to be smaller in all body dimensions and suffer from lasting damage to the brain, heart, liver, or other organs (Müller & Krawinkel, 2005). When their diets do improve, they tend to gain excessive weight (Uauy et al., 2008). A malnourished body protects itself by establishing a low basal metabolism rate, which may endure after nutrition improves. Also, malnutrition may disrupt appetite-control centers in the brain, causing the child to overeat when food becomes plentiful.

Learning and behavior are also seriously affected. In one long-term study of marasmic children, an improved diet led to some catch-up growth in height, but not in head size (Stoch et al., 1982). The malnutrition probably interfered with growth of neural fibers and myelination, causing a permanent loss in brain weight. And animal evidence reveals that a deficient diet alters the production of neurotransmitters in the brain—an effect that can disrupt all aspects of development (Haller, 2005). These children score low on intelligence tests, show poor fine-motor coordination, and have difficulty paying attention (Bryce et al., 2008; Liu et al., 2003). They also display a more intense stress response to fear-arousing situations, perhaps caused by the constant, gnawing pain of hunger (Fernald & Grantham-McGregor, 1998).

Recall from our discussion of prenatal malnutrition in Chapter 3 that the passivity and irritability of malnourished children worsen the impact of poor diet. These behaviors may appear even when protein-calorie deprivation is only mild to moderate. They also accompany *iron-deficiency anemia,* a condition affecting about 25 percent of infants and children worldwide that interferes with many central nervous system processes. Withdrawal, listlessness, and inability to be soothed when upset reduce the iron-deficient baby's capacity to pay attention, explore, and evoke sensitive caregiving from parents (Lozoff, 2007; Lozoff et al., 2008). These infants score lower than their nonanemic counterparts in motor and mental development, with iron supplementation alone failing to correct the difference. In one follow-up, young adults who had been profoundly iron-deficient as babies but iron-sufficient thereafter nevertheless performed poorly on diverse cognitive tasks (Lukowski et al., 2010). Consequently, in addition to improving early iron status, interventions must foster development by supporting the parent–child relationship.

Inadequate nutrition is not confined to developing countries. Because government-sponsored supplementary food programs do not reach all families in need, an estimated 21 percent of U.S. children suffer from *food insecurity*—uncertain access to enough food for a healthy, active life. Food insecurity is especially high among single-parent families (35 percent) and low-income ethnic minority families—for example, African Americans and

Hispanics (25 and 27 percent, respectively) (U.S. Department of Agriculture, 2011b). Although few of these children have marasmus or kwashiorkor, their physical growth and ability to learn are still affected.

Obesity Today, 32 percent of U.S. children and adolescents are overweight, more than half of them extremely so: 17 percent suffer from **obesity,** a greater-than-20-percent increase over healthy weight, based on *body mass index (BMI)*—a ratio of weight to height associated with body fat. (A BMI above the 85th percentile for the child's age and sex is considered overweight, a BMI above the 95th percentile obese.) During the past several decades, a rise in overweight and obesity has occurred in many Western nations, with large increases in Canada, Germany, Israel, Greece, Ireland, New Zealand, the United Kingdom, and the United States (Ogden et al., 2010; World Health Organization, 2009, 2010a). Smaller increases have occurred in other industrialized nations, including Australia, Finland, the Netherlands, Norway, and Sweden.

Obesity rates are also increasing rapidly in developing countries as urbanization shifts the population toward sedentary lifestyles and diets high in meats and energy-dense refined foods (World Health Organization, 2010a, 2010b). In China, for example, where obesity was nearly nonexistent a generation ago, today 20 percent of children are overweight, with 7 percent obese—a nearly fivefold increase over the past twenty-five years, with boys affected more than girls (Ding, 2008). Childhood obesity in China is especially high in cities, where it has reached 10 percent (Ji & Chen, 2008). In addition to lifestyle changes, a prevailing belief in Chinese culture that excess body fat represents prosperity and health—carried over from a half-century ago, when famine caused millions of deaths—has contributed to this alarming upsurge. High valuing of sons may induce Chinese parents to offer boys especially generous portions of meat, dairy products, and other energy-dense foods that were once scarce but now are widely available.

Overweight rises with age, from 21 percent among U.S. preschoolers to 35 percent among school-age children and adolescents (Ogden et al., 2010). In a longitudinal study of more than 1,000 U.S. children, overweight preschoolers were five times more likely than their normal-weight peers to be overweight at age 12 (Nader et al., 2006). And an estimated 70 percent of affected teenagers become overweight adults (U.S. Department of Health and Human Services, 2011b).

IMAGINECHINA VIA AP IMAGES

Chinese boys attending a weight-loss camp prepare for a swim. Such camps are a response to China's rapid increase in overweight and obesity—the result of lifestyle changes in a culture that equates excess body fat with prosperity.

Besides serious emotional and social difficulties, obese children are at risk for lifelong health problems. Symptoms that begin to appear in the early school years—high blood pressure, high cholesterol levels, respiratory abnormalities, and insulin resistance—are powerful predictors of heart disease and other circulatory difficulties, type 2 diabetes, gallbladder disease, sleep and digestive disorders, many forms of cancer, and early death (Krishnamoorthy, Hart, & Jelalian, 2006; World Cancer Research Fund, 2007). Indeed, type 2 diabetes—formerly also known as "adult-onset" diabetes because it was rarely seen in childhood—is rising rapidly among overweight children, sometimes leading to early, severe complications, including stroke, kidney failure, and circulatory problems that heighten the risk of eventual blindness and leg amputation (Hannon, Rao, & Arslanian, 2005).

Causes of Obesity. Not all children are equally at risk for excessive weight gain. Overweight children tend to have overweight parents, and identical twins are more likely to share the disorder than fraternal twins. But heredity accounts for only a *tendency* to gain weight (Kral & Faith, 2009).

The importance of environment is seen in the consistent relationship of low education and income to overweight and obesity in industrialized nations, especially among ethnic minorities—in the United States, African-American, Hispanic, and Native-American children and adults (Anand et al., 2001; Ogden et al., 2010). Factors responsible include lack of knowledge about healthy diet; a tendency to buy high-fat, low-cost foods; neighborhoods that lack convenient access to affordable, healthy foods in grocery stores and restaurants; and family stress, which can prompt overeating.

Furthermore, as noted on page 197, children who were undernourished in their early years are at risk for later excessive weight gain. In industrialized nations, many studies confirm that infants whose mothers smoked during pregnancy and who therefore are often born underweight (see Chapter 3) are more likely to suffer from childhood overweight and obesity (Rogers, 2009). Nevertheless, in the developing world (unlike in industrialized countries), obesity risk is greatest for individuals living in economically well-off households, probably because of greater food availability and reduced activity levels (Subramanian et al., 2011).

Parental feeding practices also contribute to childhood obesity. Overweight children are more likely to eat larger quantities of high-calorie sugary and fatty foods, perhaps because these foods are prominent in the diets offered by their parents, who also tend to be overweight. Interviews with more than 3,000 U.S. parents revealed that many served their 4- to 24-month-olds French fries, pizza, candy, sugary fruit drinks, and soda on a daily basis. On average, infants consumed 20 percent and toddlers 30 percent more calories than they needed (Briefel et al., 2004). Recent research confirms a strengthening relationship between rapid weight gain in infancy and later obesity (Botton et al., 2008; Chomtho et al., 2008).

Some parents anxiously overfeed, interpreting almost all their child's discomforts as a desire for food. Others pressure their children to eat, a practice common among immigrant parents and grandparents who, as children themselves, survived periods of food deprivation. Still other parents are overly controlling, restricting when, what, and how much their child eats and worrying that the child will gain too much weight (Moens, Braet, & Soetens, 2007). In each case, parents fail to help children learn to regulate their own food intake. Also, parents of overweight children often use high-fat, sugary foods to reinforce other behaviors, leading children to attach great value to treats (Sherry et al., 2004).

Because of these experiences, obese children soon develop maladaptive eating habits. They are more responsive than normal-weight individuals to external stimuli associated with food—taste, sight, smell, time of day, and food-related words—and less responsive to internal hunger cues (Jansen et al., 2003; Temple et al., 2007). They also eat faster and chew their food less thoroughly, a behavior pattern that appears as early as 18 months of age (Drabman et al., 1979).

Another factor consistently associated with weight gain is insufficient sleep (Nielsen, Danielsen, & Sørensen, 2011). Reduced sleep may increase time available for eating, leave children too fatigued for physical activity, or disrupt the brain's regulation of hunger and metabolism.

Overweight children are less physically active than their normal-weight peers. Inactivity is both cause and consequence of excessive weight gain. Research reveals that the rise in childhood obesity is due in part to the many hours U.S. children spend watching television. In a study that tracked children's TV viewing from ages 4 to 11, the more TV children watched, the more body fat they added. Children who devoted more than 3 hours per day to TV accumulated 40 percent more fat than those devoting less than 1¾ hours (see Figure 5.12) (Proctor et al., 2003). Watching TV reduces time devoted to physical exercise, and TV ads encourage children to eat fattening, unhealthy snacks. Children permitted to have a TV in their bedroom—a practice linked to especially high TV viewing—are at even greater risk for overweight (Adachi-Mejia et al., 2007).

Finally, the broader food environment affects the incidence of obesity. The Pima Indians of Arizona, who two decades ago changed from a traditional diet of plant foods to a high-fat, typically American diet, have one of the world's highest obesity rates. Compared with descendants of their

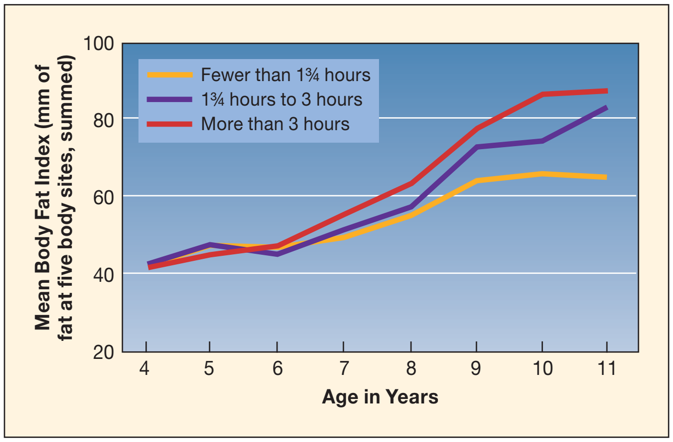


FIGURE 5.12 Relationship of television viewing to gains in body fat from ages 4 to 11. Researchers followed more than 100 children from ages 4 to 11, collecting information on hours per day of television viewing and on body fat, measured in millimeters of skinfold thickness at five body sites (upper arms, shoulders, abdomen, trunk, and thighs). The more TV children watched, the greater the gain in body fat. At ages 10 to 11, the difference between children watching fewer than 1¾ hours and those watching more than 3 hours had become large. (Adapted from M. H. Proctor et al., 2003, "Television Viewing and Change in Body Fat from Preschool to Early Adolescence: The Framingham Children's Study," *International Journal of Obesity,* 27, p. 831. Reprinted by permission from Macmillan Publishers Ltd.)

ancestors living in the remote Sierra Madre region of Mexico, the Arizona Pima have body weights 50 percent greater. Half the population has diabetes (eight times the national average), with many in their twenties and thirties already disabled by the disease—blind, in wheelchairs, and on kidney dialysis. The Pima have a genetic susceptibility to overweight, but it emerges only under Western dietary conditions (Gladwell, 1998; Traurig et al., 2009). Other ethnic groups with a hereditary tendency to gain weight are the Pacific Islanders, including native Hawaiians and Samoans (Furusawa et al., 2010). Many now eat an Americanized diet of high-calorie processed and fast foods, and over 80 percent are overweight.

Consequences of Obesity. Unfortunately, physical attractiveness is a powerful predictor of social acceptance. In Western societies, both children and adults rate obese youngsters as unlikable, stereotyping them as lazy, sloppy, dirty, ugly, stupid, and deceitful (Kilpatrick & Sanders, 1978; Penny & Haddock, 2007; Tiggemann & Anesbury, 2000). In school, obese children and adolescents are often socially isolated. They report more emotional, social, and school difficulties, including peer teasing and consequent low self-esteem, depression, and (among obese teenagers) suicidal thoughts and suicide attempts. Because unhappiness and overeating contribute to each other, the child remains overweight (Puhl & Latner, 2007; Zeller & Modi, 2006). Persistent obesity from childhood into adolescence predicts serious disorders, including defiance, aggression, and severe depression (Schwimmer, Burwinkle, & Varni, 2003; Young-Hyman et al., 2006).

The psychological consequences of obesity combine with continuing discrimination to result in reduced life chances. Overweight individuals are less likely than their normal-weight agemates to receive financial aid for college, be rented apartments, find mates, and be offered jobs. And they report frequent mistreatment by family members, peers, co-workers, and health-care professionals, which contributes further to physical and psychological health problems (Carr & Friedman, 2005; Puhl, Heuer, & Brownell, 2010).

PAUL CHINN/SAN FRANCISCO CHRONICLE

Students enjoy school lunches prepared from healthy, fresh ingredients, thanks to a program instituted by a former chef who transformed their school food service, eliminating processed foods high in fat and sugar.

Treating Obesity. Childhood obesity is difficult to treat because it is a family disorder. In one study, only one-fourth of overweight parents judged their overweight children to have a weight problem (Jeffrey, 2004). Consistent with these findings, most obese children do not get any treatment.

The most effective interventions are family-based and focus on changing behaviors (Oude et al., 2009). In one program, both parent and child revised their eating patterns, exercised daily, and reinforced each other with praise and points for progress, which they exchanged for special activities and times together. The more weight parents lost, the more their children lost (Wrotniak et al., 2004). Follow-ups after five and ten years showed that children maintained weight loss more effectively than adults—a finding that underscores the importance of intervening at an early age (Epstein, Roemmich, & Raynor, 2001). Treatment programs that focus on both diet and lifestyle can yield substantial, long-lasting weight reduction among children and adolescents. But these interventions work best when parents' and children's weight problems are not severe (Eliakim et al., 2004; Nemet et al., 2005).

Children consume one-third of their daily energy intake at school. Therefore, schools can help reduce obesity by serving healthier meals and ensuring regular physical activity. Because obesity is expected to rise further without broad prevention strategies, many U.S. states and cities have passed obesity-reduction legislation (Levi et al., 2009). Among measures taken are weight-related school screenings for all children, improved nutrition standards and limited vending machine access in schools, additional recess time in the elementary grades and increased physical education time in all grades, obesity awareness and weight-reduction programs as part of school curricula, and menu nutrition labeling (including calories counts) in chain and fast-food restaurants.

LOOK and LISTEN

Contact your state and city governments to find out about their childhood obesity prevention legislation. Can policies be improved?

Infectious Disease

In well-nourished children, ordinary childhood illnesses have no effect on physical growth. But when children are poorly fed, disease interacts with malnutrition in a vicious spiral, with potentially severe consequences.

Infectious Disease and Malnutrition

In developing nations where a large proportion of the population lives in poverty, children do not receive routine immunizations. As a result, illnesses such as measles and chicken pox, which typically do not appear until after age 3 in industrialized nations, occur much earlier. Poor diet depresses the body's immune system, making children far more susceptible to disease. Of the 9 million annual deaths of children under age 5 worldwide, 98 percent are in developing countries and 70 percent are due to infectious diseases (World Health Organization, 2010b).

Disease, in turn, is a major contributor to malnutrition, hindering both physical growth and cognitive development. Illness reduces appetite and limits the body's ability to absorb foods, especially in children with intestinal infections. In developing countries, widespread diarrhea, resulting from unsafe water and contaminated foods, leads to growth stunting and nearly 3 million childhood deaths each year (World Health Organization, 2010b). Studies carried out in the slums and shantytowns of Brazil and Peru reveal that the more persistent diarrhea is in early childhood, the shorter children are in height and the lower they score on mental tests during the school years (Checkley et al., 2003; Niehaus et al., 2002).

Most developmental impairments and deaths due to diarrhea can be prevented with nearly cost-free *oral rehydration therapy (ORT),* in which sick children are given a glucose, salt, and water solution that quickly replaces fluids the body loses. Since 1990, public health workers have taught nearly half the families in the developing world how to administer ORT. Also, supplements of zinc (essential for immune system functioning), which cost only 30 cents for a month's supply, substantially reduce the incidence of severe and prolonged diarrhea (Aggarwal, Sentz, & Miller, 2007). Through these interventions, the lives of millions of children are saved each year. Still, only a minority of children with diarrhea in the world's poorest countries—such as Chad, Morocco, Somalia, and Togo—receive ORT (World Health Organization, 2010b).

Immunization

In industrialized nations, childhood diseases have declined dramatically during the past half-century, largely as a result of widespread immunization of infants and young children. Nevertheless, about 20 percent of U.S. infants and toddlers are not fully immunized. Of the 80 percent who receive a complete schedule of vaccinations in the first two years, some do not receive the immunizations they need later, in early childhood. Overall, 30 percent of U.S. preschoolers lack essential immunizations. The rate rises to 32 percent for poverty-stricken children, many of whom do not receive full protection until age 5 or 6, when it is required for school entry (U.S. Department of Health and Human Services, 2010g). In contrast, fewer than 10 percent of preschoolers lack immunizations in Denmark and Norway, and fewer than 7 percent in Canada, the Netherlands, Sweden, and the United Kingdom (World Health Organization, 2010b).

Why does the United States lag behind these other countries in immunization? As noted in earlier chapters, many U.S. children do not have access to the health care they need. In 1994, all medically uninsured children in the United States were guaranteed free immunizations, a program that has led to gains in immunization rates. Still, the cost of the doctor's visit to obtain the immunization may not be covered.

AP IMAGES/CORPUS CHRISTI CALLER-TIMES, RACHEL DENNY CLOW

A 4-year-old receives several immunizations at a public health clinic. Such clinics are often the only option for families who lack private health insurance. About 30 percent of U.S. preschoolers lack essential immunizations.

Inability to pay for vaccines is only one cause of inadequate immunization. Parents with little education and with stressful daily lives often fail to schedule vaccination appointments, and those without a primary-care physician do not want to endure long waits in crowded U.S. public health clinics (Falagas & Zarkadoulia, 2008). Some parents have been influenced by media reports suggesting a link between a mercury-based preservative used for decades in vaccines and a rise in the number of children diagnosed with autism. But large-scale studies show no association with autism and no consistent effects on cognitive performance (Dales, Hammer, & Smith, 2001; Richler et al., 2006; Stehr-Green et al., 2003; Thompson et al., 2007). Still, as a precautionary measure, mercury-free versions of childhood vaccinations are now available.

In areas where many parents have refused to immunize their children, outbreaks of whooping cough and rubella have occurred, with life-threatening consequences (Kennedy & Gust, 2008; Tuyen & Bisgard, 2003). Public education programs directed at increasing parental knowledge about the importance and safety of timely immunizations are badly needed.

Emotional Well-Being

We may not think of affection as necessary for healthy physical growth, but it is as vital as food. **Growth faltering** is a term applied to infants whose weight, height, and head circumference are substantially below age-related growth norms and who are withdrawn and apathetic (Black, 2005). In as many as half such cases, a disturbed parent–infant relationship contributes to the failure to grow normally. These infants often keep their eyes on nearby adults, anxiously watching their every move, and they rarely smile at their caregiver (Steward, 2001).

Family circumstances surrounding growth faltering help explain these reactions. During feeding, diaper changing, and play, mothers of these infants seem cold and distant, at other times impatient and hostile (Hagekull, Bohlin, & Rydell, 1997). In response, babies try to protect themselves by keeping track of the threatening adult's whereabouts and, when she approaches, avoiding her gaze. Often an unhappy marriage or parental psychological disturbance contributes to these serious caregiving problems. And most of the time, the baby is irritable and displays abnormal feeding behaviors, such as poor sucking or vomiting, that both disrupt growth and lead parents to feel anxious and helpless, which stress the parent–infant relationship further (Batchelor, 2008; Linscheid, Budd, & Rasnake, 2005).

When treated early, by intervening in infant feeding problems, helping parents with their own life challenges, and encouraging sensitive caregiving, these babies show quick catch-up growth. But if the disorder is not corrected in infancy, most children remain small and show lasting cognitive and emotional difficulties (Black et al., 2007; Drewett, Corbett, & Wright, 2006).

Extreme emotional deprivation can interfere with the production of GH and lead to **psychosocial dwarfism,** a growth disorder that appears between 2 and 15 years of age. Typical characteristics include decreased GH secretion, very short stature, immature skeletal age, and serious adjustment problems, which help distinguish psychosocial dwarfism from normal shortness (Tarren-Sweeney, 2006). When such children are removed from their emotionally inadequate environments, their GH levels quickly return to normal, and they grow rapidly. But if treatment is delayed, the dwarfism can be permanent.

Reflect ■ In rearing a child, which feeding and other child-rearing practices would you use, and which would you avoid, to prevent overweight and obesity?

Puberty: The Physical Transition to Adulthood

- Describe sexual maturation in girls and boys, noting genetic and environmental influences on pubertal timing.

During **puberty,** young people attain an adult-sized body and become capable of producing offspring. Accompanying rapid body growth are changes in physical features related to sexual functioning. Some, called **primary sexual characteristics,** involve the reproductive organs directly (ovaries, uterus, and vagina in females; penis, scrotum, and testes in males). Others, called **secondary sexual characteristics,** are visible on the outside of the body and serve as additional signs of sexual maturity (for example, breast development in females and the appearance of underarm and pubic hair in both sexes). As the Milestones table on page 204 shows, these characteristics develop in a fairly standard sequence, although the ages at which each begins and is completed vary greatly. Typically, pubertal development takes about four years, but some adolescents complete it in two years, whereas others take five to six years.

Sexual Maturation in Girls

Female puberty usually begins with the budding of the breasts and the growth spurt. **Menarche,** or first menstruation (from the Greek word *arche,* meaning "beginning"), typically occurs relatively late in the sequence of pubertal events—around age 12½ for North American girls, 13 for Western Europeans. But the age range is wide, from 10½ to 15½ years. Following menarche, breast and pubic hair growth are completed, and underarm hair appears.

Notice in the Milestones table that nature delays sexual maturity until the girl's body is large enough for childbearing; menarche takes place after the peak of the height spurt. As an extra measure of security, for 12 to 18 months following menarche, the menstrual cycle often occurs without the release of an ovum from the ovaries (Archibald, Graber, & Brooks-Gunn, 2006; Bogin, 2001). But this temporary period of sterility does not occur in all girls, and it cannot be counted on for protection against pregnancy.

© MARY KATE DENNY/PHOTOEDIT

Sex differences in pubertal growth are obvious in these middle school students. Although all are about the same age, the girl is much taller and more mature-looking than the boys.

Sexual Maturation in Boys

The first sign of puberty in boys is the enlargement of the testes (glands that manufacture sperm), accompanied by changes in the texture and color of the scrotum. Pubic hair emerges soon after, about the same time the penis begins to enlarge (Rogol, Roemmich, & Clark, 2002).

Refer again to the Milestones table, and you will see that the growth spurt occurs much later in the sequence of pubertal events for boys than for girls. Also, boys' height gain is more intense and longer lasting. When it reaches its peak around age 14, enlargement of the testes and penis is nearly complete, and underarm hair appears. Facial and body hair also emerge just after the peak in body growth and increase gradually for several years. Another landmark of male physical maturity is the deepening of the voice as the larynx enlarges and the vocal cords lengthen. (Girls' voices also deepen slightly.) Voice change usually takes place at the peak of the male growth spurt and often is not complete until puberty is over (Archibald, Graber, & Brooks-Gunn, 2006).

Milestones

Pubertal Development in North American Girls and Boys

GIRLS	AVERAGE AGE ATTAINED	AGE RANGE
Breasts begin to “bud”	10	8–13
Height spurt begins	10	8–13
Pubic hair appears	10.5	8–14
Peak strength spurt	11.6	9.5–14
Peak height spurt	11.7	10–13.5
Menarche (first menstruation) occurs	12.5	10.5–14
Peak weight spurt	12.7	10–14
Adult stature reached	13	10–16
Pubic hair growth completed	14.5	14–15
Breast growth completed	15	10–17

BOYS	AVERAGE AGE ATTAINED	AGE RANGE
Testes begin to enlarge	11.5	9.5–13.5
Pubic hair appears	12	10–15
Penis begins to enlarge	12	10.5–14.5
Height spurt begins	12.5	10.5–16
Spermarche (first ejaculation) occurs	13.5	12–16
Peak height spurt	14	12.5–15.5
Peak weight spurt	14	12.5–15.5
Facial hair begins to grow	14	12.5–15.5
Voice begins to deepen	14	12.5–15.5
Penis and testes growth completed	14.5	12.5–16
Peak strength spurt	15.3	13–17
Adult stature reached	15.5	13.5–17.5
Pubic hair growth completed	15.5	14–17

While the penis is growing, the prostate gland and seminal vesicles (which together produce semen, the fluid containing sperm) enlarge. Then, around age 13½, **spermarche,** or first ejaculation, occurs (Rogol, Roemmich, & Clark, 2002). For a while, the semen contains few living sperm. So, like girls, boys have an initial period of reduced fertility.

Individual and Group Differences in Pubertal Growth

Heredity contributes substantially to the timing of pubertal changes. Identical twins are more similar than fraternal twins in attainment of most pubertal milestones, including growth spurt, menarche, breast development, body hair, and voice change (Eaves et al., 2004; Mustanski et al., 2004). Nutrition and exercise also make a difference. In females, a sharp rise in body weight and fat may trigger sexual maturation. Fat cells release a protein called *leptin,* which is believed to signal the brain that girls’ energy stores are sufficient for puberty—a likely reason that breast and pubic hair growth and menarche occur earlier for heavier and, especially, obese girls. In contrast, girls who begin rigorous athletic training at an early age or who eat very little (both of which reduce the percentage of body fat) usually experience later puberty (Kaplowitz, 2008; Lee et al., 2007; Rubin et al., 2009). Few studies, however, report a link between body fat and puberty in boys.

Variations in pubertal growth also exist between regions of the world and between income and ethnic groups. Physical health plays a major role. In poverty-stricken regions where malnutrition and infectious disease are common, menarche is greatly delayed, occurring as late as age 14 to 16 in many parts of Africa. Within developing countries, girls from higher-income families consistently reach menarche 6 to 18 months earlier than those from economically disadvantaged homes (Parent et al., 2003).

But in industrialized nations where food is abundant, the joint roles of heredity and environment in pubertal growth are apparent. For example, breast and pubic hair growth begin, on average, around age 9 in African-American girls—a year earlier than in Caucasian-American girls. And African-American girls reach menarche about six months earlier, around age 12. Although widespread overweight and obesity in the black population contribute, a genetically influenced faster rate of physical maturation is also involved. Black girls usually reach menarche before white girls of the same age and body weight (Chumlea et al., 2003; Herman-Giddens, 2006; Hillard, 2008).

Early family experiences may also affect pubertal timing. One theory suggests that humans have evolved to be sensitive to the emotional quality of their childhood environments. When children's safety and security are at risk, it is adaptive for them to reproduce early. Research indicates that girls and (less consistently) boys with a history of family conflict, harsh parenting, or parental separation tend to reach puberty early. In contrast, those with warm, stable family ties reach puberty relatively late (Belsky et al., 2007; Bogaert, 2005; Ellis & Essex, 2007; Mustanski et al., 2004; Tremblay & Frigon, 2005). Critics offer an alternative explanation—that mothers who reached puberty early are more likely to bear children earlier, which increases the likelihood of marital conflict and separation (Mendle et al., 2006). But longitudinal evidence on a large, ethnically diverse sample of U.S. girls followed from birth through age 15 confirmed the former chain of influence: from harsh parenting in childhood to earlier menarche to increased sexual risk taking in adolescence (Belsky et al., 2010).

The Psychological Impact of Pubertal Events

- What factors influence adolescents' reactions to the physical changes of puberty?
- Describe the impact of pubertal timing on adolescent adjustment, noting sex differences.

TAKE A MOMENT... Think back to your late elementary school and junior high days. As you reached puberty, how did your feelings about yourself and your relationships with others change? Were your reactions similar to those predicted by Rousseau and Hall, described at the beginning of this chapter?

Is Puberty Inevitably a Period of Storm and Stress?

Contemporary research suggests that the notion of adolescence as a biologically determined period of storm and stress is greatly exaggerated. Certain problems, such as eating disorders, depression, suicide (see Chapter 11), and lawbreaking (see Chapter 12), occur more often than earlier (Farrington, 2009; Graber, 2004). But the overall rate of serious psychological disturbance rises only slightly (by about 3 percent) from childhood to adolescence, when it is nearly the same as in the adult population—about 15 percent (Roberts, Attkisson, & Rosenblatt, 1998). Although some teenagers encounter serious difficulties, emotional turbulence is not routine.

The first researcher to point out the wide variability in adolescent adjustment was anthropologist Margaret Mead (1928). She returned from the Pacific islands of Samoa with a startling conclusion: Because of the culture's relaxed social relationships and openness toward sexuality, adolescence "is perhaps the pleasantest time the Samoan girl (or boy) will ever know" (p. 308). In Mead's alternative view, the social environment is entirely responsible for the range of teenage experiences, from erratic and agitated to calm and stress-free.

Later researchers found that Samoan adolescence was not as untroubled as Mead had assumed (Freeman, 1983). Still, Mead's work had an enormous impact. Today we know that biological, psychological, and social forces combine to influence adolescent development (Susman & Dorn, 2009). Most tribal and village societies have a briefer transition to adulthood, but adolescence is not absent (Weisfield, 1997). In industrialized nations, where successful participation in economic life requires many years of education, young people face prolonged dependence on parents and postponement of sexual gratification. As a result, adolescence is greatly extended, and teenagers confront a wider array of psychological challenges. In the following sections, we will see many examples of how multiple factors combine to affect teenagers' adjustment.

Reactions to Pubertal Changes

Two generations ago, menarche was often traumatic. Today, girls commonly react with surprise, undoubtedly due to the sudden onset of the event. Otherwise, they typically report a mixture of positive and negative emotions (DeRose & Brooks-Gunn, 2006). Yet wide individual differences exist that depend on prior knowledge and support from family members, which in turn are influenced by cultural attitudes toward puberty and sexuality.

For girls who have no advance information, menarche can be shocking and disturbing. In the 1950s, up to 50 percent received no prior warning, and of those who did, many were given negative, "grin-and-bear-it" messages (Costos, Ackerman, & Paradis, 2002; Shainess, 1961). Today, few girls are uninformed, a shift that is probably due to parents' greater willingness to discuss sexual matters and to the spread of health education classes (Omar, McElderry, & Zakharia, 2003). Almost all girls get some information from their mothers. And some evidence suggests that compared with Caucasian-American families, African-American families may better prepare girls for menarche, treat it as an important milestone, and express less conflict over girls reaching sexual maturity—factors that lead African-American girls to react more favorably (Martin, 1996).

Like girls' reactions to menarche, boys' reactions to spermarche reflect mixed feelings. Virtually all boys know about ejaculation ahead of time, but many say that no one spoke to them before or during puberty about physical changes (Omar, McElderry, & Zakharia, 2003). Usually they get their information from reading materials or websites. Even boys who had advance information often say that their first ejaculation occurred earlier than they expected and that they were unprepared for it. As with girls, boys who feel better prepared tend to react more positively (Stein & Reiser, 1994). But whereas almost all girls tell a friend that they are menstruating, far fewer boys tell anyone about spermarche (DeRose & Brooks-Gunn, 2006; Downs & Fuller, 1991). Overall, boys get much less social support than girls for the physical changes of puberty. They might benefit, especially, from opportunities to ask questions and discuss feelings with a sympathetic parent or health professional.

Many tribal and village societies celebrate physical maturity with an *adolescent initiation ceremony,* a ritualized announcement to the community that marks an important change in privilege and responsibility. Consequently, young people know that reaching puberty is valued in their culture. In contrast, Western societies grant little formal recognition to movement from childhood to adolescence or from adolescence to adulthood. Ceremonies such as the Jewish bar or bat mitzvah and the *quinceañera* in Hispanic communities (celebrating a 15-year-old girl's sexual maturity and marriage availability) resemble initiation ceremonies, but only within the ethnic or religious subculture. They do not mark a significant change in social status in the larger society.

Instead, Western adolescents are granted partial adult status at many different ages—for example, an age for starting employment, for driving, for leaving high school, for voting, and for drinking. And in some contexts (at home and at school), they may still be regarded as children. The absence of a single widely accepted marker of physical and social maturity makes the process of becoming an adult more confusing.

© ISRAEL IMAGES/ALAMY

This 13-year-old's bat mitzvah ceremony, the culmination of extensive study and reflection, recognizes her as an adult with moral and religious responsibilities in the Jewish community. In the larger society, however, she will experience no change in status.

Pubertal Change, Emotion, and Social Behavior

A common belief is that puberty has something to do with adolescent moodiness and the desire for greater physical and psychological separation from parents. Let's see what research says about these relationships.

Adolescent Moodiness Higher pubertal hormone levels are linked to greater moodiness, but only modestly so (Buchanan, Eccles, & Becker, 1992; Graber, Brooks-Gunn, & Warren, 2006). What other factors might contribute? In several studies, the moods of children, adolescents, and adults were monitored by having them carry electronic pagers. Over a one-week period, they were beeped at random intervals and asked to write down what they were doing, whom they were with, and how they felt.

As expected, adolescents reported less favorable moods than school-age children and adults (Larson et al., 2002; Larson & Lampman-Petraitis, 1989). But negative moods were linked to a greater number of negative life events, such as difficulties getting along with parents, disciplinary actions at school, and breaking up with a boyfriend or girlfriend. Negative events increased steadily from childhood to adolescence, and teenagers also seemed to react to them with greater emotion than children (Larson & Ham, 1993). (Recall that stress reactivity is heightened by changes in brain neurotransmitter activity during adolescence.)

Compared with the moods of older adolescents and adults, those of younger adolescents (ages 12 to 16) were less stable, often varying from cheerful to sad and back again. These mood swings were strongly related to situational changes. High points of adolescents' days were times spent with friends and in self-chosen leisure activities. Low points tended to occur in adult-structured settings—class, job, and religious services. Furthermore, emotional highs coincided with Friday and Saturday evenings, especially in high school (see Figure 5.13). Going out with friends and romantic partners increases so dramatically during adolescence that it becomes a "cultural script" for what is *supposed* to happen. Teenagers who spend weekend evenings at home often feel profoundly lonely (Larson & Richards, 1998).

Yet another contributor to adolescent moodiness is change in sleep schedules. Although teenagers need almost as much sleep as they did in middle childhood (about nine hours), they go to bed much later than they did as children, perhaps because of increased neural sensitivity to evening light. This sleep "phase delay" strengthens with pubertal development. But today's teenagers—with more evening social activities, part-time jobs, and bedrooms equipped with TVs, computers, and phones—get much less sleep than teenagers of previous generations (Carskadon, Acebo, & Jenni, 2004; Carskadon et al., 2002). Sleep-deprived adolescents are more likely to suffer from depressed mood, achieve poorly in school, and engage in high-risk behaviors, including drinking and reckless driving (Dahl & Lewin, 2002; Hansen et al., 2005). Later school start times ease but do not eliminate sleep loss.

Fortunately, frequent reports of negative mood level off in late adolescence, when teenagers' emotions also become more stable (Holsen, Kraft, & Vittersø, 2000; Natsuaki, Biehl, & Ge, 2009). And overall, teenagers with supportive family and peer relationships more often report positive and less often negative moods than their agemates with few social supports (Weinstein et al., 2006). In contrast, poorly adjusted young people—with low self-esteem, conduct difficulties, or delinquency—tend to react with stronger negative emotion to unpleasant daily experiences, perhaps compounding their adjustment problems (Schneiders et al., 2006).

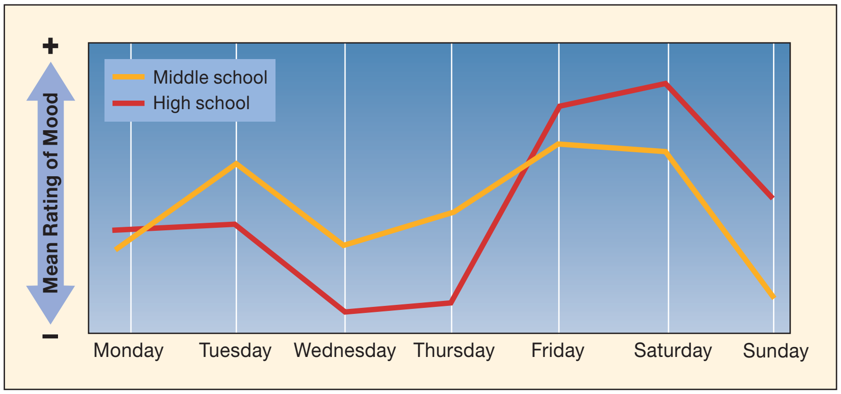

FIGURE 5.13 Younger and older adolescents' emotional experiences across the week. Adolescents' reports revealed that emotional high points are on Fridays and Saturdays. Mood drops on Sunday, before returning to school, and during the week, as students spend much time in adult-structured settings in school. (From R. Larson & M. Richards, 1998, "Waiting for the Weekend: Friday and Saturday Night as the Emotional Climax of the Week," in A. C. Crouter & R. Larson [Eds.], *Temporal Rhythms in Adolescence: Clocks, Calendars, and the Coordination of Daily Life,* San Francisco: Jossey-Bass, p. 41. Reprinted by permission of John Wiley & Sons, Inc.)

Puberty brings an increase in parent–child conflict—psychological distancing that may be a modern substitute for physical departure from the family. Unlike nonhuman primates and adolescents in many nonindustrialized cultures, teenagers in industrialized societies continue living with their parents.

Parent–Child Relationships Recall the observations of Sabrina's father in the introduction to this chapter—that as children enter adolescence, they resist spending time with the family and become more argumentative. Research in cultures as diverse as the United States and Turkey shows that puberty is related to a rise in parent–child conflict, which persists into the mid-teenage years (Gure, Ucanok, & Sayil, 2006; Laursen, Coy, & Collins, 1998; McGue et al., 2005).

Why should a youngster's more adultlike appearance trigger these disputes? From an evolutionary perspective, the association may have adaptive value. Among nonhuman primates, the young typically leave the family group around the time of puberty. The same is true in many nonindustrialized cultures (Caine, 1986; Schlegel & Barry, 1991). Departure of young people discourages sexual relations between close blood relatives. But adolescents in industrialized nations, who are still economically dependent on parents, cannot leave the family. Consequently, a modern substitute seems to have emerged: psychological distancing.

As children become physically mature, they demand to be treated in adultlike ways. And as we will see in later chapters, adolescents' new powers of reasoning may also contribute to a rise in family tensions. Parent–adolescent disagreements focus largely on everyday matters such as driving, dating partners, and curfews (Adams & Laursen, 2001). But beneath these disputes lie serious concerns: parental efforts to protect teenagers from substance use, auto accidents, and early sex. The larger the gap between parents' and adolescents' views of teenagers' readiness for new responsibilities, the more they quarrel (Deković, Noom, & Meeus, 1997).

Parent–daughter conflict tends to be more intense than conflict with sons, perhaps because girls reach puberty earlier and parents place more restrictions on girls (Allison & Schultz, 2004). But most disputes are mild, and by late adolescence, only a small minority of families experience continuing friction. Parents and teenagers display both conflict and affection, and they usually agree on important values, such as honesty and the importance of education.

Although separation from parents is adaptive, both generations benefit from warm, protective family bonds throughout the lifespan. As the teenage years conclude, parent–adolescent interactions are less hierarchical, setting the stage for mutually supportive relationships in adulthood (Laursen & Collins, 2009).

Pubertal Timing

In addition to dramatic physical change, the timing of puberty has a major impact on psychological adjustment. Findings of several studies indicate that both adults and peers viewed early-maturing boys as relaxed, independent, self-confident, and physically attractive. Popular with agemates, they tended to hold leadership positions in school and to be athletic stars. In contrast, late-maturing boys expressed more anxiety and depressed mood than their on-time counterparts (Brooks-Gunn, 1988; Huddleson & Ge, 2003). But early-maturing boys, though viewed as well-adjusted, reported slightly more psychological stress, depressed mood, and problem behaviors (sexual activity, smoking, drinking, aggression, delinquency) than both their on-time and later-maturing agemates (Ge, Conger, & Elder, 2001; Natsuaki, Biehl, & Ge, 2009; Susman & Dorn, 2009).

LOOK and LISTEN

Interview several classmates of both sexes about their own pubertal timing. Were they early or late maturers? How did pubertal timing affect their experiences in school and with peers?

In contrast, early-maturing girls were unpopular, withdrawn, lacking in self-confidence, anxious, and prone to depression, and they held few leadership positions and achieved less well in school (Ge, Conger, & Elder, 1996; Graber et al., 1997; Graber, Brooks-Gunn, & Warren, 2006; Jones & Mussen, 1958). And like early-maturing boys, they were more involved in deviant behavior (smoking, drinking, early sexual activity) (Caspi et al., 1993; Dick et al., 2000; Ge et al., 2006). In contrast, their later-maturing counterparts were regarded as physically attractive, lively, sociable, and leaders at school. In one study of several hundred eighth graders, however, negative effects were not evident among early-maturing African-American girls, whose families—and perhaps friends as well—tend to be more unconditionally welcoming of menarche (see page 206) (Michael & Eccles, 2003).

Two factors largely account for these trends: (1) how closely the adolescent's body matches cultural ideals of physical attractiveness and (2) how well young people fit in physically with their agemates.

The Role of Physical Attractiveness **TAKE A MOMENT...** Flip through the pages of your favorite popular magazine. You will see evidence of our society's view of an attractive female as thin and long-legged and of a good-looking male as tall, broad-shouldered, and muscular. The female image is a girlish shape that favors the late developer. The male image fits the early-maturing boy.

Consistent with these preferences, early maturing Caucasian girls tend to report a less positive **body image**—conception of and attitude toward their physical appearance—than their on-time and late-maturing agemates. Compared with African-American and Hispanic girls, Caucasian girls are more likely to have internalized the cultural ideal of female attractiveness. Most want to be thinner (Rosen, 2003; Stice, Presnell, & Bearman, 2001; Williams & Currie, 2000). Although boys are less consistent, early, rapid maturers are more likely to be satisfied with their physical characteristics (Alsaker, 1995; Sinkkonen, Anttila, & Siimes, 1998).

Body image is a strong predictor of young people's self-esteem (Harter, 2006). But the negative effects of pubertal timing on body image and—as we will see next—emotional adjustment are greatly amplified when accompanied by other stressors (Stice, 2003).

The Importance of Fitting in with Peers Physical status in relation to peers also explains differences in adjustment between early and late maturers. From this perspective, early-maturing girls and late-maturing boys have difficulty because they fall at the extremes in physical development. Recall that Sabrina felt "out of place" when with her agemates. Not surprisingly, adolescents feel most comfortable with peers who match their own level of biological maturity (Stattin & Magnusson, 1990).

Because few agemates of the same pubertal status are available, early-maturing adolescents of both sexes seek out older companions, who often encourage them into activities they are not yet ready to handle. And hormonal influences on the brain's emotional/social network (see pages 190–191) are stronger for early maturers, further magnifying their receptiveness to sexual activity, drug and alcohol use, and minor delinquent acts (Ge et al., 2002; Steinberg, 2008). Perhaps because of such involvements, early maturers of both sexes report feeling emotionally stressed and show declines in academic performance (Mendle, Turkheimer, & Emery, 2007; Natsuaki, Biehl, & Ge, 2009).

At the same time, the young person's context greatly increases the likelihood that early pubertal timing will lead to negative outcomes. Early maturers in economically disadvantaged neighborhoods are especially vulnerable to establishing ties with deviant peers, which heightens their defiant, hostile behavior (Obeidallah et al., 2004). And because families in such neighborhoods tend to be exposed to chronic, severe stressors and to have few social supports, these early maturers are also more likely to experience harsh, inconsistent parenting, which, in turn, predicts both deviant peer associations and antisocial activity (Ge et al., 2002, 2011).

© ELIZABETH CREWS/THE IMAGE WORKS

These 11-year-olds vary greatly in pubertal timing. Outside of school, early maturers often seek out older companions, who may encourage them into deviant activities. Early-maturing girls, especially, are at risk for lasting difficulties.

Long-Term Consequences Do the effects of pubertal timing persist? Follow-ups reveal that early-maturing girls, especially, are prone to lasting difficulties. In one study, early-maturing boys' depression subsided by age 13, but depressed early-maturing girls tended to remain depressed (Ge at al., 2003). In another study, which followed young people from ages 14 to 24, early-maturing boys again showed good adjustment. Early-maturing girls, however, reported poorer-quality relationships with family and friends, smaller social networks, and lower life satisfaction into early adulthood than their on-time counterparts (Graber et al., 2004). Similarly, in a Swedish investigation, achievement and substance use difficulties of early-maturing girls lingered, in the form of greater alcohol abuse and lower educational attainment than their agemates (Andersson & Magnusson, 1990; Stattin & Magnusson, 1990).

Recall that childhood family conflict and harsh parenting are linked to earlier pubertal timing, more so for girls than for boys (see page 205). Perhaps many early-maturing girls enter adolescence with emotional and social difficulties. As the stresses of puberty interfere with school performance and lead to unfavorable peer pressures, poor adjustment extends and deepens (Graber, 2003). Clearly, interventions that target at-risk early-maturing adolescents are needed. These include educating parents and teachers and providing adolescents with counseling and social supports so they will be better prepared to handle the emotional and social challenges of this transition.

ASK YOURSELF

Review ■ Summarize the impact of pubertal timing on adolescent development.

Connect ■ How might adolescent moodiness contribute to the psychological distancing between parents and children that accompanies puberty? (*Hint:* Think about bidirectional influences in parent–child relationships.)

Apply ■ As a school-age child, Chloe enjoyed leisure activities with her parents. Now, as a 14-year-old, she spends hours in her room and resists going on weekend family excursions. Explain Chloe's behavior.

Reflect ■ Recall your own reactions to the physical changes of puberty. Are they consistent with research findings? Explain.

- What factors contribute to eating disorders in adolescence?
- Discuss cultural, social, and personal influences on adolescent sexual attitudes and behavior.
- Cite factors involved in the development of homosexuality.
- Discuss factors related to sexually transmitted disease and teenage pregnancy and parenthood, noting prevention and intervention strategies.

Puberty and Adolescent Health

The arrival of puberty brings new health concerns related to the young person's efforts to meet physical and psychological needs. As adolescents attain greater autonomy, their personal decision making becomes important, in health as well as other areas. Yet none of the health concerns we are about to discuss can be traced to a single cause. Rather, biological, psychological, family, peer, and cultural factors jointly contribute.

Eating Disorders

Girls who reach puberty early, who are very dissatisfied with their body image, and who grow up in homes where concern with weight and thinness is high are at risk for eating problems. Severe dieting is the strongest predictor of an eating disorder in adolescence (Lock & Kirz, 2008). The two most serious are anorexia nervosa and bulimia nervosa.

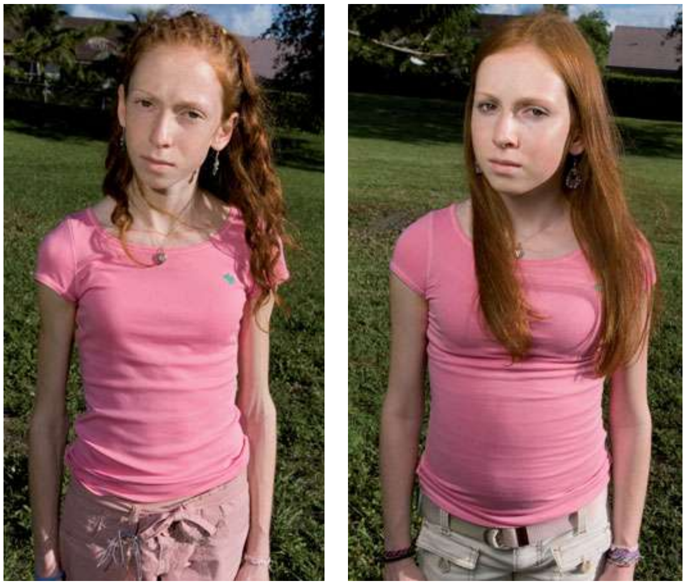
Anorexia Nervosa **Anorexia nervosa** is a tragic eating disorder in which young people starve themselves because of a compulsive fear of getting fat. Typically appearing between ages 14 and 16, it affects about 1 percent of North American and Western European teenage girls. During the past half-century, cases have increased sharply, fueled by cultural admiration of female thinness. Anorexia nervosa is equally common in all social-class groups, but Asian-American, Caucasian-American, and Hispanic girls are at greater risk than African-American girls, who tend to be more satisfied with their size and shape (Granillo, Jones-Rodriguez, & Carvajal, 2005; Ozer & Irwin, 2009; Steinhausen, 2006). Boys account for 10 to 15 percent of anorexia cases; about half of these are gay or bisexual young people who are uncomfortable with a strong, muscular appearance (Raevuori et al., 2009; Robb & Dadson, 2002).

Individuals with anorexia have an extremely distorted body image. Even after they have become severely underweight, they see themselves as too heavy. Most go on self-imposed diets so strict that they struggle to avoid eating in response to hunger. To enhance weight loss, they exercise strenuously.

In their attempt to reach "perfect" slimness, individuals with anorexia lose between 25 and 50 percent of their body weight. Because a normal menstrual cycle requires about 15 percent body fat, either menarche does not occur or menstrual periods stop. Malnutrition causes pale skin, brittle discolored nails, fine dark hairs all over the body, and extreme sensitivity to cold. If it continues, the heart muscle can shrink, the kidneys can fail, and irreversible brain damage and loss of bone mass can occur. About 6 percent of individuals with anorexia die of the disorder, as a result of either physical complications or suicide (Katzman, 2005).

Forces within the person, the family, and the larger culture give rise to anorexia nervosa. Identical twins share the disorder more often than fraternal twins, indicating a genetic influence. Abnormalities in neurotransmitters in the brain, linked to anxiety and impulse control, may make some individuals more susceptible (Kaye, 2008; Lock & Kirz, 2008). And problem eating behavior in early childhood—persistently refusing to eat or eating very little—is linked to anorexia in adolescence (Nicholls & Viner, 2009). Many young people with anorexia have unrealistically high standards for their own behavior and performance, are emotionally inhibited, and avoid intimate ties outside the family. Consequently, they are often excellent students who are responsible and well-behaved. But as we have seen, the societal image of "thin is beautiful" contributes to the poor body image of many girls—especially early-maturing girls, who are at greatest risk for anorexia nervosa (Hogan & Strasburger, 2008).

In addition, parent–adolescent interactions reveal problems related to adolescent autonomy. Often the mothers of these girls have high expectations for physical appearance, achievement, and social acceptance and are overprotective and controlling. Fathers tend to be emotionally distant. These parental attitudes and behavior may contribute to affected girls' persistent anxiety and fierce pursuit of perfection in achievement, respectable behavior, and thinness (Kaye, 2008). Nevertheless, it remains unclear whether maladaptive parent–child relationships precede the disorder, emerge as a response to it, or both. In a longitudinal study in which 12- to 16-year-old girls were followed for four years, unhealthy eating behaviors led to conflict-ridden interactions with parents, not the reverse (Archibald et al., 2002).



© LAUREN GREENFIELD/INSTITUTE

Aiva, age 16, an anorexia nervosa patient, is shown at left weighing just 77 pounds on the day she entered treatment. At right, Aiva appears 10 weeks later, on her last day of treatment. Less than 50 percent of young people with anorexia fully overcome the disorder.

Because individuals with anorexia typically deny or minimize the seriousness of their disorder, treating it is difficult (Couturier & Lock, 2006). Hospitalization is often necessary to prevent life-threatening malnutrition. The most successful treatment is family therapy plus medication to reduce anxiety and neurotransmitter imbalances (Robin & Le Grange, 2010; Treasure & Schmidt, 2005). As a supplementary approach, behavior modification—in which individuals hospitalized with anorexia are rewarded with praise, social contact, and opportunities for exercise when they eat and gain weight—is helpful.

Still, less than 50 percent of young people with anorexia recover fully. For many, eating problems continue in less extreme form. About 10 percent show signs of a less severe, but nevertheless debilitating, disorder: bulimia nervosa. And the chronic anxiety associated with both eating disorders increases girls' risk for major depression in both adolescence and adulthood (Godart et al., 2006).

Bulimia Nervosa

In **bulimia nervosa,** young people (again, mainly girls, but gay and bisexual boys are also vulnerable) engage in strict dieting and excessive exercise accompanied by binge eating, often followed by deliberate vomiting and purging with laxatives (Herzog, Eddy, & Beresin, 2006; Wichstrøm, 2006). Bulimia typically appears in late adolescence and is more common than anorexia nervosa, affecting about 2 to 4 percent of teenage girls, only 5 percent of whom previously suffered from anorexia.

Twin studies show that bulimia, like anorexia, is influenced by heredity (Klump, Kaye, & Strober, 2001). Overweight and early menarche increase the risk. Some adolescents with bulimia, like those with anorexia, are perfectionists. But most are impulsive, sensation-seeking young people who lack self-control in many areas, engaging in petty shoplifting, alcohol abuse, and other risky behaviors. And although girls with bulimia, like those with anorexia, are pathologically anxious about gaining weight, they may have experienced their parents as disengaged and emotionally unavailable rather than overcontrolling (Fairburn & Harrison, 2003).

In contrast to young people with anorexia, those with bulimia usually feel depressed and guilty about their abnormal eating habits and desperately want help. As a result, bulimia is usually easier to treat than anorexia, through support groups, nutrition education, training in changing eating habits, and anti-anxiety, antidepressant, and appetite-control medication (Hay & Bacaltchuk, 2004).

Sexuality

With the arrival of puberty, hormonal changes—in particular, the production of androgens in young people of both sexes—lead to an increase in sex drive (Halpern, Udry, & Suchindran, 1997). In response, adolescents become very concerned about managing sexuality in social relationships. New cognitive capacities involving perspective taking and self-reflection affect their efforts to do so. Yet like the eating behaviors we have just discussed, adolescent sexuality is heavily influenced by the young person's social context.

The Impact of Culture **TAKE A MOMENT...** When did you first learn "the facts of life"—and how? Was sex discussed openly in your family, or was it treated with secrecy? Exposure to sex, education about it, and efforts to limit the sexual curiosity of children and adolescents vary widely around the world. At one extreme are a number of Middle Eastern peoples, who murder girls if they lose their virginity before marriage. At the other extreme are several Asian and Pacific Island groups with highly permissive sexual attitudes and practices. For example, among the Trobriand Islanders of Papua New Guinea, older companions provide children with instruction in sexual practices, and adolescents are expected to engage in sexual experimentation with a variety of partners (Weiner, 1988).

Despite the prevailing image of sexually free adolescents, sexual attitudes in North America are relatively restrictive. Typically, parents provide little or no information about sex, discourage sex play, and rarely talk about sex in children's presence. When young people become interested in sex, only about half report getting information from parents about intercourse, pregnancy prevention, and sexually transmitted disease. Many parents avoid meaningful discussions about sex out of fear of embarrassment or concern that the adolescent will not take them seriously (Wilson et al., 2010). Yet warm, open give-and-take, as described in Applying What We Know on the following page, is associated with teenagers' adoption of parents' views and with reduced sexual risk taking (Jaccard, Dodge, & Dittus, 2003; Usher-Seriki, Bynum, & Callands, 2008).

Adolescents who do not get information about sex from their parents are likely to learn from friends, books, magazines, movies, TV, and the Internet (Jaccard, Dodge, & Dittus, 2002; Sutton et al., 2002). On prime-time TV shows, which adolescents watch more than other TV offerings, 80 percent of programs contain sexual content. Most depict partners as spontaneous and passionate, taking no steps to avoid pregnancy or sexually transmitted disease, and experiencing no negative consequences (Roberts, Henriksen, & Foehr, 2004). In several studies, teenagers' media exposure to sexual content positively predicted current sexual activity, intentions to be sexually active in the future, and subsequent sexual activity, pregnancies, and sexual harassment behaviors (offensive name-calling or touching, pressuring a peer for a date), even after many other relevant factors were controlled (Brown & L'Engle, 2009; Chandra et al., 2008; Roberts, Henriksen, & Foehr, 2009).

Not surprisingly, adolescents who are prone to early sexual activity choose to consume more sexualized media (Steinberg & Monahan, 2011). Still, the Internet is a hazardous "sex educator." In a survey of a large sample of U.S. 10- to 17-year-old Web users, 42 percent said they had viewed online pornographic websites (images of naked people or people having sex) while surfing the Internet in the past 12 months. Of these, 66 percent indicated they had encountered the images accidentally and did not want to view them. Youths who felt depressed, had been bullied by peers, or were involved in delinquent activities had more encounters with Internet pornography, which may have intensified their adjustment problems (Wolak, Mitchell, & Finkelhor, 2007).

Consider the contradictory messages young people receive. On one hand, adults emphasize that sex at a young age and outside marriage is wrong. On the other hand, the social

APPLYING WHAT WE KNOW

Communicating with Adolescents About Sexual Issues

STRATEGY	EXPLANATION
Foster open communication.	Let the teenager know you are a willing and trustworthy resource by stating that you are available when questions arise and will answer fully and accurately.
Use correct terms for body parts.	Correct vocabulary gives the young person a basis for future discussion and also indicates that sex is not a forbidden topic.
Use effective discussion techniques.	Listen, encourage the adolescent to participate, ask open-ended rather than yes/no questions, and give supportive responses. Avoid dominating and lecturing, which cause teenagers to withdraw.
Reflect before speaking.	When the adolescent asks questions or offers opinions about sex, remain nonjudgmental. If you differ with the teenager's views, convey your perspective in a nonthreatening manner, emphasizing that although you disagree, you are not attacking his or her character. Trying to dictate the young person's behavior generally results in alienation.
Keep conversations going.	Many parents think their job is finished once they have had the "big talk" in early adolescence. But young people are more likely to be influenced by an accumulation of smaller discussions. If open communication begins early and is sustained, the teenager is more likely to return with thoughts and questions.

Source: Berkowitz, 2004; Wilson et al., 2010.

environment extols sexual excitement, experimentation, and promiscuity. American teenagers are left bewildered, poorly informed about sexual facts, and with little sound advice on how to conduct their sex lives responsibly.

Adolescent Sexual Attitudes and Behavior Although differences between subcultural groups exist, the sexual attitudes of U.S. adolescents and adults have become more liberal over the past 40 years. Compared with a generation ago, more people approve of sexual intercourse before marriage, as long as two people are emotionally committed to each other (ABC News, 2004; Hoff, Greene, & Davis, 2003). During the past decade, adolescents have swung slightly back toward more conservative sexual beliefs, largely in response to the risk of sexually transmitted disease, especially AIDS, and to teenage sexual abstinence programs sponsored by schools and religious organizations (Akers et al., 2011; Ali & Scelfo, 2002).

Trends in adolescents' sexual behavior are consistent with their attitudes. Rates of extramarital sex among U.S. young people rose for several decades but have recently declined (U.S. Department of Health and Human Services, 2010g). Nevertheless, as Figure 5.14 reveals, a substantial percentage of young people are sexually active by ninth grade (age 14 to 15).

Overall, teenage sexual activity rates are similar in the United States and other Western countries: Nearly half of adolescents have had intercourse. But quality of sexual experiences differs. U.S. youths become sexually active earlier than their Canadian and European counterparts (Boyce et al., 2006; U.S. Department of Health and Human Services, 2010g). And about 14 percent of adolescent boys in the United States—more than in other Western nations—have had sexual relations

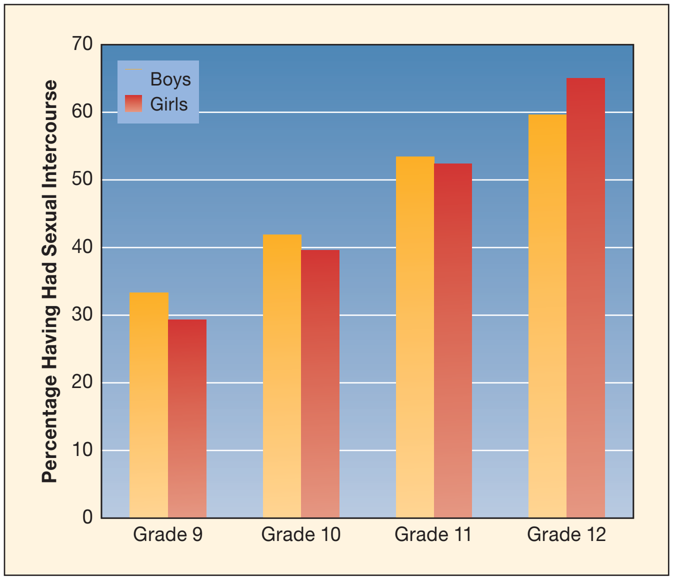


FIGURE 5.14 U.S. adolescents who report ever having had sexual intercourse. Many young U.S. adolescents are sexually active—more than in other Western nations. Boys tend to have their first intercourse earlier than girls. In tenth and eleventh grades, rates of boys and girls having had sexual intercourse are similar. In twelfth grade, girls' rate exceeds boys'. (From U.S. Department of Health and Human Services, 2010d.)

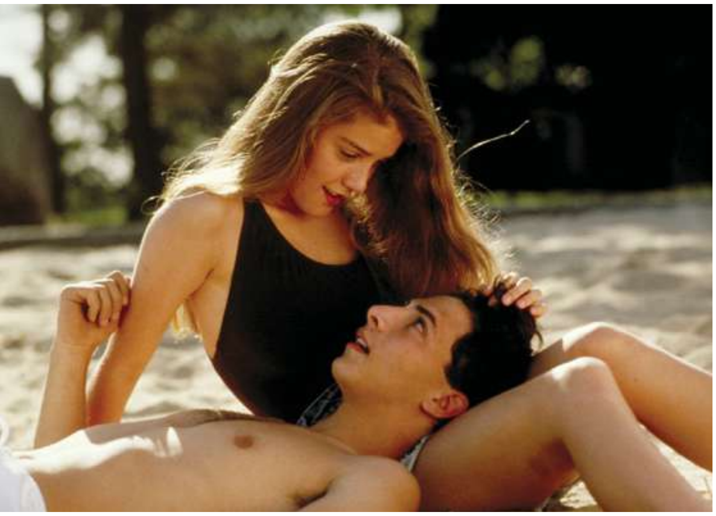

© RICHARD HUTCHINGS/PHOTOEDIT

Adolescence is an especially important time for the development of sexuality. But American teenagers receive contradictory and confusing messages about the appropriateness of sex.

with three or more partners in the past year (Alan Guttmacher Institute, 2010). Most teenagers, however, have had only one or two sexual partners by the end of high school.

Characteristics of Sexually Active Adolescents Early and frequent sexual activity is linked to personal, family, peer, and educational characteristics. These include childhood impulsivity, weak sense of personal control over life events, early pubertal timing, parental divorce, single-parent and stepfamily homes, large family size, little or no religious involvement, weak parental monitoring, disrupted parent–child communication, sexually active friends and older siblings, poor school performance, lower educational aspirations, and tendency to engage in norm-violating acts, including alcohol and drug use and delinquency (Coley, Votruba-Drzal, & Schindler, 2009; Crockett, Raffaelli, & Shen, 2006; Siebenbruner, Zimmer-Gembeck, & Egeland, 2007; Zimmer-Gembeck & Helfand, 2008).

Because many of these factors are associated with growing up in a low-income family, it is not surprising that early sexual activity is more common among young people from economically disadvantaged homes. Living in a neighborhood high in physical deterioration, crime, and violence also increases the likelihood that teenagers will be sexually active (Ge et al., 2002). In such neighborhoods, social ties are weak, adults exert little oversight or control over adolescents' activities, and negative peer influences are widespread. In fact, the high rate of sexual activity among African-American teenagers—65 percent report having had sexual intercourse, compared with 46 percent of all U.S. young people—is largely accounted for by widespread poverty in the black population (Darroch, Frost, & Singh, 2001; U.S. Department of Health and Human Services, 2010g).

Early and prolonged father absence predicts higher rates of intercourse and pregnancy among adolescent girls, after many family background and personal characteristics are controlled (Ellis et al., 2003). Perhaps father absence exposes young people to the dating and sexual behaviors of their mothers, who serve as models for their physically maturing children. An alternative, evolutionary account proposes that fathers' investment in parenting encourages daughters to delay sexual activity in favor of seeking a similarly committed male partner to ensure their offspring's well-being. Because father-absent girls view male commitment as uncertain, they may readily enter into casual sexual relationships.

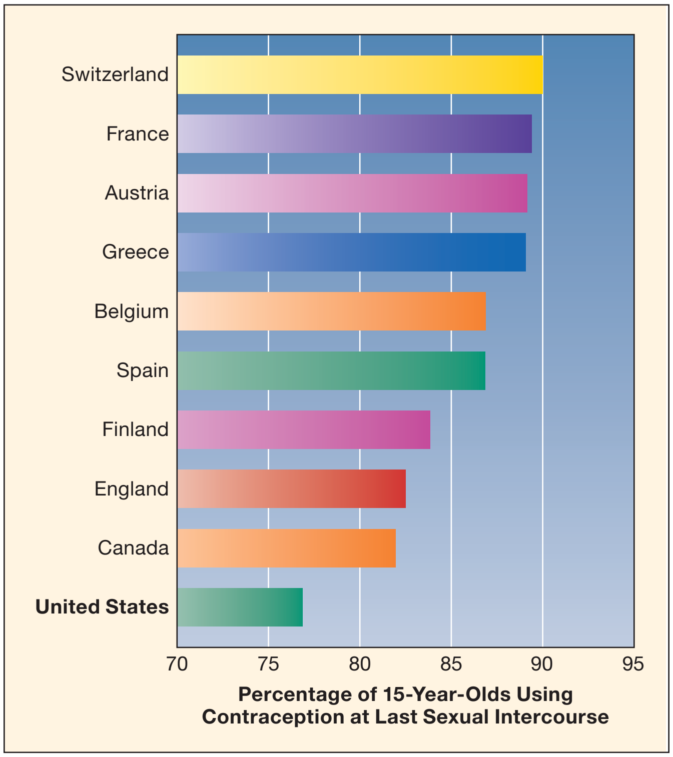

FIGURE 5.15 **Contraceptive use by sexually active 15-year-olds in ten industrialized nations.** Sexually active U.S. teenagers are less likely to use contraception (condom, contraceptive pill, or both) consistently than teenagers in other industrialized nations. (Adapted from Godeau et al., 2008; U.S. Department of Health and Human Services, 2010g.)

Contraceptive Use Although adolescent contraceptive use has increased in recent years, about 20 percent of sexually active teenagers in the United States are at risk for unintended pregnancy because they do not use contraception consistently (see Figure 5.15) (Alan Guttmacher Institute, 2002, 2005; Fortenberry et al., 2010). Why do so many fail to take precautions? Typically, teenagers respond, "I was waiting until I had a steady boyfriend," or "I wasn't planning to have sex." As we will see in Chapter 6, although adolescents can consider multiple possibilities when faced with a theoretical problem, they often fail to apply this advanced reasoning to everyday situations.

One reason is that advances in perspective taking—the capacity to imagine what others may be thinking and feeling—lead teenagers, for a time, to be extremely concerned about what others think of them. Also, in the midst of everyday social pressures, adolescents often overlook the potential consequences of risky behaviors. And many teenagers—especially those from troubled, low-income families—do not have realistic expectations about the impact of early parenthood on their current and future lives (Stevens-Simon, Sheeder, & Harter, 2005).

As these findings suggest, the social environment also contributes to adolescents' reluctance to use contraception. Those without the rewards of meaningful education and work are especially likely to engage in irresponsible sex, sometimes within relationships characterized by exploitation. About 11 percent of U.S. girls and 5 percent of boys say they were pressured to have intercourse when they were unwilling (U.S. Department of Health and Human Services, 2010g).

In contrast, teenagers who report good relationships with parents and who talk openly with them about sex and contraception are more likely to use birth control (Henrich et al., 2006; Kirby, 2002a). But few adolescents believe their parents would be understanding and supportive. School sex education classes, as well, often leave teenagers with incomplete or incorrect knowledge. Some do not know where to get birth control counseling and devices; those who do often worry that a doctor or family planning clinic might not keep their visits confidential. About 20 percent of adolescents using health services say that if their parents were notified, they would still have sex, but without contraception (Jones et al., 2005).

Sexual Orientation So far, we have focused only on heterosexual behavior. About 4 percent of U.S. 15- to 44-year-olds identify as lesbian, gay, or bisexual (Mosher, Chandra, & Jones, 2005). An unknown number experience same-sex attraction but have not come out to friends or family (see the Social Issues: Health box on page 216). Adolescence is an equally crucial time for the sexual development of these individuals, and societal attitudes, again, loom large in how well they fare.

Heredity makes an important contribution to homosexuality: Identical twins of both sexes are more likely than fraternal twins to share a homosexual orientation; so are biological (as opposed to adoptive) relatives (Kendler et al., 2000; Kirk et al., 2000). Furthermore, male homosexuality tends to be more common on the maternal than on the paternal side of families, suggesting that it may be X-linked (see Chapter 3). Indeed, one gene-mapping study found that among 40 pairs of homosexual brothers, 33 (82 percent) had an identical segment of DNA on the X chromosome. One or several genes in that region might predispose males to become homosexual (Hamer et al., 1993).

How might heredity lead to homosexuality? According to some researchers, certain genes affect the level or impact of prenatal sex hormones, which modify brain structures in ways that induce homosexual feelings and behavior (Bailey et al., 1995; LeVay, 1993). Keep in mind, however, that both genetic and environmental factors can alter prenatal hormones. Girls exposed prenatally to very high levels of androgens or estrogens—either because of a genetic defect or from drugs given to the mother to prevent miscarriage—are more likely to become lesbian or bisexual (Meyer-Bahlburg et al., 1995). Furthermore, gay men also tend to be later in birth order and to have a higher-than-average number of older brothers (Blanchard & Bogaert, 2004). One possibility is that mothers with several male children sometimes produce antibodies to androgens, reducing the prenatal impact of male sex hormones on the brains of later-born boys.

Stereotypes and misconceptions about homosexuality and bisexuality continue to be widespread. For example, contrary to common belief, most homosexual adolescents are not "gender-deviant" in dress or behavior. Also, attraction to members of the same sex is not limited to lesbian, gay, and bisexual teenagers. About 50 to 60 percent of adolescents who report having engaged in homosexual acts identify as heterosexual (Savin-Williams & Diamond, 2004). And a study of lesbian, bisexual, and "unlabeled" young women confirmed that bisexuality is not, as often assumed, a transient state (Diamond, 2008). Over a 10-year period, few bisexuals changed to a lesbian or heterosexual orientation, and most reported stable proportions of same-sex versus other-sex attractions over time.

The evidence to date indicates that genetic and prenatal biological influences are largely responsible for homosexuality; the origins of bisexuality are not yet known. In our evolutionary past, homosexuality may have served the adaptive function of reducing aggressive competition for other-sex mates, thereby promoting the survival of group members (Rahman & Wilson, 2003).

SOCIAL ISSUES: HEALTH

Lesbian, Gay, and Bisexual Youths: Coming Out to Oneself and Others

Cultures vary as much in their acceptance of homosexuality as in their approval of extramarital sex. In the United States, homosexuals are stigmatized, as shown by the degrading language often used to describe them. This makes forming a sexual identity a much greater challenge for lesbian, gay, and bisexual youths than for their heterosexual counterparts.

Wide variations in sexual identity formation exist, depending on personal, family, and community factors. Yet interviews with gay and lesbian adolescents and adults reveal that many (though not all) move through a three-phase sequence in coming out to themselves and others.

Feeling Different

Many gay men and lesbians say they felt different from other children when they were young. Typically, this first sense of their biologically determined sexual orientation appears between ages 6 and 12, in play interests more like those of the other gender (Rahman & Wilson, 2003). Boys may find that they are less interested in sports, more drawn to quieter activities, and more emotionally sensitive than other boys; girls that they are more athletic and active than other girls.

By age 10, many of these children start to engage in *sexual questioning*—wondering why the typical heterosexual orientation does not apply to them. Often, they experience their sense of being different as deeply distressing. Compared with children who are confident of their homosexuality, sexual-questioning children report greater anxiety about peer relationships and greater dissatisfaction with their biological gender over time (Carver, Egan, & Perry, 2004).

Confusion

With the arrival of puberty, feeling different clearly encompasses feeling sexually different. In research on ethnically diverse lesbian, gay, and bisexual youths, awareness of a same-sex physical attraction occurred, on average, between ages 11 and 12 for boys and 14 and 15 for girls, perhaps because adolescent social pressures toward heterosexuality are particularly intense for girls (D'Augelli, 2006; Diamond, 1998).

Realizing that homosexuality has personal relevance generally sparks additional confusion. A few adolescents resolve their discomfort by crystallizing a lesbian, gay, or bisexual identity quickly, with a flash of insight into their sense of being different. But most experience an inner struggle and a deep sense of isolation—outcomes intensified by lack of role models and social support (D'Augelli, 2002; Safren & Pantalone, 2006).

Some throw themselves into activities they associate with heterosexuality. Boys may go out for athletic teams; girls may drop softball and basketball in favor of dance. And many homosexual youths (more females than males) try heterosexual dating, sometimes to hide their sexual orientation and at other times to develop intimacy skills that they later apply to same-sex relationships (D'Augelli, 2006; Dubé, Savin-Williams, & Diamond, 2001). Those who are extremely troubled and guilt-ridden may escape into alcohol, drugs, and suicidal thinking. Suicide attempts are unusually high among lesbian, gay, and bisexual young people (Morrow, 2006; Teasdale & Bradley-Engen, 2010).

BE AN ALLY
BE THE CHANGE

COURTESY OF GLSEN.ORG

Teenagers prepare to celebrate ALLY week, which encourages students to be allies against bullying and harassment of gay, lesbian, bisexual, and transgender schoolmates. When people react positively, coming out strengthens the young person's view of homosexuality as a fulfilling identity.

Self-Acceptance

By the end of adolescence, the majority of gay, lesbian, and bisexual teenagers accept their sexual identity. But they face another crossroad: whether to tell others. Powerful stigma against their sexual orientation leads some to decide that disclosure is impossible: While self-defining as gay, they otherwise "pass" as heterosexual (Savin-Williams, 2001). When homosexual youths do come out, they often face intense hostility, including verbal abuse and physical attacks because of their sexual orientation. These experiences trigger emotional distress, depression, suicidal thoughts, school truancy, and drug use in victims (Almeida et al., 2009; Birkett, Espelage, & Koenig, 2009).

Nevertheless, many young people eventually acknowledge their sexual orientation publicly, usually by telling trusted friends first. Once teenagers establish a same-sex sexual or romantic relationship, many come out to parents. Few parents respond with severe rejection; most are either positive or slightly negative and disbelieving. Still, lesbian, gay, and bisexual young people report lower levels of family support than their heterosexual agemates (Needham & Austin, 2010; Savin-Williams & Ream, 2003). Yet parental understanding is the strongest predictor of favorable adjustment—including reduced *internalized homophobia,* or societal prejudice turned against the self (D'Augelli, Grossman, & Starks, 2005, 2008).

When people react positively, coming out strengthens the young person's view of homosexuality as a valid, meaningful, and fulfilling identity. Contact with other gays and lesbians is important for reaching this phase, and changes in society permit many adolescents in urban areas to attain it earlier than their counterparts did a decade or two ago. Gay and lesbian communities exist in large cities, along with specialized interest groups, social clubs, religious groups, newspapers, and periodicals. But teenagers in small towns and rural areas may have difficulty meeting other gay and lesbian youths and finding a supportive environment. These adolescents have a special need for caring adults and peers who can help them find self- and social acceptance.

Lesbian, gay, and bisexual teenagers who succeed in coming out to themselves and others integrate their sexual orientation into a broader sense of identity, a process we will address in Chapter 11. As a result, energy is freed for other aspects of psychological growth. In sum, coming out can foster many aspects of adolescent development, including self-esteem, psychological well-being, and relationships with family and friends.

Sexually Transmitted Disease

Sexually active adolescents, both homosexual and heterosexual, are at risk for sexually transmitted diseases (STDs). Adolescents have the highest incidence of STDs of all age groups. Despite a recent decline in STDs in the United States, one out of six sexually active teenagers contracts one of these illnesses each year—a rate three or more times as high as that of Canada and Western Europe (Health Canada, 2008; U.S. Department of Health and Human Services, 2009b). Teenagers at greatest risk are the same ones most likely to engage in irresponsible sexual behavior—poverty-stricken young people who feel a sense of hopelessness (Niccolai et al., 2004). Left untreated, STDs can lead to sterility and life-threatening complications.

By far the most serious STD is AIDS. In contrast to other Western nations, where the incidence of AIDS among people under age 30 is low, one-fifth of U.S. AIDS cases occur in young people between ages 20 and 29. Because AIDS symptoms typically do not emerge until 8 to 10 years after infection with the HIV virus, nearly all these cases originated in adolescence. Drug-abusing teenagers who share needles and male adolescents who have sex with HIV-positive same-sex partners account for most cases, but heterosexual spread of the disease remains high, especially among teenagers with more than one partner in the previous 18 months. It is at least twice as easy for a male to infect a female with any STD, including AIDS, as for a female to infect a male. Currently, females account for about 25 percent of new U.S. cases among adolescents and young adults (U.S. Department of Health and Human Services, 2010c).

As a result of school courses and media campaigns, about 60 percent of U.S. middle-school students and 90 percent of high school students are aware of basic facts about AIDS. But most have limited understanding of other STDs and their consequences, underestimate their own susceptibility, and are poorly informed about how to protect themselves (Ethier et al., 2003; U.S. Centers for Disease Control and Prevention, 2007).

Furthermore, high school students report engaging in oral sex much more often than intercourse, and with more partners. But few say they are consistently using STD protection during oral sex, which is a significant mode of transmission of several STDs, including chlamydia, gonorrhea, herpes, and perhaps AIDS (Prinstein, Meade, & Cohen, 2003; U.S. Centers for Disease Control and Prevention, 2010). Concerted efforts are needed to educate young people about the full range of STDs and risky sexual behaviors.

Adolescent Pregnancy and Parenthood

About 740,000 U.S. teenage girls (15,000 of them younger than age 15)—an estimated 20 percent of those who had sexual intercourse—became pregnant in the most recently reported year. Although the U.S. adolescent pregnancy rate declined steadily over the past two decades, it remains higher than that of most other industrialized countries. Three factors heighten the incidence of adolescent pregnancy: (1) Effective sex education reaches too few teenagers; (2) convenient, low-cost contraceptive services for adolescents are scarce; and (3) many families live in poverty, which encourages young people to take risks without considering the future implications of their behavior.

Because nearly one-third of U.S. adolescent pregnancies end in abortion, the number of American teenage births is considerably lower than it was 50 years ago (Alan Guttmacher Institute, 2011). Still, it is up to nine times higher than in most other developed nations (see Figure 5.16). But teenage parenthood is a much greater problem today because adolescents are far less likely to marry before childbirth. In 1960, only 15 percent of teenage births were to unmarried females, compared

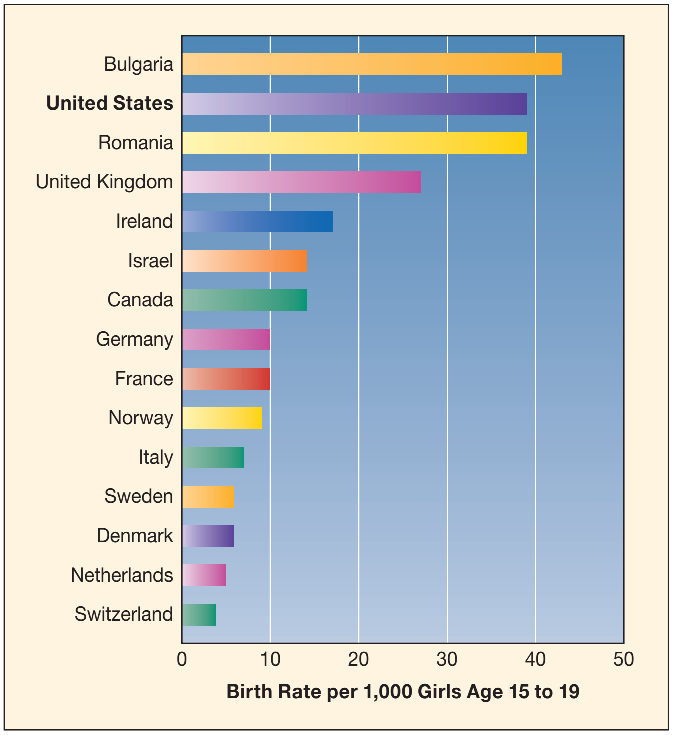

FIGURE 5.16 Birth rates among 15- to 19-year-olds in 15 industrialized nations. The U.S. adolescent birth rate greatly exceeds that of most other industrialized nations. (From U.S. Centers for Disease Control and Prevention, 2011.)

with 87 percent today (Child Trends, 2011). Increased social acceptance of single motherhood, along with the belief of many teenage girls that a baby might fill a void in their lives, means that very few girls give up their infants for adoption.

© ERICA LANSNER/GETTY IMAGES/PHOTODISC

For a young couple who face limited educational and career prospects, becoming parents seems to offer a direct route to adulthood. But teenage parenthood is typically associated with poverty, low educational attainment, and marital instability.

Correlates and Consequences of Adolescent Parenthood Becoming a parent is especially challenging for adolescents, who have not yet established a clear sense of direction for their own lives. Longitudinal research tracking girls from birth through adolescence reveals that life conditions and personal attributes jointly contribute to adolescent childbearing and also interfere with teenage mothers' capacity to parent effectively (Jaffee et al., 2001).

Teenage parents are far more likely to be poor than their agemates who postpone childbearing. Their backgrounds often include low parental warmth and involvement, domestic violence and child abuse, repeated parental divorce and remarriage, adult models of unmarried parenthood, and residence in neighborhoods where other adolescents display these risks. Girls at risk for early pregnancy do poorly in school, engage in alcohol and drug use, have a childhood history of aggressive and antisocial behavior, associate with deviant peers, and experience high rates of depression (Elfenbein & Felice, 2003; Hillis et al., 2004; Luster & Haddow, 2005). A high percentage of out-of-wedlock births are to low-income minority teenagers. Many turn to early parenthood as a way to move into adulthood when educational and career avenues are unavailable.

The lives of expectant teenagers, already troubled in many ways, tend to worsen in several respects after the baby is born:

- *Educational attainment.* Only about 70 percent of U.S. adolescent mothers graduate from high school, compared with 95 percent of girls who wait to become parents (National Women's Law Center, 2007). Lack of material resources—often due to living apart from one's own parents and not having access to child care—greatly reduces the likelihood of earning a high school diploma (Mollborn, 2007).
- *Marital patterns.*Teenage motherhood reduces the chances of marriage and, for those who do marry, increases the likelihood of divorce compared with peers who delay childbearing (Moore & Brooks-Gunn, 2002). Consequently, teenage mothers spend more of their parenting years as single parents. About 35 percent become pregnant again within two years. Of these, about half go on to deliver a second child (Child Trends, 2011).
- *Economic circumstances.* Because of low educational attainment, marital instability, and poverty, many teenage mothers are on welfare. If they are employed, their limited education restricts them to unsatisfying, low-paid jobs. Many adolescent fathers, as well, are unemployed or work at unskilled jobs, usually earning too little to provide their children with basic necessities (Bunting & McAuley, 2004). An estimated 50 percent have committed illegal acts resulting in imprisonment (Elfenbein & Felice, 2003). And for both mothers and fathers, reduced educational and occupational attainment often persists well into adulthood (Furstenberg, 2007; Taylor, 2009).

Because many pregnant teenage girls have inadequate diets, smoke, use alcohol and other drugs, and do not receive early prenatal care, their babies often experience pregnancy and birth complications—especially preterm and low birth weight (Khashan, Baker, & Kenny, 2010). And compared with adult mothers, adolescent mothers know less about child development, have unrealistically high expectations of their infants, perceive their babies as more difficult, interact less effectively with them, and more often engage in child abuse (Moore & Florsheim, 2001; Pomerleau, Scuccimarri, & Malcuit, 2003; Sieger & Renk, 2007). Their children tend to score low on intelligence tests, achieve poorly in school, and engage in disruptive social behavior.

Furthermore, adolescent parenthood frequently is repeated in the next generation (Brooks-Gunn, Schley, & Hardy, 2002). In longitudinal studies that followed mothers—some who gave birth as teenagers, others who postponed parenting—and their children for several decades, mothers' age at first childbirth strongly predicted the age at which their offspring, both daughters and sons, became parents (Barber, 2001; Campa & Eckenrode, 2006; Hardy et al., 1998; Meade, Kershaw, & Ickovics, 2008). The researchers found that adolescent parenthood was linked to a set of related, unfavorable family conditions and personal characteristics that negatively influenced development over an extended time and, therefore, often transferred to the next generation.

One important factor was quality of the home environment: Compared with children in other families, children of unmarried adolescent mothers had families that were less warm, supportive, and stimulating, even after mothers' prebirth education and income were controlled. Younger mothers' cognitive deficits and reduced educational attainment played a part, increasing the likelihood that their children would experience long-term poor-quality home environments. Another factor was father absence: Consistent with findings reported earlier for sexual activity and pregnancy (see page 214), several studies found far greater intergenerational continuity in adolescent parenthood, especially for daughters, when teenage mothers remained unmarried (Barber, 2001; Campa & Eckenrode, 2006; Meade, Kershaw, & Ickovics, 2008).

Even when children born to teenage mothers do not become early childbearers, their development is often compromised in terms of likelihood of high school graduation, financial independence in adulthood, and long-term physical and mental health (Moore, Morrison, & Greene, 1997; Pogarsky, Thornberry, & Lizotte, 2006). Still, outcomes vary widely. If a teenage mother finishes high school, secures gainful employment, avoids additional births, and finds a stable partner, long-term disruptions in her own and her child's development will be less severe.

Prevention Strategies Preventing teenage pregnancy means addressing the many factors underlying early sexual activity and lack of contraceptive use. Too often, sex education courses are given late (after sexual activity has begun), last only a few sessions, and are limited to a catalog of facts about anatomy and reproduction. Sex education that goes beyond this minimum does not encourage early sex, as some opponents claim (Kirby, 2002c). It does improve awareness of sexual facts—knowledge that is necessary for responsible sexual behavior.

Knowledge, however, is not enough. Sex education must help teenagers build a bridge between what they know and what they do. Today, the most effective sex education programs combine these key elements:

- They teach techniques for handling sexual situations—including refusal skills for avoiding risky sexual behaviors and communication skills for improving contraceptive use—through role-playing and other activities in which young people practice those behaviors.
- They deliver clear, accurate messages that are appropriate for participating adolescents' culture and sexual experiences.
- They last long enough to have an impact.
- They provide specific information about contraceptives and ready access to them.

Many studies show that sex education that includes these components can delay the initiation of sexual activity, increase contraceptive use, change attitudes (for example, strengthen future orientation), and reduce pregnancy rates (Kirby, 2002b, 2008; Thomas & Dimitrov, 2007).

Proposals to increase access to contraceptives are the most controversial aspect of U.S. adolescent pregnancy prevention efforts. Many adults argue that placing birth control pills or condoms in the hands of teenagers is equivalent to approving of early sex. Yet sex education programs focusing on abstinence have little or no impact on delaying teenage sexual activity or preventing pregnancy (Rosenbaum, 2009; Underhill, Montgomery, & Operario, 2007).

In Canada and Western Europe, where community- and school-based clinics offer adolescents contraceptives and where universal health insurance helps pay for them, teenage sexual activity is no higher than in the United States—but pregnancy, childbirth, and abortion rates are much lower (Schalet, 2007). Radio and TV campaigns promoting contraceptive use—used widely in Africa, Europe, India, and South America—are associated with a reduction in early sexual activity and with an increase in teenagers' use of birth control (Keller & Brown, 2002).

LOOK and LISTEN

Contact a nearby public school district and ask for information about its sex education curriculum. Considering research findings, do you think it is likely to be effective in delaying initiation of sexual activity and reducing adolescent pregnancy rates?

COURTESY OF THE WYMAN CENTER

A young teenager involved in a Teen Outreach service project prepares a meal for cancer patients. Volunteer work and related class discussions aimed at skill-building promote self-respect and community connection while reducing adolescent pregnancy and school failure.

Efforts to prevent adolescent pregnancy and parenthood must go beyond improving sex education and access to contraception to build academic and social competence (Allen, Seitz, & Apfel, 2007). In one study, researchers randomly assigned at-risk high school students to either a year-long community service class, called Teen Outreach, or regular classroom experiences in health or social studies. In Teen Outreach, adolescents spent at least 20 hours per week in volunteer work tailored to their interests. They returned to school for discussions that focused on enhancing their community service skills and ability to cope with everyday challenges. At the end of the school year, pregnancy, school failure, and school suspension were substantially lower in the group enrolled in Teen Outreach, which fostered social skills, connection to the community, and self-respect (Allen et al., 1997).

Finally, school involvement is linked to delayed initiation of sexual activity and to reduced teenage pregnancy, perhaps because it increases interaction with and attachment to adults who discourage risk taking, and it strengthens belief in a promising future (Harris, 2008). We will take up factors that promote adolescents' commitment to school in Chapter 15.

Intervening with Adolescent Parents The most difficult and costly way to deal with adolescent parenthood is to wait until it happens. Young mothers need health care, encouragement to stay in school, job training, instruction in parenting and life-management skills, and high-quality, affordable child care. School programs that provide these services reduce the incidence of low-birth-weight babies, increase mothers' educational success, and prevent additional childbearing (Key et al., 2008; Seitz & Apfel, 2005).

Adolescent mothers also benefit from relationships with family members and other adults who are sensitive to their developmental needs. In one study, African-American teenage mothers who had a long-term "mentor" relationship—an aunt, neighbor, or teacher who provided emotional support and guidance—were far more likely than those without a mentor to stay in school and graduate (Klaw, Rhodes, & Fitzgerald, 2003).

Home visiting programs are also helpful. The Nurse–Family Partnership, currently implemented in hundreds of counties across 29 U.S. states, aims to reduce pregnancy and birth complications, promote competent parenting, and improve family conditions for first time, low-income expectant mothers, many of them teenagers. A registered nurse visits the home regularly during pregnancy and the baby's first two years to provide intensive social support—a sympathetic ear; assistance in accessing community services and the help of family members; and encouragement to finish high school, find work, and engage in future family planning.

To evaluate the intervention, researchers randomly assigned over 1,000 mothers to nurse-visiting or comparison conditions (just prenatal care, or prenatal care plus infant referral for developmental problems) and followed the families through the child's first three years of elementary school (Olds et al., 2004, 2007). From their baby's birth on, home visited mothers were on a more favorable life course: They had fewer subsequent births, longer intervals between births, more frequent contact with the child's father, more stable intimate partnerships, less welfare dependence, and a greater sense of control over their lives. At school age, intervention children exceeded comparison children in language development, intelligence test scores, and academic achievement, and they also displayed fewer behavior problems.

Programs focusing on fathers attempt to increase their financial and emotional commitment to the baby. Although nearly half of young fathers visit their children during the first few years, contact usually diminishes. By the time the child starts school, fewer than one-fourth have regular paternal contact. As with teenage mothers, support from family members helps fathers stay involved (Bunting & McAuley, 2004). Teenage mothers who receive financial and child-care assistance and emotional support from the child's father are less distressed and more likely to sustain a relationship with him (Cutrona et al., 1998; Gee & Rhodes, 2003). And infants with lasting ties to their teenage fathers receive warmer, more stimulating caregiving and show better long-term adjustment (Florsheim & Smith, 2005; Furstenberg & Harris, 1993).

A Concluding Note

The rapid, complex physical and psychological changes of puberty make teenagers vulnerable to certain problems. Yet adolescents' unhealthy behaviors are not an irrational response to inner turmoil, as theorists once believed. Rather, every level of the ecological system affects teenagers' well-being.

Furthermore, we have seen that teenagers with one problem frequently display others—a co-occurrence that you will encounter again when we look at delinquency, depression, suicide, substance abuse, and school underachievement and failure. To design more powerful interventions, researchers must deal with simultaneous risks and the multiple factors that contribute to them. **TAKE A MOMENT...** Think back to the successful intervention efforts discussed in the preceding sections. Notice how they employ several strategies, target multiple behaviors, and involve several contexts.

Finally, adolescence is not only a time of risk but also a time of tremendous opportunity. Teenagers gain a better understanding of how the world works, greater control over their own social contexts, broader access to social support, and increased ability to avoid or alter risky behaviors. Families, schools, communities, and nations must create conditions that enable adolescents to exercise their expanding capacity for positive health practices. This is a theme we will revisit in later chapters.

ASK YOURSELF

Review ■ Compare risk factors for anorexia nervosa and bulimia nervosa. How do treatments and outcomes differ for the two disorders?

Connect ■ Explain how unfavorable life experiences and personal attributes associated with teenage parenthood increase the chances that it will be repeated in the next generation.

Apply ■ At age 17, Veronica dropped out of school, moved in with her boyfriend Todd, and gave birth to Ben. A few months later, Todd left Veronica, saying he couldn't stand being tied down with the baby. Suggest interventions likely to protect Veronica and Ben from lasting hardships.

Reflect ■ Describe sex education classes that you experienced in school. Did they help you postpone early sex and engage in more responsible sexual behavior? Explain.

SUMMARY

The Course of Physical Growth (p. 176)

Describe the course of physical growth, including changes in body size, proportions, muscle–fat makeup, and skeleton, and their relationship to gains in gross-motor skills.

- **Distance** and **velocity curves** show the overall pattern of change in body size: Gains in height and weight are rapid during infancy, slower during early and middle childhood, and rapid again during puberty.
- In childhood, physical growth follows **cephalocaudal** and **proximodistal trends**. During puberty, growth proceeds in the reverse direction, and sex differences in body proportions appear. Body fat increases quickly during the first nine months, then rapidly again at adolescence for girls. Muscle accumulates slowly until puberty, when it rises dramatically, especially for boys.
- The best measure of a child's physical maturity is **skeletal age,** which is based on the number of **epiphyses** and the extent to which they are fused. Girls are ahead of boys, a gap that widens over infancy and childhood.
- In early childhood, body growth causes the child's center of gravity to shift toward the trunk, which paves the way for new gross-motor skills. During the school years, improved balance, strength, agility, and flexibility support refinements in running, jumping, hopping, and ball skills. Increased body size and muscle strength lead to continued motor gains in adolescence. As they develop, children integrate previously acquired motor skills into more complex, dynamic systems of action.
- In childhood, boys' advantage over girls in many gross-motor skills largely reflects parental expectations and practice. By adolescence, sex differences in size and strength play a greater role.

Describe hormonal influences on physical growth.

- Physical growth is controlled by two vital hormones released by the **pituitary gland,** located at the base of the brain near the **hypothalamus,** which initiates and regulates pituitary secretions: **growth hormone (GH),** which affects the development of almost all body tissues; and **thyroid-stimulating hormone (TSH),** which—by prompting the thyroid gland to release thyroxine—affects brain development and body size. Sexual maturation is controlled by the sex hormones—**estrogens** and **androgens**.

Discuss factors that contribute to worldwide variations and secular trends in physical growth.

- Worldwide variations in body size are the combined result of heredity and environment, including evolutionary adaptations to climate, availability of food, and prevalence of disease.

- **Secular trends in physical growth** have occurred in industrialized nations, where, because of improved health and nutrition, most children are taller and heavier than their ancestors and reach puberty earlier.

Brain Development (p. 184)

Cite major milestones in brain development, at the level of individual brain cells and at the level of the cerebral cortex.

- The human brain reaches its adult size earlier than any other organ. Once **neurons** are in place, they rapidly form **synapses** and release **neurotransmitters,** which cross synapses to send messages to other neurons. As the brain grows, **programmed cell death** occurs, making room for growth of neural fibers that form synaptic connections.
- Stimulation determines which neurons will continue to establish new synapses and which will undergo **synaptic pruning. Glial cells,** responsible for **myelination,** multiply rapidly through the second year and continue to do so more slowly through adolescence, contributing to large gains in brain weight.
- Regions of the **cerebral cortex** develop in the order in which various capacities emerge in the infant and child. The frontal lobes, which contain the **prefrontal cortex,** have the most extended period of development, reaching an adult level of synapses in adolescence. Although some **lateralization,** or specialization of the cerebral hemispheres, exists at birth, **brain plasticity** remains high for the first few years. Both heredity and early experience contribute to brain organization.
- Hand preference, which reflects an individual's **dominant cerebral hemisphere,** first appears in infancy and gradually extends to a wider range of skills. Research on handedness supports the joint contribution of nature and nurture to brain lateralization.

Describe changes in other brain structures and in the adolescent brain, and discuss evidence on sensitive periods in brain development.

- In childhood and adolescence, connections strengthen among parts of the brain. Fibers linking the **cerebellum** to the cerebral cortex grow and myelinate, enhancing motor coordination and cognition. The **reticular formation,** responsible for alertness and consciousness; the **hippocampus,** which plays a vital role in memory and spatial orientation; and the **amygdala,** which is centrally involved in processing emotional information, also develop and link with the cerebral cortex. The **corpus callosum,** which connects the two cerebral hemispheres, supports coordinated movement and cognitive activities.
- Pruning of unused synapses in the cerebral cortex continues during adolescence, and growth and myelination of stimulated neural fibers accelerate, supporting diverse cognitive skills. Because advances in cognitive control are gradual, teenagers tend to perform less well than adults on tasks requiring inhibition, planning, and future orientation.
- Neurons become more responsive to excitatory neurotransmitters during adolescence, contributing to teenagers' drive for novel experiences. Heightened sensitivity to oxytocin increases responsiveness to emotional and social stimuli, including peer influence. These changes in the brain's emotional/social network outpace those in the cognitive-control network, resulting in self-regulation difficulties.
- Animal and human studies reveal the existence of sensitive periods in which appropriate stimulation is necessary for optimal brain development. **Experience-expectant brain growth** depends on ordinary experiences—early opportunities to interact with people, hear language, and explore the environment. No evidence exists for a sensitive period in the first five or six years of life for **experience-dependent brain growth,** which relies on specific learning experiences. Environments that overwhelm children with inappropriately advanced expectations can harm the brain's potential.

Factors Affecting Physical Growth (p. 192)

How do heredity, nutrition, infectious disease, and parental affection contribute to physical growth and health?

- With adequate diet and health, height and rate of physical growth depend largely on heredity. Although genetic makeup also affects weight, nutrition and eating habits are powerful influences.
- Breast milk is ideally suited to infants' nutritional needs and is crucial for protecting their health in the developing world. As growth slows around age 2, appetites become unpredictable, and many children become picky eaters. Repeated, unpressured exposure to a new food increases acceptance. During puberty, food intake rises dramatically, but adolescents' eating habits are the poorest. Family mealtimes increase healthy eating.
- Many children in developing countries suffer from **marasmus** and **kwashiorkor,** two diseases caused by malnutrition that can permanently impair body growth and brain development. Food insecurity affects children even in industrialized countries.
- **Obesity** is a growing problem in both industrialized and developing nations. Although heredity contributes to obesity, parental feeding practices, maladaptive eating habits, reduced sleep, lack of exercise, and Western high-fat diets are more powerful influences. Obese children are often socially isolated and display more emotional, social, and school difficulties and behavior problems than their normal-weight peers. Effective treatments for obesity are family-based; schools can also help by serving healthier meals and ensuring physical activity.
- Malnutrition interacts with infectious disease to undermine physical growth. In developing countries, where diarrhea leads to millions of childhood deaths, oral rehydration therapy (ORT) and zinc supplements can save lives. Widespread immunization has led to a dramatic decline in childhood diseases, but rates are lower in the United States than in other industrialized nations because many economically disadvantaged children lack access to necessary health care. Parental stress and misconceptions about vaccine safety also contribute.
- **Growth faltering** illustrates the importance of parental affection for healthy infant physical growth. Extreme and prolonged emotional deprivation in childhood can lead to **psychosocial dwarfism**.

Puberty: The Physical Transition to Adulthood (p. 203)

Describe sexual maturation in girls and boys, noting genetic and environmental influences on pubertal timing.

- At **puberty,** changes in **primary** and **secondary sexual characteristics** accompany rapid body growth. **Menarche** occurs relatively late in the girl's sequence of pubertal events, after the growth spurt, breast growth, and appearance of pubic and underarm hair. In boys, the growth spurt occurs later, preceded by enlargement of the sex organs and **spermarche.** This is followed by growth of facial and body hair and deepening of the voice.
- Heredity, nutrition, overall health, and early family experiences all contribute to the timing of puberty. Menarche is delayed in regions of the world with widespread malnutrition and infectious disease. In industrialized nations, ethnic variations—for example, earlier menarche in African-American than in Caucasian-American girls—reflect both heredity and environment.

The Psychological Impact of Pubertal Events (p. 205)

What factors influence adolescents' reactions to the physical changes of puberty?

- Puberty is not a biologically determined period of storm and stress. Adjustment varies widely and is a product of biological, psychological, and social forces.

© ISRAEL IMAGES/ALAMY

- Girls generally react to menarche with mixed emotions, although those who receive advance information and support from family members respond more positively. Boys, who receive less social support than girls for the physical changes of puberty, react to spermarche with mixed feelings.
- Besides higher pubertal hormone levels, negative life events, sleep loss, and adult-structured situations are associated with adolescents' negative moods. Psychological distancing between parent and child at puberty may be a modern substitute for physical departure from the family, which typically occurs at puberty in primate species. Parent–adolescent conflict also reflects teenagers' new powers of reasoning and efforts by their parents to protect teenagers from risky situations.

Describe the impact of pubertal timing on adolescent adjustment, noting sex differences.

- Early-maturing boys and late-maturing girls have a more positive **body image** and usually adjust well in adolescence. In contrast, early-maturing girls and late-maturing boys experience emotional and social difficulties, which—for girls—persist into young adulthood.

Puberty and Adolescent Health (p. 210)

What factors contribute to eating disorders in adolescence?

- Girls who reach puberty early, who are dissatisfied with their body image, and who grow up in families where thinness is emphasized are at risk for eating disorders. Heredity seems to make some adolescents more susceptible.
- **Anorexia nervosa** typically affects girls who are perfectionists and have overprotective, controlling mothers and emotionally distant fathers. **Bulimia nervosa** is often associated with lack of self-control and disengaged parenting.

Discuss cultural, social, and personal influences on adolescent sexual attitudes and behavior.

- North American attitudes toward adolescent sex are relatively restrictive, and parents and the mass media deliver contradictory messages. Over the past 40 years, sexual attitudes and behavior of adolescents have become more liberal.
- Early, frequent sexual activity is linked to factors associated with economic disadvantage, including weak parental monitoring and hazardous neighborhoods. Many sexually active teenagers do not practice contraception consistently. Adolescent cognitive processes and weak social supports for responsible sexual behavior, including access to birth control, underlie this failure to take precautions against pregnancy.

Cite factors involved in the development of homosexuality.

- Biological factors, including heredity and prenatal hormone levels, play an important role in homosexuality. Lesbian, gay, and bisexual teenagers face special challenges in establishing a positive sexual identity.

Discuss factors related to sexually transmitted disease and teenage pregnancy and parenthood, noting prevention and intervention strategies.

- Early sexual activity, combined with inconsistent contraceptive use, results in high rates of sexually transmitted diseases (STDs) among U.S. teenagers.

© RICHARD HUTCHINGS/PHOTOEDIT

- Life conditions linked to poverty, along with personal attributes, contribute to adolescent childbearing. Teenage parenthood is associated with school dropout, reduced chances of marriage, greater likelihood of divorce, and long-term economic disadvantage.
- Effective sex education, access to contraceptives, and programs that build academic and social competence help prevent early pregnancy. Young mothers need school programs that provide job training, instruction in parenting and life-management skills, and child care. They also benefit from positive family relationships and from home visiting programs that provide intensive social support. When teenage fathers stay involved, children develop more favorably.

Cognitive Development: Piagetian, Core Knowledge, and Vygotskian Perspectives

Leslie, a preschool teacher, paused to look around her class of busy 3- and 4-year-olds. "Their minds are such a curious blend of logic, fantasy, and faulty reasoning," she remarked to a visiting parent. "Every day, I'm startled by the maturity and originality of what they say and do. Yet at other times, their thinking seems limited and inflexible."

Leslie's comments sum up the puzzling contradictions of young children's thought. Hearing a loud thunderclap outside, 3-year-old Sammy exclaimed, "A magic man turned on the thunder!" Even after Leslie explained that thunder is caused by lightning, not by a person turning it on or off, Sammy persisted: "Then a magic lady did it."

In other respects, Sammy's thinking was surprisingly advanced. He could name, categorize, and identify similarities and differences among dozens of dinosaurs in his favorite picture books. "Anatosaurus and Tyrannosaurus walk on their back legs," he told the class during group time. "Then they can use their front legs to pick up food!" But at the snack table, while watching Priti pour her milk from a short, wide carton into a tall, thin glass, Sammy looked at his own identical carton and asked, "How come you got lots of milk, and I only got this little bit?" He did not realize that he had just as much—that his carton, though shorter than Priti's glass, was also wider.

Cognition refers to the inner processes and products of the mind that lead to "knowing." It includes all mental activity—attending, remembering, symbolizing, categorizing, planning, reasoning, problem solving, creating, and fantasizing. Indeed, mental processes make their way into virtually everything human beings do. To adapt to changing environmental conditions, other species benefit from camouflage, feathers or fur coats, and remarkable speed. Humans, in contrast, rely on thinking, not only adapting to their environments but also transforming them. Our extraordinary mental capacities are crucial for our survival.

This chapter and the two that follow examine cognitive development: how the intellectual capacities of infants change into the capacities of the child, adolescent, and adult. Researchers studying cognitive development address three main issues:

- They chart its *typical course,* identifying transformations that most children undergo from birth to maturity. They ask: Do all aspects of cognition develop uniformly, or do some develop at faster rates than others?
- They examine *individual differences*. At every age, some children think more or less maturely, and differently, than others. Chapters 6 and 7 focus primarily on the general course of cognitive development, Chapter 8 on individual differences. But we will encounter both concerns in all three chapters.
- They uncover the *mechanisms* of cognitive development—how genetic and environmental factors combine to yield patterns of change.

In this chapter, we address three distinct perspectives on how cognitive development occurs. Two, *Piaget's cognitive-developmental theory* and the *core knowledge perspective,*

have a biological emphasis. The third, *Vygotsky's sociocultural theory,* stresses social and cultural contributions to children's thinking.

In considering each of these views, we will see that children move from simpler to more complex cognitive skills, becoming more effective thinkers with age. But children's immature capacities are not merely incomplete, less effective versions of adults'. For children, focusing on a limited amount of information may be adaptive (Bjorklund, 2012). For example, noticing only a few features of an intricate pattern probably protects against overstimulation in young babies. And comparing the amounts of milk in a short, wide carton and a tall, thin glass by attending only to height, not width, may allow preschoolers to develop a thorough grasp of height, in preparation for effectively integrating height with other dimensions.

The adaptiveness of cognitive immaturity has important implications for education. It suggests that hurrying children to higher levels may undermine their progress. Piaget was among the first theorists to stress the importance of *readiness* to learn—presenting appropriately challenging tasks while avoiding overly complex stimulation that may confuse and overwhelm children. Let's begin with Piaget's theory. ■

▶ According to Piaget, how does cognition develop?

Piaget's Cognitive-Developmental Theory

Swiss cognitive theorist Jean Piaget received his education in zoology, and his theory has a distinct biological flavor. According to Piaget, human infants do not start out as cognitive beings. Instead, out of their perceptual and motor activities, they build and refine psychological structures—organized ways of making sense of experience that permit them to adapt more effectively to the environment. Children develop these structures actively, using current structures to select and interpret experiences, and modifying those structures to take into account more subtle aspects of reality. Because Piaget viewed children as discovering, or *constructing*, virtually all knowledge about their world through their own activity, his theory is described as a **constructivist approach** to cognitive development.

Basic Characteristics of Piaget's Stages

Piaget believed that children move through four stages—sensorimotor, preoperational, concrete operational, and formal operational—during which infants' exploratory behaviors transform into the abstract, logical intelligence of adolescence and adulthood. Piaget's stage sequence has three important characteristics:

- The stages provide a *general theory* of development, in which all aspects of cognition change in an integrated fashion, following a similar course.
- The stages are *invariant;* they always occur in a fixed order, and no stage can be skipped.
- The stages are *universal;* they are assumed to characterize children everywhere. (Piaget, Inhelder, & Szeminska, 1948/1960)

Piaget regarded the order of development as rooted in the biology of the human brain. But he emphasized that individual differences in genetic and environmental factors affect the speed with which children move through the stages (Piaget, 1926/1928). Let's consider some of Piaget's central concepts.

Piaget's Ideas About Cognitive Change

According to Piaget, specific psychological structures called **schemes**—organized ways of making sense of experience—change with age. At first, schemes are sensorimotor action patterns. Watch a 6-month-old baby catch sight of, grasp, and release objects. Her "dropping scheme" is fairly rigid—she simply lets go of a rattle or teething ring. By 18 months, her dropping scheme has become deliberate and creative. Given an opportunity, she might toss all sorts of objects down the basement stairs, throwing some up in the air, bouncing others off walls, releasing some gently and others forcefully.

Soon, instead of just acting on objects, the toddler shows evidence of thinking before she acts. For Piaget, this change marks the transition from a sensorimotor approach to the world to a cognitive approach based on **mental representations**—internal depictions of information that the mind can manipulate. Our most powerful mental representations are *images*—mental pictures of objects, people, and spaces—and *concepts,* categories in which similar objects or events are grouped together. We use a mental image to retrace our steps when we've misplaced something or to imitate another's behavior long after observing it. By thinking in concepts and labeling them (for example, *ball* for all rounded, movable objects used in play), we become more efficient thinkers, organizing our diverse experiences into meaningful, manageable, and memorable units.

In Piaget's theory, two processes account for this change from sensorimotor to representational schemes and for further changes in representational schemes from childhood to adulthood: *adaptation* and *organization.*

© LAURA DWIGHT PHOTOGRAPHY

In Piaget's theory, the baby's first schemes are sensorimotor action patterns. As this 11-month-old experiments with her dropping scheme, her behavior becomes more deliberate and varied.

Adaptation

TAKE A MOMENT... The next time you have a chance, notice how young children tirelessly repeat actions that lead to interesting effects. They are illustrating a key Piagetian concept. **Adaptation** involves building schemes through direct interaction with the environment. It consists of two complementary activities: *assimilation* and *accommodation.* During **assimilation,** we use our current schemes to interpret the external world. The infant who repeatedly drops objects is assimilating them into his sensorimotor "dropping scheme." And the preschooler who, seeing a camel at the zoo, calls out, "Horse!" has sifted through her conceptual schemes until she finds one that resembles the strange-looking creature. In **accommodation,** we create new schemes or adjust old ones after noticing that our current way of thinking does not capture the environment completely. The baby who drops objects in different ways is modifying his dropping scheme to take account of the varied properties of objects. And the preschooler who calls a camel a "lumpy horse" has noticed that camels differ from horses in certain ways and has revised her scheme accordingly.

According to Piaget, the balance between assimilation and accommodation varies over time. When children are not changing much, they assimilate more than they accommodate—a steady, comfortable state that Piaget called cognitive *equilibrium.* During times of rapid cognitive change, children are in a state of *disequilibrium,* or cognitive discomfort. Realizing that new information does not match their current schemes, they shift from assimilation to accommodation. After modifying their schemes, they move back toward assimilation, exercising their newly changed structures until they are ready to be modified again.

Piaget's term for this back-and-forth movement between equilibrium and disequilibrium is **equilibration.** Each time equilibration occurs, more effective schemes are produced. Because the times of greatest accommodation are the earliest ones, the sensorimotor stage is Piaget's most complex period of development.

Organization

Schemes also change through **organization,** a process that occurs internally, apart from direct contact with the environment. Once children form new schemes, they rearrange them, linking them with other schemes to create a strongly interconnected cognitive system. For example, eventually the baby relates "dropping" to "throwing" and to his developing understanding of "nearness" and "farness." According to Piaget, schemes truly reach equilibrium when they become part of a broad network of structures that can be jointly applied to the surrounding world (Piaget, 1936/1952).

In the following sections, we begin by considering development as Piaget saw it, noting research that supports his observations. Then, for each stage, we look at more recent evidence, some inspired by Piaget's theory and some that challenges his ideas.

- Describe major cognitive attainments of Piaget's sensorimotor stage.
- What does follow-up research reveal about infant cognitive development and the accuracy of Piaget's sensorimotor stage?

The Sensorimotor Stage: Birth to 2 Years

The **sensorimotor stage** spans the first two years of life. Its name reflects Piaget's belief that infants and toddlers "think" with their eyes, ears, hands, and other sensorimotor equipment. They cannot yet carry out many activities mentally. Yet the advances of the sensorimotor stage are so vast that Piaget divided it into six substages, summarized in Table 6.1. Piaget based this sequence on a very small sample: his own three children. He observed his son and two daughters carefully and presented them with everyday problems (such as hidden objects) that helped reveal their understanding of the world.

According to Piaget, at birth infants know so little that they cannot explore purposefully. The **circular reaction** provides a special means of adapting their first schemes. It involves stumbling onto a new experience caused by the baby's own motor activity. The reaction is "circular" because, as the infant tries to repeat the event again and again, a sensorimotor response that originally occurred by chance strengthens into a new scheme. Imagine a 2-month-old who accidentally makes a smacking noise after a feeding. Finding the sound intriguing, the baby tries to repeat it until she becomes quite expert at smacking her lips.

The circular reaction initially centers on the infant's own body but later turns outward, toward manipulation of objects. In the second year, it becomes experimental and creative, aimed at producing novel effects in the environment. Infants' difficulty inhibiting new and interesting behaviors may underlie the circular reaction. This immaturity in inhibition seems to be adaptive, helping to ensure that new skills will not be interrupted before they strengthen (Carey & Markman, 1999). Piaget considered revisions in the circular reaction so important that, as Table 6.1 shows, he named the sensorimotor substages after them.

Sensorimotor Development

Piaget saw newborn reflexes as the building blocks of sensorimotor intelligence. In Substage 1, babies suck, grasp, and look in much the same way, no matter what experiences they encounter. In one amusing example, a mother described how her 2-week-old daughter lay on the bed next to her sleeping father, who suddenly awoke with a start. The baby had latched on and begun to suck on his back!

Repeating Chance Behaviors

Around 1 month, as babies enter Substage 2, they start to gain voluntary control over their actions through the *primary circular reaction*, by repeating chance behaviors largely motivated by basic needs. This leads to some simple motor habits, such as sucking the fist or thumb. Babies in this substage also begin to vary their

TABLE 6.1 Summary of Piaget's Sensorimotor Stage

SENSORIMOTOR SUBSTAGE	TYPICAL ADAPTIVE BEHAVIORS
1. Reflexive schemes (birth–1 month)	Newborn reflexes (see Chapter 4, page 130)
2. Primary circular reactions (1–4 months)	Simple motor habits centered around the infant's own body; limited anticipation of events
3. Secondary circular reactions (4–8 months)	Actions aimed at repeating interesting effects in the surrounding world; imitation of familiar behaviors
4. Coordination of secondary circular reactions (8–12 months)	Intentional, or goal-directed, behavior; ability to find a hidden object in the first location in which it is hidden (object permanence); improved anticipation of events; imitation of behaviors slightly different from those the infant usually performs
5. Tertiary circular reactions (12–18 months)	Exploration of the properties of objects by acting on them in novel ways; imitation of novel behaviors; ability to search in several locations for a hidden object (accurate A–B search)
6. Mental representation (18 months–2 years)	Internal depictions of objects and events, as indicated by sudden solutions to problems; ability to find an object that has been moved while out of sight (invisible displacement); deferred imitation; and make-believe play

behavior in response to environmental demands. For example, they open their mouths differently for a nipple than for a spoon. And they start to anticipate events: A hungry 3-month-old is likely to stop crying as soon as his mother enters the room—a signal that feeding time is near.

During Substage 3, from 4 to 8 months, infants sit up and become skilled at reaching for and manipulating objects—motor achievements that strengthen the *secondary circular reaction,* through which they try to repeat interesting events in the surrounding environment that are caused by their own actions. For example, Piaget (1936/1952) dangled several dolls in front of his 4-month-old son, Laurent. After accidentally knocking them and producing a fascinating swinging motion, Laurent gradually built the sensorimotor scheme of "hitting." Improved control over their own behavior also permits infants to imitate others' behavior more effectively. However, 4- to 8-month-olds cannot adapt flexibly and quickly enough to imitate novel behaviors (Kaye & Marcus, 1981). Although they enjoy watching an adult demonstrate a game of pat-a-cake, they are not yet able to participate.

© M. DOMINIK/ZEFA/CORBIS

Seeing his hands touch, open, and close, a 3-month-old tries to repeat the movements. This primary circular reaction helps him gain voluntary control over his actions.

Intentional Behavior In Substage 4, 8- to 12-month-olds combine schemes into new, more complex action sequences. Now, behaviors leading to new schemes no longer have a random, hit-or-miss quality—*accidentally* bringing the thumb to the mouth or *happening* to hit the doll. Instead, 8- to 12-month-olds can engage in **intentional,** or **goal-directed, behavior,** coordinating schemes deliberately to solve simple problems. The clearest example comes from Piaget's famous object-hiding task, in which he shows the baby an attractive toy and then hides it behind his hand or under a cover. Infants in this substage can find the object by coordinating two schemes—"pushing" aside the obstacle and "grasping" the toy. Piaget regarded these *means–end action sequences* as the foundation for all problem solving.

Retrieving hidden objects is evidence that infants have begun to master **object permanence,** the understanding that objects continue to exist when they are out of sight. But this awareness is not yet complete. Babies still make the **A-not-B search error:** If they reach several times for an object at one hiding place (A), then see it moved to another (B), they still search for it in the first hiding place (A). Piaget concluded that the babies do not yet have a clear image of the object as persisting when hidden from view.

Infants in Substage 4, who can better anticipate events, sometimes use their capacity for intentional behavior to try to change those events. A 10-month-old might crawl after his mother when she is putting on her coat, whimpering to keep her from leaving. Also, babies can imitate behaviors slightly different from those they usually perform. After watching someone else, they try to stir with a spoon, push a toy car, or drop raisins into a cup (Piaget, 1945/1951).

In Substage 5, the *tertiary circular reaction,* in which toddlers repeat behaviors with variation, emerges. Recall the example on page 227 of the child dropping objects over the basement steps in diverse ways. This deliberately exploratory approach makes 12- to 18-month-olds better problem solvers. For example, they can figure out how to fit a shape through a hole in a container by turning and twisting it, and they can use a stick to obtain a toy that is out of reach. According to Piaget, this capacity to experiment leads to a more advanced understanding of object permanence. Toddlers look for a hidden toy in more than one location, displaying an accurate A–B search. Their more flexible action patterns also permit them to imitate many more behaviors—stacking blocks, scribbling on paper, and making funny faces.

© CREASOURCE/CORBIS

After accidentally batting the dangling fish, this 4-month-old tries to recapture the fascinating swinging motion, in a secondary circular reaction.

© LAURA DWIGHT/PHOTOEDIT

To find the toy hidden under the cloth, a 10-month-old engages in intentional, goal-directed behavior—the basis for all problem solving.

© MYRLEEN FERGUSON CATE/PHOTOEDIT

Using the tertiary circular reaction, this baby takes a deliberately exploratory approach to problem solving, twisting and turning a block until it fits through its matching hole.

© ELLEN B. SENISI PHOTOGRAPHY

The capacity for mental representation enables this 2-year-old to engage in make-believe play. As pretending expands in early childhood, mental symbols become major instruments of thinking.

Mental Representation

In Substage 6, sensorimotor development culminates in mental representation. One sign of this capacity is that 18- to 24-month-olds arrive at solutions to problems suddenly rather than through trial-and-error behavior, apparently experimenting with actions inside their heads. Seeing her doll carriage stuck against the wall, Piaget's daughter Lucienne paused for a moment, as if to "think," then immediately turned the toy in a new direction.

Representation also enables older toddlers to solve advanced object-permanence problems involving *invisible displacement*—finding a toy moved while out of sight, such as into a small box while under a cover. Second, it permits **deferred imitation**—the ability to remember and copy the behavior of models who are not present. And it makes possible **make-believe play,** in which children act out everyday and imaginary activities. As the sensorimotor stage draws to a close, mental symbols have become major instruments of thinking.

Follow-Up Research on Infant Cognitive Development

Many studies suggest that infants display a variety of understandings earlier than Piaget believed. Recall the operant conditioning research reviewed in Chapter 4, in which newborns sucked vigorously on a nipple to gain access to interesting sights and sounds. This behavior, which closely resembles Piaget's secondary circular reaction, shows that infants explore and control their external world long before 4 to 8 months. In fact, they do so as soon as they are born.

To discover what infants know about hidden objects and other aspects of physical reality, researchers often use the **violation-of-expectation method.** They may *habituate* babies to a physical event (expose them to the event until their looking declines) to familiarize them with a situation in which their knowledge will be tested. Or they may simply show babies an *expected event* (one that follows physical laws) and an *unexpected event* (a variation of the first event that violates physical laws). Heightened attention to the unexpected event suggests that the infant is "surprised" by a deviation from physical reality—and, therefore, is aware of that aspect of the physical world.

The violation-of-expectation method is controversial. Some critics believe that it indicates limited, implicit (nonconscious) awareness of physical events—not the full-blown, conscious understanding that was Piaget's focus in requiring infants to act on their surroundings, as in searching for hidden objects (Campos et al., 2008; Munakata, 2001; Thelen & Smith, 1994). Others maintain that the method reveals only babies' perceptual preference for novelty, not their knowledge of the physical world (Bremner, 2010; Cohen, 2010; Hood, 2004; Kagan, 2008). Let's examine this debate in light of recent research on object permanence.

Object Permanence

In a series of studies using the violation-of-expectation method, Renée Baillargeon and her collaborators claimed to have found evidence for object permanence in the first few months of life. Figure 6.1 illustrates one of these studies (Aguiar & Baillargeon, 2002; Baillargeon & DeVos, 1991). After habituating to a short and a tall carrot moving behind a screen, babies were given two test events: (1) an *expected event,* in which the short carrot moved behind a screen, could not be seen in its window, and reappeared on the other side, and (2) an *unexpected event,* in which the tall carrot moved behind a screen, could not be seen in its window (although it was taller than the window's lower edge), and reappeared. Infants as young as 2½ to 3½ months looked longer at the unexpected event, suggesting that they had some awareness that an object moved behind a screen would continue to exist.

Additional violation-of-expectation studies yielded similar results (Baillargeon, 2004; Wang, Baillargeon, & Paterson, 2005). But several researchers using similar procedures failed to confirm some of Baillargeon's findings (Bogartz, Shinskey, & Schilling, 2000; Cashon & Cohen, 2000; Cohen & Marks, 2002; Rivera, Wakeley, & Langer, 1999). Baillargeon and others maintain that these opposing investigations did not include crucial controls. And they emphasize that infants look longer at a wide variety of unexpected events involving hidden objects (Newcombe, Sluzenski, & Huttenlocher, 2005; Wang, Baillargeon, & Paterson, 2005). Still, critics question what babies' looking preferences tell us about what they actually know.

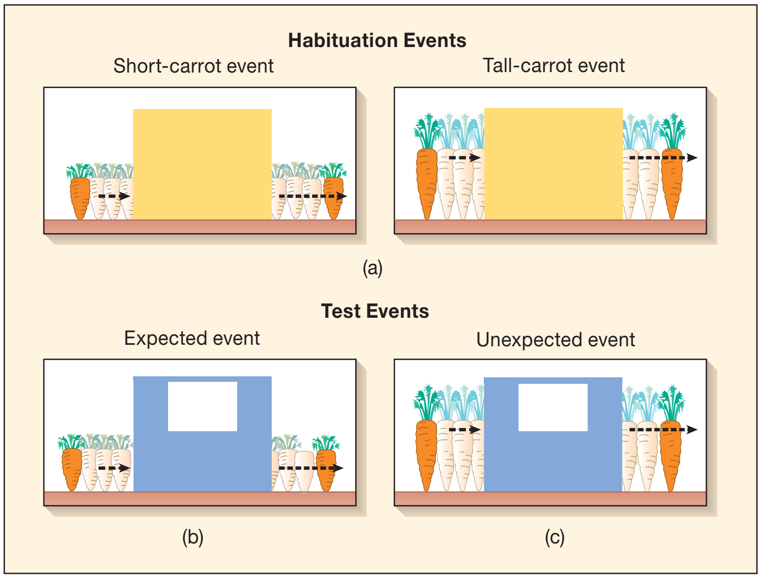

FIGURE 6.1 Testing young infants for understanding of object permanence using the violation-of-expectation method. (a) First, infants were habituated to two events: a short carrot and a tall carrot moving behind a yellow screen, on alternate trials. Next, the researchers presented two test events. The color of the screen was changed to help infants notice its window. (b) In the *expected event,* the carrot shorter than the window's lower edge moved behind the blue screen and reappeared on the other side. (c) In the *unexpected event,* the carrot taller than the window's lower edge moved behind the screen, did not appear in the window, but then emerged intact on the other side. Infants as young as 2½ to 3½ months looked longer at the *unexpected event,* suggesting that they had some understanding of object permanence. (Adapted from R. Baillargeon & J. DeVos, 1991, "Object Permanence in Young Infants: Further Evidence," *Child Development, 62,* p. 1230. © 1991, John Wiley and Sons. Adapted with permission of John Wiley and Sons.)

But recall from Chapter 4 that 4- and 5-month-olds will track a ball's path of movement as it disappears and reappears from behind a barrier, even gazing ahead to where they expect it to emerge—a behavior suggesting awareness that objects persist when out of view. As further support for such awareness, 5- to 9-month-olds more often engaged in such predictive tracking when a ball viewed on a computer screen gradually rolled behind a barrier than when it disappeared instantaneously or imploded (rapidly decreased in size) at the barrier's edge (see Figure 6.2 on page 232) (Bertenthal, Longo, & Kenny, 2007). Babies seemed to interpret a ball rolling behind a barrier as continued existence, instantaneous disappearance or implosion as disappearance (or at least a discontinuous path of movement).

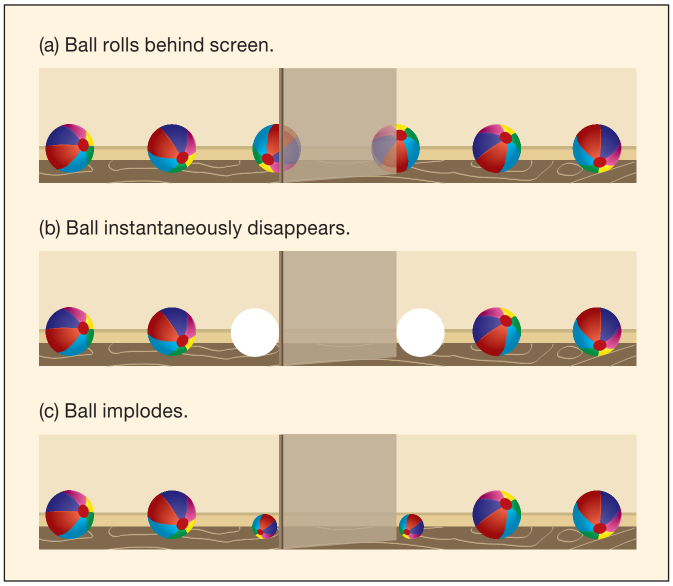
In related research, 6-month-olds' ERP brain-wave activity was recorded as they watched two events on a computer screen. In one event, a black square moved until it covered an object, then moved away to reveal the object (object permanence). In the other event, as a black square began to move across an object, the object disintegrated (object disappearance) (Kaufman, Csibra, & Johnson, 2005). Only while watching the first event did the infants display a particular brain-wave pattern in the right temporal lobe—the same pattern adults exhibit when told to sustain a mental image of an object.

If young infants do have some notion of object permanence, how do we explain Piaget's finding that even infants capable of reaching do not try to search for hidden objects before 8 months of age? Violation-of-expectation tasks require only that the baby react (through looking) to whether a post-object-hiding scene accords with ordinary experience. Searching for a hidden object is far more cognitively demanding: The baby must *predict* where the hidden object is. Consistent with this idea, infants solve some object-hiding tasks before others: Eight- to 10-month-olds remove the cover from a partially hidden object before they are able to do so from a fully covered object (Moore & Meltzoff, 2008). And 10-month olds search for an object placed on a table and covered by a cloth before they search for an object that a hand deposits under a cloth (Moore & Meltzoff, 1999). In the second, more difficult task, infants seem to expect the object to reappear in the hand because that is where the object initially disappeared. When the hand emerges without the object, they conclude that there is no other place the object could be. Not until 14 months can most babies infer that the hand deposited the object under the cloth.

Around this age, toddlers also know that objects continue to exist in their hidden locations after the babies have left the location. After seeing an object hidden in a cupboard, when toddlers returned the next day, they correctly searched for the object in its original location (Moore & Meltzoff, 2004). When exposed to a similar cupboard in a new room, the toddlers behaved as adults do: They saw no reason to search.

LOOK and LISTEN

Using an attractive toy and cloth, try several object-hiding tasks with 8- to 14-month-olds. Is their search behavior consistent with research findings?



(a) Ball rolls behind screen.
(b) Ball instantaneously disappears.
(c) Ball implodes.

FIGURE 6.2 Testing 5- to 9-month-olds for understanding of object permanence using predictive eye tracking. When a ball viewed on a computer screen rolled behind a barrier (a), 5- to 9-month-olds engaged in predictive tracking—gazing ahead to the edge of the screen where they expected the ball to emerge. Babies were much less likely to predictively track when (b) a ball instantaneously disappeared on reaching the location of the first white circle and abruptly reappeared at the location of the second white circle or (c) a ball imploded—rapidly decreased in size—as it approached the barrier's edge, then rapidly increased in size as it reappeared on the other side. These findings suggest that by the middle of the first year, babies interpret a ball rolling behind a barrier as continuing to exist. (Adapted from Bertenthal, Longo, & Kenny, 2007.)

Searching for Objects Hidden in More Than One Location Once 8- to 12-month-olds search for hidden objects, they make the A-not-B search error. For some years, researchers thought that infants make this mistake because they have trouble remembering an object's new location after it has been hidden in more than one place. But many studies indicate that poor memory cannot account for infants' unsuccessful performance. For example, between 6 and 12 months, infants increasingly *look* at the correct location, even while *reaching* incorrectly (Ahmed & Ruffman, 1998; Hofstadter & Reznick, 1996).

Some evidence suggests that 8- to 12-month-olds search at A (where they found the object on previous reaches) instead of B (its most recent location) because they have trouble inhibiting a previously rewarded motor response (Diamond, Cruttenden, & Neiderman, 1994). In support of this view, the more prior reaches to A, the greater the likelihood that the infant will reach again toward A when the object is hidden at B. Another possibility is that after finding the object several times at A, babies do not attend closely when it is hidden at B (Ruffman & Langman, 2002).

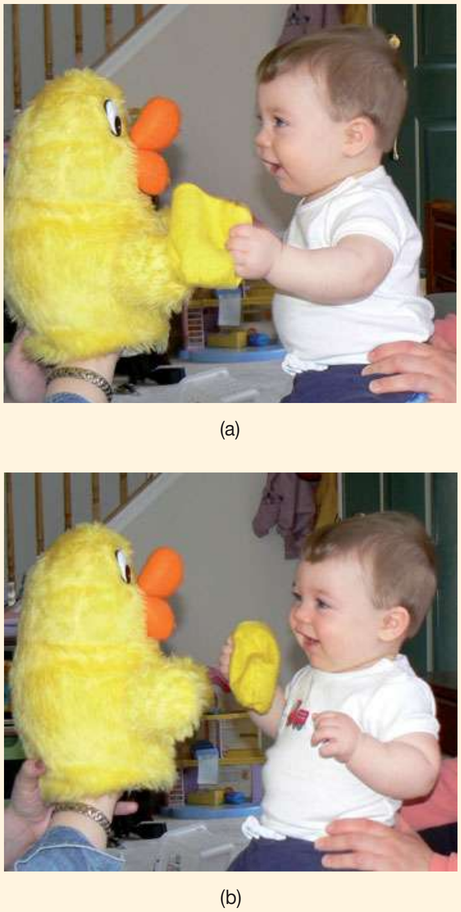
A more comprehensive explanation is that a complex, dynamic system of factors—having built a habit of reaching toward A, continuing to look at A, having the hiding place at B appear similar to the one at A, and maintaining a constant body posture—increases the chances that the baby will make the A-not-B search error. Disrupting any one of these factors increases accurate searching at B (Thelen et al., 2001). Adult communicative cues are an added influence—eye contact, smiling, speech ("Look here!"), and pointing after repeatedly hiding at A, which bias the baby to search A (Topál et al., 2008). When these cues are removed, the A-not-B error is reduced. Furthermore, infant expertise at the motor skills required by the search task is vital (Berger, 2010). Older infants are still perfecting reaching and grasping (see Chapter 4). If these skills are challenging, they have little attention left to focus on inhibiting their habitual reach toward A.

In sum, mastery of object permanence is a gradual achievement. Babies' understanding becomes increasingly complex with age: They must perceive an object's identity by integrating feature and movement information (see Chapter 4, page 165), distinguish the object from the barrier concealing it and the surface on which it rests, keep track of the object's whereabouts, and use this knowledge to obtain the object (Cohen & Cashon, 2006; Moore & Meltzoff, 2008). Success at simple object search and A–B search tasks coincides with rapid development of the frontal lobes of the cerebral cortex (Bell, 1998). Also crucial are a wide variety of experiences perceiving, acting on, and remembering objects.

Mental Representation In Piaget's theory, before about 18 months, infants are unable to mentally represent experience. Yet 8- to 10-month-olds' ability to recall the location of hidden objects after delays of more than a minute, and 14-month olds' recall after delays of a day or more, indicate that babies construct mental representations of objects and their whereabouts (McDonough, 1999; Moore & Meltzoff, 2004). And in studies of deferred imitation, categorization, and problem solving, representational thought is evident even earlier.

Deferred and Inferred Imitation. Piaget studied imitation by noting when his three children demonstrated it in their everyday behavior. Under these conditions, a great deal must be known about the infant's daily life to be sure that deferred imitation—which requires infants to represent a model's past behavior—has occurred.

Laboratory research suggests that deferred imitation is present at 6 weeks of age! Infants who watched an unfamiliar adult's facial expression imitated it when exposed to the same adult the next day (Meltzoff & Moore, 1994). As motor capacities improve, infants copy actions with objects. In one study, adults showed 6- and 9-month-olds a novel series of actions with a puppet: taking its glove off, shaking the glove to ring a bell inside, and replacing the glove. When tested a day later, infants who had seen the novel actions were far more likely to imitate them (see Figure 6.3). And when researchers paired a second, motionless puppet with the first puppet a day before the demonstration, 6-month-olds generalized the actions to this new, very different-looking puppet (Barr, Marrott, & Rovee-Collier, 2003). Even more impressive, after having seen Puppet A paired with B and Puppet B paired with C on successive days, infants transferred modeled actions from A to C and from C to A, though they had not directly observed this pair together (Townsend & Rovee-Collier, 2007). Already, infants can form flexible mental representations that include chains of relevant associations.



COURTESY OF CAROLYN ROVEE-COLLIER

FIGURE 6.3 Testing infants for deferred imitation. After researchers performed a novel series of actions with a puppet, this 6-month-old imitated the actions a day later—(a) removing the glove; (b) shaking the glove to ring a bell inside. With age, gains in recall are evident in deferred imitation of others' behavior over longer delays.

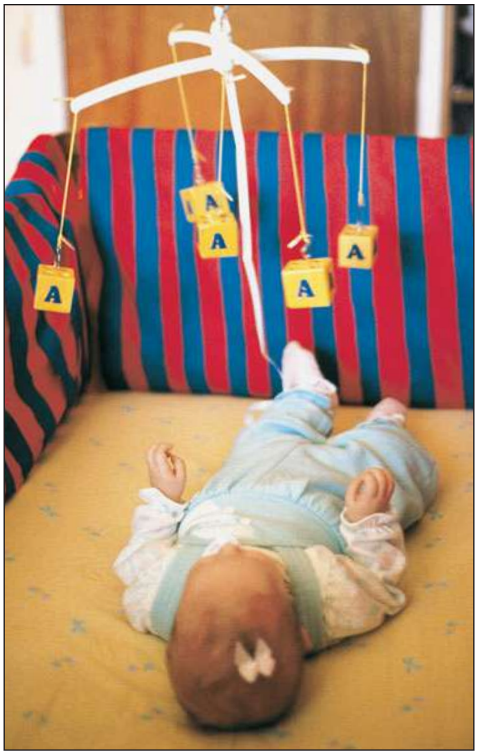
Gains in recall, expressed through deferred imitation, are accompanied by changes in brain-wave activity during memory tasks. This suggests that improvements in memory storage in the cerebral cortex contribute to these advances (Bauer et al., 2006). Between 12 and 18 months, toddlers use deferred imitation skillfully to enrich their range of schemes. They retain modeled behaviors for at least several months, copy the actions of peers as well as adults, and imitate across a change in context—for example, enact at home a behavior seen at child care (Klein & Meltzoff, 1999; Meltzoff & Williamson, 2010). The ability to recall modeled behaviors in the order they occurred—evident as early as 6 months—also strengthens over the second year (Bauer, 2006; Rovee-Collier & Cuevas, 2009). And when toddlers imitate in correct sequence, they remember more behaviors (Knopf, Kraus, & Kressley-Mba, 2006).

Toddlers even imitate rationally, by *inferring* others' intentions! They are more likely to imitate purposeful than accidental behaviors (Carpenter, Akhtar, & Tomasello, 1998a). And they adapt their imitative acts to a model's goals. If 12-month-olds see an adult perform an unusual action for fun (make a toy dog enter a miniature house by jumping through the chimney, even though its door is wide open), they copy the behavior. But if the adult engages in the odd behavior because she *must* (she makes the dog go through the chimney only after first trying to use the door and finding it locked), 12-month-olds typically imitate the more efficient action (putting the dog through the door) (Schwier et al., 2006; see also Gergely, Bekkering, & Király, 2003).

Between 14 and 18 months, toddlers become increasingly adept at imitating actions an adult *tries* to produce, even if these are not fully realized (Bellagamba, Camaioni, & Colonnesi, 2006; Meltzoff, 1995; Olineck & Poulin-Dubois, 2007). On one occasion, a mother attempted to pour some raisins into a bag but missed, spilling them onto the counter. A moment later, her 18-month-old son climbed onto a stool and began dropping the raisins into the bag, indicating that he had inferred his mother's intention and used it to guide his imitative actions (Falck-Ytter, Gredebäck, & von Hofsten, 2006). By age 2, children mimic entire social roles—Mommy, Daddy, baby—during make-believe play.

Though advanced in terms of Piaget's predictions, toddlers' ability to represent others' intentions—a cornerstone of social understanding and communication—seems to have roots in earlier sensorimotor activity. Infants' skill at engaging in goal-directed actions—reaching for objects at 3 to 4 months, pointing to objects at 9 months—predicts their awareness of an adult's similar behavior as goal-directed in a violation-of-expectation task (Gerson & Woodward, 2010; Woodward, 2009). And the better 10-month-olds are at detecting the goals of others' gazes and reaches, the more accurately they infer an adult's intention from her incomplete actions four months later (Olineck & Poulin-Dubois, 2009).

Categorization. Even young infants can *categorize,* grouping similar objects and events into a single representation—an ability that is incompatible with a strictly sensorimotor approach to the world. Categorization reduces the enormous amount of new information infants encounter every day, helping them learn and remember (Rakison, 2010).



COURTESY OF DR. CAROLYN ROVEE-COLLIER

FIGURE 6.4 **Investigating infant categorization using operant conditioning.** Three-month-olds were taught to kick to move a mobile made of small blocks, all with the letter *A* on them. After a delay, kicking returned to a high level only if the babies were shown a mobile whose elements were labeled with the same form (the letter *A*). If the form was changed (from *A*s to *2*s), infants no longer kicked vigorously. While making the mobile move, the babies had grouped together its features. They associated the kicking response with the category *A* and, at later testing, distinguished it from the category *2*. (Bhatt, Rovee-Collier, & Weiner, 1994; Hayne, Rovee-Collier, & Perris, 1987.)

Recall the operant conditioning research in which infants kicked to move a mobile attached to their foot by a long cord (see Chapter 4, page 141). Figure 6.4 illustrates a creative variation of this task, used to investigate infant categorization. Similar studies reveal that in the first few months, babies categorize stimuli on the basis of shape, size, and other physical properties (Wasserman & Rovee-Collier, 2001). By 6 months of age, they can categorize on the basis of two correlated features—for example, the shape and color of the alphabet letter (Bhatt et al., 2004). This ability to categorize using clusters of features prepares babies for acquiring many complex everyday categories.

Habituation has also been used to study infant categorization. Researchers show babies a series of pictures belonging to one category and then see whether they recover to (look longer at) a picture that is not a member of the category (see Figure 6.5). Findings reveal that in the second half of the first year, infants group objects into an impressive array of categories—food items, furniture, birds, land animals, air animals, sea animals, plants, vehicles, kitchen utensils, and spatial location ("above" and "below," "on" and "in") (Bornstein, Arterberry, & Mash, 2010; Casasola, Cohen, & Chiarello, 2003; Oakes, Coppage, & Dingel, 1997). Besides organizing the physical world, infants of this age categorize their emotional and social worlds. They sort people and their voices by gender and age, have begun to distinguish emotional expressions, can separate people's natural actions (walking) from other motions, and expect people (but not inanimate objects) to move spontaneously (Spelke, Phillips, & Woodward, 1995; see also Chapter 4, page 163).

Babies' earliest categories are based on similar overall appearance or prominent object part: legs for animals, wheels for vehicles. By the second half of the first year, more categories appear to be based on subtle sets of features (Cohen, 2003; Mandler, 2004a; Quinn, 2008). Older infants can even make categorical distinctions when the perceptual contrast between two categories is minimal (birds versus airplanes).

As they gain experience in comparing to-be-categorized items in varied ways and as their store of verbal labels expands, toddlers start to categorize flexibly: When 14-month-olds are given four balls and four blocks, some made of soft rubber and some of rigid plastic, their sequence of object touching reveals that after classifying by shape, they can switch to classifying by material (soft versus hard) if an adult calls their attention to the new basis for grouping (Ellis & Oakes, 2006).

In addition to touching and sorting, toddlers' categorization skills are evident in their play behaviors. After watching an adult give a toy dog a drink from a cup, most 14-month-olds shown a rabbit and a motorcycle offered the drink only to the rabbit (Mandler & McDonough, 1998). They clearly understood that certain actions are appropriate for some categories of items (animals) but not others (vehicles).

By the end of the second year, toddlers' grasp of the animate–inanimate distinction expands. Nonlinear motions are typical of animates (a person or a dog jumping), linear motions of inanimates (a car or a table pushed along a surface). At 18 months, toddlers more often imitate a nonlinear motion with a toy that has animate-like parts (legs), even if it represents an inanimate (a bed). At 22 months, displaying a fuller understanding, they imitate a nonlinear motion only with toys in the animate category (a cat but not a bed) (Rakison, 2005, 2006). They seem to realize that whereas animates are self-propelled and therefore have varied paths of movement, inanimates move only when acted on, in highly restricted ways.

Researchers disagree on how babies arrive at these impressive attainments. One view holds that older infants and toddlers categorize more effectively because they become increasingly sensitive to fine-grained perceptual features and to stable relations among these features—for example, objects with flapping wings and feathers belong to one category; objects with rigid wings, windows, and a smooth surface belong to another category (Cohen & Cashon, 2006; Oakes et al., 2009; Rakison & Lupyan, 2008). An alternative view is that before

LOOK and LISTEN

Observe a toddler playing with a variety of small toys—some representing animals and some representing household objects. What play behaviors reveal the child's ability to categorize?

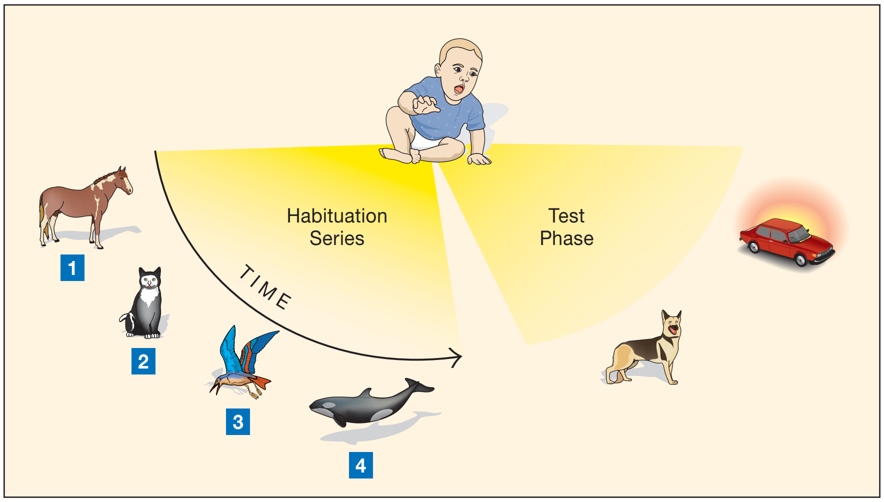


FIGURE 6.5 **Using habituation to study infant categorization.** After habituating to a series of items belonging to one category (in this example, animals), infants are shown two novel items, one that is a member of the category (dog) and one that is not (car). If infants recover to (look longer at or spend more time manipulating) the out-of-category item (car), this indicates that they distinguish it from the set of within-category items (animals). Habituating another group of infants to a series of vehicles and seeing if, when presented with the two test items, they recover to the dog confirms that babies can distinguish animals from vehicles.

the end of the first year, babies undergo a fundamental shift from a perceptual to a conceptual basis for constructing categories, increasingly grouping objects by their common function or behavior (birds versus airplanes, cars versus motorcycles, dogs versus cats) (Mandler, 2004b).

All researchers acknowledge that infants' and toddlers' exploration and expanding knowledge of objects contribute to advances in categorization, eventually enriching conceptual understanding. In addition, adult labeling of a set of objects with a consistently applied word ("Look at the car!" "Do you see the car?") calls babies' attention to commonalities among objects, fostering categorization as early as 3 to 4 months of age (Ferry, Hespos, & Waxman, 2010). Toddlers' vocabulary growth, in turn, enhances categorization by highlighting new categorical distinctions (Cohen & Brunt, 2009; Waxman, 2003).

Variations among languages lead to cultural differences in development of categories. Korean toddlers, who learn a language in which object names are often omitted from sentences, develop object-sorting skills later than their English-speaking counterparts (Gopnik & Choi, 1990). At the same time, Korean contains a common word, *kkita,* with no English equivalent, referring to a tight fit between objects in contact—a ring on a finger, a cap on a pen—and Korean toddlers are advanced in forming the spatial category "tight-fit" (Choi et al., 1999). After English-speaking 18-month-olds heard the word *tight* while observing several instances of objects fitting together tightly, they readily acquired the tight-fit category (Casasola, Bhagwat, & Burke, 2009). Those who viewed the events without the label did not form this challenging category.

Problem Solving. As Piaget indicated, around 7 to 8 months, infants develop intentional means–end action sequences, which they use to solve simple problems, such as pulling on a cloth to obtain a toy resting on its far end (Willatts, 1999). Soon after, infants' representational skills permit more effective problem solving than Piaget's theory suggests.

By 10 to 12 months, infants can engage in **analogical problem solving**—applying a solution strategy from one problem to other relevant problems. In one study, babies of this age were given three similar problems, each requiring them to overcome a barrier, grasp a string, and pull it to get an attractive toy. The problems differed in many aspects of their superficial features—texture and color of the string, barrier, and floor mat and type of toy (horse, doll, or car). For the first problem, the parent demonstrated the solution, encouraging the infant to imitate. Babies obtained the toy more readily with each additional problem (Chen, Sanchez, & Campbell, 1997). Similarly, 12-month-olds who were repeatedly presented with a spoon in the same orientation (handle to one side) readily adapted their motor actions when the spoon was presented in the opposite orientation (handle to the other side), successfully transporting food to their mouths most of the time (McCarty & Keen, 2005).

These findings suggest that at the end of the first year, infants form flexible mental representations of how to use tools to get objects. With age, children become better at reasoning by analogy, generalizing across increasingly dissimilar situations (Goswami, 1996). But even in the first year, infants have some ability to move beyond trial-and-error experimentation, represent a solution mentally, and use it in new contexts.

Symbolic Understanding. One of the most momentous advances in early development is the realization that words can be used to cue mental images of things not physically present—a symbolic capacity called **displaced reference** that emerges around the first birthday. It greatly expands toddlers' capacity to learn about the world through communicating with others.

Observations of 12-month-olds reveal that they respond to the label of an absent toy by looking at and gesturing toward the spot where it usually rests (Saylor, 2004). And on hearing the name of a parent or sibling who has just left the room, most 13-month-olds turn toward the door (DeLoache & Ganea, 2009). The more experience toddlers have with an object and its verbal label, the more likely they are to call up a mental representation when they hear the object's name. As memory and vocabulary improve, skill at displaced reference expands.

But at first, toddlers have difficulty using language to acquire new information about an absent object—an ability that is essential to learn from symbols. In one study, an adult taught 19- and 22-month-olds a name for a stuffed animal—"Lucy" for a frog. Then, with the frog out of sight, the adult told the toddler that some water had spilled, so "Lucy's all wet!" Finally, the adult showed the toddler three stuffed animals—a wet frog, a dry frog, and a pig—and said, "Get Lucy!" (Ganea et al., 2007). Although all the children remembered that Lucy was a frog, only the 22-month-olds identified the wet frog as Lucy. Nevertheless, older toddlers' reliance on verbal information is fragile. When a verbal message about a toy's new location conflicts with a previously observed location, most 23-month-olds simply go to the initial location. At 30 months, children succeed at finding the toy (Ganea & Harris, 2010). The capacity to use language as a flexible symbolic tool—to modify an existing mental representation—improves from the end of the second into the third year.

Awareness of the symbolic function of pictures also emerges in the second year. Even newborns perceive a relation between a picture and its referent, as indicated by their preference for looking at a photo of their mother's face (see page 164 in Chapter 4). At the same time, infants do not treat pictures as symbols. Rather, they touch, rub, and pat a color photo of an object, or pick it up and manipulate it—behaviors that reveal confusion about the picture's true nature. This manual exploration increases from 4 to 9 months and then declines, becoming rare around 18 months (DeLoache et al., 1988; DeLoache & Ganea, 2009).

As long as pictures strongly resemble real objects, by the middle of the second year toddlers treat them symbolically. After hearing a novel label ("blicket") applied to a color photo of an unfamiliar object, most 15- to 24-month-olds—when presented with both the real object and its picture and asked to indicate the "blicket"—gave a symbolic response. They selected either the real object or both the object and its picture, not the picture alone, a tendency that strengthened with age (Ganea et al., 2009). Around this time, toddlers increasingly use pictures as vehicles for communicating with others and acquiring new knowledge. They point to, name, and talk about pictures, and they can apply something learned from a book with realistic-looking pictures to real objects, and vice versa (Ganea, Pickard, & DeLoache, 2008).

But even after coming to appreciate the symbolic nature of pictures, young children continue to have difficulty grasping the distinction between some pictures (such as line drawings) and their referents, as we will see shortly when address the symbolic capacities of preschoolers. How do infants and toddlers interpret another ever-present, pictorial medium—video? Turn to the Social Issues: Education box on the following page to find out.

Did this toddler learn to build a block tower through repeatedly acting on objects, as Piaget assumed? Or was he born with built-in cognitive equipment that jump-starts his understanding of relationships between objects?

Evaluation of the Sensorimotor Stage

The Milestones table on page 238 summarizes the remarkable cognitive attainments we have just considered, along with related milestones that we will take up later in this chapter. **TAKE A MOMENT...** Compare this table with the description of Piaget's account of sensorimotor development on pages 228–230. You will see that infants anticipate events, actively search for hidden objects, display an accurate A–B search, flexibly vary their sensorimotor schemes, engage in make-believe play, and treat pictures and video images symbolically within Piaget's time frame. Yet other capacities—including secondary circular reactions, first signs of object permanence, deferred imitation, categorization, problem solving by analogy, and displaced reference of words—emerge earlier than Piaget expected. These findings show that the cognitive attainments of infancy and toddlerhood do not develop together in the neat, stepwise fashion Piaget predicted.

SOCIAL ISSUES: EDUCATION

Baby Learning from TV and Video: The Video Deficit Effect

Children first become TV and video viewers in early infancy, as they are exposed to programs watched by parents and older siblings. Many parents also turn on TV shows or videos aimed at viewers not yet out of diapers, such as the Baby Einstein products. About 40 percent of U.S. 3-month-olds watch regularly, a figure that rises to 90 percent at age 2, a period during which average viewing time increases from just under an hour to 1½ hours per day (Zimmerman, Christakis, & Meltzoff, 2007). Although parents assume that babies learn from TV and videos, research indicates that they cannot take full advantage of them.

Initially, infants respond to videos of people as if viewing people directly—smiling, moving their arms and legs, and (by 6 months) imitating actions of a televised adult. But they confuse the images with the real thing (Barr, Muentener, & Garcia, 2007; Marian, Neisser, & Rochat, 1996). When 9- to 19-month-olds were shown videos of attractive toys, the 9-month-olds manually explored the screen, as they do with pictures. By 19 months, touching and grabbing had declined in favor of pointing at the images (Pierroutsakos & Troseth, 2003). Nevertheless, toddlers continue to have difficulty applying what they see on video to real situations.

In a series of studies, some 2-year-olds watched through a window while a live adult hid an object in an adjoining room, while others watched the same event on a video screen. Children in the direct viewing condition retrieved the toy easily; those in the video condition had trouble doing so (Troseth, 2003; Troseth & DeLoache, 1998). This **video deficit effect**—poorer performance after a video than a live demonstration—has also been found for 2-year-olds' deferred imitation, word learning, and means–end problem solving (Deocampo, 2003; Hayne, Herbert, & Simcock, 2003; Krcmar, Grela, & Linn, 2007).

One explanation for the video deficit effect is that 2-year-olds typically do not view a video character as offering socially relevant information. After an adult on video announced where she hid a toy, few 2-year-olds searched (Schmidt, Crawley-Davis, & Anderson, 2007). In contrast, when the adult stood in front of the child and uttered the same words, 2-year-olds promptly retrieved the object.

© NIAMH BALDOCK/ALAMY

This baby thinks the child she sees on the TV screen is real. Not until she is about 2½ will she understand how onscreen images relate to real people and objects.

Toddlers seem to discount information on video as relevant to their everyday experiences because people do not look at, converse, and play with them directly, as their caregivers do. In one study, researchers gave some 2-year-olds an interactive video experience (using a two-way, closed-circuit video system). An adult on video interacted with the child for five minutes—calling the child by name, talking about the child's siblings and pets, waiting for the child to respond, and playing interactive games (Troseth, Saylor, & Archer, 2006). Compared with 2-year-olds who viewed the same adult in a noninteractive video, those in the interactive condition were far more successful in using a verbal cue from a person on video to retrieve a toy.

Around age 2½, the video deficit effect declines. Before this age, the American Academy of Pediatrics (2001) recommends against mass media exposure, emphasizing that babies require rich responsive exchanges with caregivers and exploration of their physical surroundings for optimal brain growth and psychological development (see Chapter 5, page 191). In support of this advice, amount of TV viewing is negatively related to 8- to 18-month-olds' language progress (Tanimura et al., 2004; Zimmerman, Christakis, & Meltzoff, 2007). And 1- to 3-year-old heavy viewers tend to have attention, memory, and reading difficulties in the early school years (Christakis et al., 2004; Zimmerman & Christakis, 2005).

Toddlers face a complex task in making sense of video. Although they no longer confuse it with reality, they do not know how to mentally represent the relationship between video images and real objects and people. Video for 2-year-olds is likely to work best as a teaching tool when it is rich in social cues—close-ups of characters who look directly at the camera, address questions to viewers, and pause to invite their response. Repetition of video programs also helps children over age 2 make sense of video content (Anderson, 2004).

Recent research raises questions about Piaget's view of how infant development takes place. Consistent with Piaget's ideas, sensorimotor action helps infants construct some forms of knowledge. For example, in Chapter 4 we saw that experience in crawling enhances depth perception and ability to find hidden objects. Yet we have also seen evidence that infants comprehend a great deal before they are capable of the motor behaviors that Piaget assumed led to those understandings. How can we account for babies' amazing cognitive accomplishments?

Unlike Piaget, who thought infants constructed all mental representations out of sensorimotor activity, most researchers now believe that young babies have some built-in cognitive equipment for making sense of experience. But intense disagreement exists over the extent of this initial understanding. As we have seen, much evidence on infant cognition rests on the violation-of-expectation method. Researchers who lack confidence in this

Milestones

Some Cognitive Attainments of Infancy and Toddlerhood

APPROXIMATE AGE	COGNITIVE ATTAINMENTS
Birth–1 month 	• Secondary circular reactions using limited motor skills, such as sucking a nipple to gain access to interesting sights and sounds
1–4 months 	• Awareness of many physical properties, including object permanence, object solidity, and object support, as suggested by violation-of-expectation findings (see pages 262–263) • Deferred imitation of an adult's facial expression after a short delay (one day) • Categorization of objects perceptually, on the basis of similar overall appearance or prominent object part
4–8 months 	• Improved physical knowledge and basic numerical knowledge (see pages 263–264) • Deferred imitation of an adult's novel actions on objects over a short delay (one to three days) • Categorization of objects on the basis subtle sets of features, even when the perceptual contrast between categories is minimal
8–12 months 	• Ability to search for a hidden object when covered by a cloth, then when a hand deposits it under a cloth • Ability to solve simple problems by analogy to a previous problem
12–18 months 	• Ability to search in several locations for a hidden object (accurate A–B search) • Awareness that objects continue to exist in their hidden locations even after the toddler has left the location • Deferred imitation of an adult's novel actions on objects after long delays (at least several months) and across a change in context, such as from child care to home • Rational imitation, inferring the model's intentions • Flexible categorization of objects, first on one basis and then on another • Displaced reference of words
18 months–2 years 	• Ability to find an object moved while out of sight (invisible displacement) • Deferred imitation of actions an adult tries to produce, even if these are not fully realized, indicating a capacity to infer others' intentions • Deferred imitation of everyday behaviors in make-believe play • Beginning awareness of pictures and video as symbols of reality

Note: These milestones represent overall age trends. Individual differences exist in the precise age at which each milestone is attained.

TAKE A MOMENT... Which of the capacities listed in this table indicate that mental representation emerges earlier than Piaget believed?

method argue that babies' cognitive starting point is limited. For example, some believe that newborns begin life with a set of biases for attending to certain information and with general-purpose learning procedures—such as powerful techniques for analyzing complex perceptual information. Together, these capacities enable infants to construct a wide variety of schemes (Bahrick, 2010; Huttenlocher, 2002; Quinn, 2008; Rakison, 2010). Others, convinced by violation-of-expectation findings, argue that infants start life with considerable innate knowledge, which "jump-starts" their cognitive development. This *core knowledge perspective* has gained ground in the past decade. We will discuss its strengths and limitations after considering Piaget's stages of childhood and adolescence.

ASK YOURSELF

Review ■ Using the discussion on pages 230–236, construct your own summary table of infant and toddler cognitive development. Which entries in your table are consistent with Piaget's sensorimotor stage? Which ones develop earlier than Piaget anticipated?

Connect ■ Recall from Chapter 4 (page 163) that by the middle of the first year, infants identify objects by their features and paths of movement, even when they cannot observe the entire path. How might these attainments contribute to understanding of object permanence?

Apply ■ Several times, after her father hid a teething biscuit under a red cup, 10-month-old Mimi retrieved it easily. Then Mimi's father hid the biscuit under a nearby yellow cup, but Mimi persisted in searching for it under the red cup. What factors might be contributing to Mimi's inaccurate search behavior?

Reflect ■ What advice would you give the typical U.S. parent about permitting an infant or toddler to watch as much as 1 to 1½ hours of TV or video per day? Explain.

The Preoperational Stage: 2 to 7 Years

- Describe advances in mental representation and cognitive limitations during the preoperational stage.
- What does follow-up research reveal about preschoolers' cognitive development and the accuracy of Piaget's preoperational stage?

As children move from the sensorimotor to the **preoperational stage,** which spans the years 2 to 7, the most obvious change is an extraordinary increase in representational, or symbolic, activity. Infants' and toddlers' mental representations are impressive, but in early childhood, representational capacities blossom.

Advances in Mental Representation

Piaget acknowledged that language is our most flexible means of mental representation. By detaching thought from action, it permits far more efficient thinking than was possible earlier. When we think in words, we can deal with past, present, and future at once and combine concepts in unique ways, as when we imagine a hungry caterpillar eating bananas or monsters flying through the forest at night.

But Piaget did not regard language as the primary ingredient in childhood cognitive change. Instead, he believed that sensorimotor activity leads to internal images of experience, which children then label with words (Piaget, 1936/1952). In support of Piaget's view, children's first words have a strong sensorimotor basis, usually referring to objects that move or can be acted on or to familiar actions (see Chapter 9). And as we have seen, infants acquire an impressive range of categories long before they use words to label them.

Still, Piaget underestimated the power of language to spur children's cognition. Research inspired by Vygotsky's theory, which we take up later, confirms that language is a powerful source of cognitive development, not just an indicator of it.

Make-Believe Play

Make-believe is another excellent example of the development of representation in early childhood. Piaget believed that through pretending, children practice and strengthen newly acquired representational schemes. Drawing on his ideas, researchers have traced changes in make-believe play during the preschool years.

Development of Make-Believe Play. **TAKE A MOMENT...** Visit a child-care center or a family with several young children, and compare an 18-month-old's pretending with that of a 2- to 3-year-old. Jot down examples of the following three advances:

- *Play detaches from the real-life conditions associated with it.* In early pretending, toddlers use only realistic objects—a toy telephone to talk into or a cup to drink from. Their earliest pretend acts usually imitate adults' actions and are not yet flexible. Children younger than age 2, for example, will pretend to drink from a cup but refuse to pretend a cup is a hat (Rakoczy, Tomasello, & Striano, 2005). They have trouble using an object (cup) that already has an obvious use as a symbol for another object (hat).

After age 2, children pretend with less realistic toys (a block for a telephone receiver). Gradually, they can imagine objects and events, without any support from the real world (O'Reilly, 1995; Striano, Tomasello, & Rochat, 2001). And by age 3, they flexibly understand that an object (a yellow stick) may take on one fictional identity in one pretend game (a toothbrush) and another fictional identity (a carrot) in a different pretend game (Wyman, Rakoczy, & Tomasello, 2009).

- *Play becomes less self-centered.* At first, make-believe is directed toward the self; for example, children pretend to feed only themselves. Soon, children direct pretend actions toward other people or objects, pouring tea for a parent or feeding a doll. Early in the third year, they become detached participants, assigning make-believe intentions to objects—making a doll feed itself or pushing a button to launch a rocket. Make-believe becomes less self-centered as children realize that agents and recipients of pretend actions can be independent of themselves (McCune, 1993).
- *Play includes more complex combinations of schemes.* An 18-month-old can pretend to drink from a cup but does not yet combine pouring and drinking. Later, children combine pretend schemes with those of peers in **sociodramatic play,** the make-believe with others that is under way by the end of the second year and increases rapidly in complexity during early childhood (Kavanaugh, 2006a). By age 4 to 5, children build on one another's play ideas, create and coordinate several roles, and have a sophisticated understanding of story lines (Göncü, 1993).

LOOK and LISTEN

Observe the make-believe play of several 2- to 4-year-olds at home or in a preschool or child-care center. Describe pretend acts that exemplify important developmental changes.

Children as young as age 2 display awareness that make-believe is a representational activity. They distinguish make-believe from real experiences and grasp that pretending is a deliberate effort to act out imaginary ideas—an understanding that strengthens over early childhood (Lillard, 2003; Rakoczy, Tomasello, & Striano, 2004; Sobel, 2006). **TAKE A MOMENT...** Listen closely to a group of preschoolers as they assign roles and negotiate plans in sociodramatic play: "*You pretend to be* the astronaut," "Wait, *I gotta set up* the spaceship." In communicating about pretend, children think about their own and others' fanciful representations—evidence that they have begun to reason about people's mental activities.

© LAURA DWIGHT PHOTOGRAPHY

Make-believe play becomes more sophisticated over the preschool years. Children increasingly coordinate make-believe roles and pretend with less realistic toys—for example, a toy truck as an electric hair clipper.

Benefits of Make-Believe. Today, Piaget's view of make-believe as mere practice of representational schemes is regarded as too limited. Play not only reflects but also contributes to children's cognitive and social skills. Sociodramatic play has been studied most thoroughly. Compared with social nonpretend activities (such as drawing or putting puzzles together), during sociodramatic play preschoolers' interactions last longer, show more involvement, draw more children into the activity, and are more cooperative (Creasey, Jarvis, & Berk, 1998).

It is not surprising, then, that preschoolers who devote more time to sociodramatic play are seen as more socially competent by their teachers (Connolly & Doyle, 1984). And many studies reveal that make-believe strengthens a wide variety of mental abilities, including sustained attention, memory, logical reasoning, language and literacy, imagination, creativity, understanding of emotions, and the ability to reflect on one's own thinking and take another's perspective (Bergen & Mauer, 2000; Elias & Berk, 2002; Hirsh-Pasek et al., 2009; Lindsey & Colwell, 2003; Ogan & Berk, 2009; Ruff & Capozzoli, 2003).

Between 25 and 45 percent of preschoolers and young school-age children spend much time in solitary make-believe, creating *imaginary companions*—special fantasized friends endowed with humanlike qualities. For example, one preschooler created Nutsy and Nutsy, a pair of boisterous birds who lived outside her bedroom window (Gleason, Sebanc, & Hartup, 2000; Taylor et al., 2004). Imaginary companions were once viewed as a sign of maladjustment, but research challenges this assumption. Children with an invisible playmate typically treat it with kindness and affection and say it offers caring, comfort, and good company, just as their real friendships do (Gleason & Hohmann, 2006; Hoff, 2005). Such children also display more complex and imaginative pretend play, produce more elaborate narratives about their personal

APPLYING WHAT WE KNOW

Enhancing Make-Believe Play in Early Childhood

STRATEGY	DESCRIPTION
Provide sufficient space and play materials.	Generous space and materials allow for many play options and reduce conflict.
Encourage children's play without controlling it.	Model, guide, and build on young preschoolers' play themes. Provide open-ended suggestions ("Would the animals like a train ride?"), and talk with the child about the thoughts, motivations, and emotions of play characters. These forms of adult support lead to more elaborate pretending. Refrain from directing the child's play; excessive adult control destroys the creativity and pleasure of make-believe.
Offer a variety of both realistic materials and materials without clear functions.	Children use realistic materials—trucks, dolls, tea sets, dress-up clothes, and toy scenes (house, farm, garage, airport)—to act out everyday roles in their culture. Materials without clear functions (blocks, cardboard cylinders, paper bags, sand) inspire fantastic role play—"pirate" and "creature from outer space."
Ensure that children have many rich real-world experiences to inspire positive fantasy play.	Opportunities to participate in real-world activities with adults and to observe adult roles in the community provide children with rich social knowledge to integrate into make-believe. Restricting television viewing, especially programs with violent content, limits the degree to which violent themes and aggressive behavior become part of children's play (see Chapter 15).
Help children solve social conflicts constructively.	Cooperation is essential for sociodramatic play. Help children resolve disagreements constructively. For example, ask, "What could you do if you want a turn?" If the child doesn't know, suggest some options and help the child implement them.

experiences and about events in storybooks, are advanced in understanding others' viewpoints and emotions, and are more sociable with peers (Bouldin, 2006; Gleason, 2002; Taylor & Carlson, 1997; Trionfi & Reese, 2009).

Refer to Applying What We Know above for ways to enhance preschoolers' make-believe. Later we will return to the origins and consequences of make-believe from an alternative perspective—that of Vygotsky.

Drawings When given crayon and paper, even toddlers scribble in imitation of others. Gradually, marks on the page take on meaning. A variety of cognitive factors influence the development of children's artful representations (Golomb, 2004). These include the realization that pictures can serve as symbols, improved planning and spatial understanding, and the emphasis that the child's culture places on artistic expression.

From Scribbles to Pictures. Typically, drawing progresses through the following sequence:

1. *Scribbles.* At first, children's intended representation is contained in their gestures rather than in the resulting marks on the page. For example, one 18-month-old made her crayon hop around the page and, as it produced a series of dots, explained, "Rabbit goes hop-hop" (Winner, 1986).

   Recall from page 236 that by the middle of the second year, toddlers treat realistic-looking pictures symbolically. But they have difficulty interpreting line drawings. When an adult held up a drawing indicating which of two objects preschoolers should drop down a chute, 3-year-olds used the drawing as a symbol to guide their behavior but 2-year-olds did not (Callaghan, 1999).
2. *First representational forms.* Around age 3, children's scribbles start to become pictures, although few 3-year olds spontaneously draw so others can tell what their picture represents. Often children make a gesture with the crayon, notice that they have drawn a

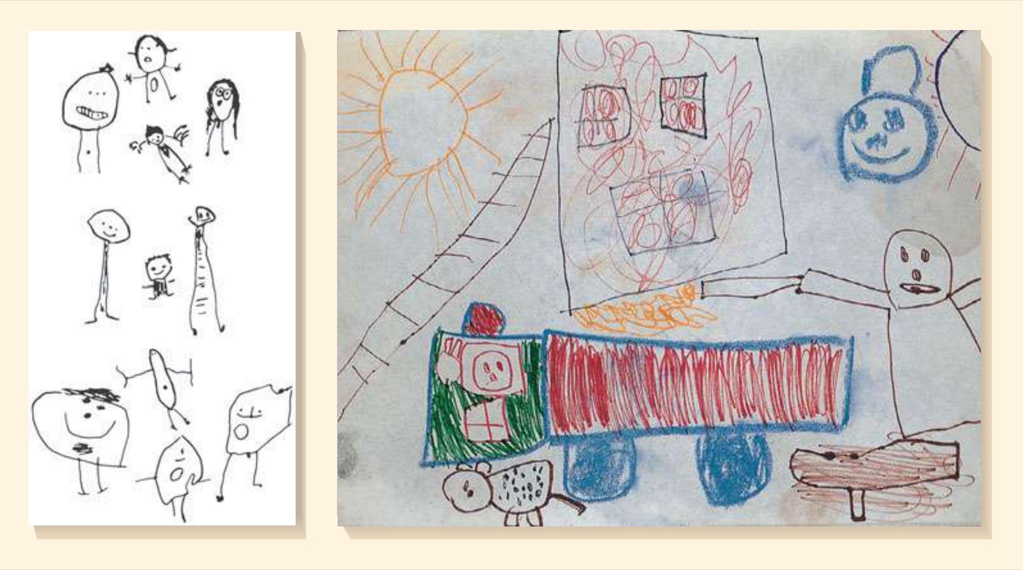

FIGURE 6.6 **Examples of young children's drawings.** The universal tadpolelike shape that children use to draw their first picture of a person is shown on the left. The tadpole soon becomes an anchor for greater detail as arms, fingers, toes, and facial features sprout from the basic shape. By the end of the preschool years, children produce more complex, differentiated pictures like the one on the right, drawn by a 6-year-old. (*Left:* From H. Gardner, 1980, *Artful Scribbles: The Significance of Children's Drawings,* New York: Basic Books, p. 64. Reprinted by permission of Basic Books, a member of Perseus Book Group. *Right:* From E. Winner, August 1986, "Where Pelicans Kiss Seals," *Psychology Today, 20*[8], p. 35. Reprinted by permission from the collection of Ellen Winner.)

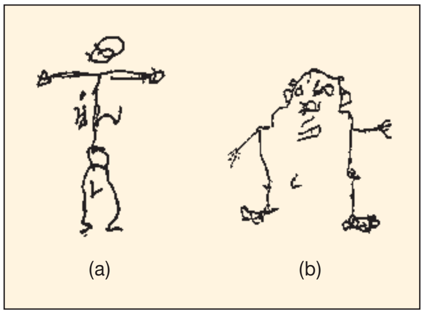
recognizable shape, and then label it—as with a child who made some random marks on a page and then, noticing that his scribbles resembled noodles, called his creation "chicken pie and noodles" (Winner, 1986).

A major milestone in drawing occurs when children use lines to represent the boundaries of objects. This enables 3- and 4-year-olds to draw their first picture of a person. Fine-motor and cognitive limitations lead the preschooler to reduce the figure to the simplest form that still looks human—the universal "tadpole" image, a circular shape with lines attached, shown on the left in Figure 6.6. Four-year-olds add features, such as eyes, nose, mouth, hair, fingers, and feet, as the tadpole drawings illustrate.

3. *More realistic drawings.* Greater realism in drawings develops gradually, as perception, language (ability to describe visual details), memory, and fine-motor capacities improve (Toomela, 2002). Five- and 6-year-olds create more complex drawings, like the one on the right in Figure 6.6, containing more conventional human and animal figures, with the head and body differentiated.

   Older preschoolers' drawings still contain perceptual distortions because they have just begun to represent depth (Cox & Littlejohn, 1995). Use of depth cues, such as overlapping objects, smaller size for distant than for near objects, diagonal placement, and converging lines, increases during middle childhood (Nicholls & Kennedy, 1992). And instead of depicting objects separately (as in the drawing in Figure 6.6), older school-age children relate them in an organized spatial arrangement (Case & Okamoto, 1996).

FIGURE 6.7 **Human figure drawings produced by nonschooled 10- to 15-year-olds of the Jimi Valley of Papua New Guinea.** Many produced (a) "stick" figures or (b) "contour" figures, which resemble the tadpole form of young preschoolers. (From M. Martlew & K. J. Connolly, 1996, "Human Figure Drawings by Schooled and Unschooled Children in Papua New Guinea," *Child Development, 67,* pp. 2750–2751. © 1996, John Wiley and Sons. Adapted with permission of John Wiley and Sons.)



Cultural Variations in Development of Drawing. In cultures with rich artistic traditions, children create elaborate drawings that reflect the conventions of their culture. Adults encourage young children in drawing activities by offering suggestions, modeling ways to draw, and asking children to label their pictures. Peers, as well, discuss one another's drawings and copy from one another's artwork (Boyatzis, 2000; Braswell, 2006). All of these cultural practices enhance young children's drawing progress.

But in cultures with little interest in art, even older children and adolescents produce only simple forms. In the Jimi Valley, a remote region of Papua New Guinea with no indigenous pictorial art, many children do not attend school and therefore have little opportunity to develop drawing skills. When asked to draw a human figure for the first time, most nonschooled Jimi 10- to 15-year-olds produced nonrepresentational scribbles and shapes or simple "stick" or "contour" images (see Figure 6.7) (Martlew & Connolly, 1996). These forms seem to be a universal beginning in drawing. Once children realize that lines must evoke human features, they find solutions to figure drawing that follow the general sequence of development described earlier.

© ARIEL SKELLEY/CORBIS

Children who experience a variety of symbols come to understand that one object—a birdhouse—can stand for another: a full-sized house that people live in.

Symbol–Real-World Relations

To make believe and draw—and to understand other forms of representation, such as photographs, models, and maps—preschoolers must realize that each symbol corresponds to something specific in everyday life. Grasping this correspondence grants children a powerful cognitive tool for finding out about objects and places they have not experienced directly. Earlier in this chapter, we saw that by the middle of the second year, children grasp the symbolic function of realistic-looking pictures (such as photos). When do children comprehend other more challenging symbols—for example, three-dimensional models that stand for real-world spaces?

In one study, 2½- and 3-year-olds watched an adult hide a small toy (Little Snoopy) in a scale model of a room and then were asked to retrieve it. Next, they had to find a larger toy (Big Snoopy) hidden in the room that the model represented. Not until age 3 could most children use the model as a guide to finding Big Snoopy in the real room (DeLoache, 1987). The 2½-year-olds did not realize that the model could be both *a toy room* and *a symbol of another room.* They had trouble with **dual representation**—viewing a symbolic object as both an object in its own right and a symbol.

In support of this interpretation, when researchers made the model room less prominent as an object, by placing it behind a window and preventing children from touching it, more 2½-year-olds succeeded at the search task (DeLoache, 2000, 2002). Recall, also, that in make-believe play, 1½- to 2-year-olds cannot use an object that has an obvious use (cup) to stand for another object (hat). And 2-year-olds do not yet realize that a line drawing—an object in its own right—also represents real-world objects (see page 241).

Similarly, when presented with objects disguised in various ways and asked what each "looks like" and what each "is really and truly," preschoolers have difficulty. For example, when asked whether a candle that looks like a crayon "is really and truly" a crayon or whether a stone painted to look like an egg "is really and truly" an egg, children younger than age 6 often responded "yes" (Flavell, Green, & Flavell, 1987). But simplify these *appearance–reality tasks* by permitting children to solve them nonverbally, by selecting from an array of objects the one that "really" has a particular identity, and most 3-year-olds perform well (Deák, Ray, & Brenneman, 2003). They realize that an object can be one thing (a candle) while symbolizing another (a crayon).

How do children grasp the dual representation of symbolic objects? When adults point out similarities between models and real-world spaces, 2½-year-olds perform better on the find-Snoopy task (Peralta de Mendoza & Salsa, 2003). Also, insight into one type of symbol–real-world relation helps preschoolers master others. For example, children regard realistic-looking pictures as symbols early because a picture's primary purpose is to stand for something; it is not an interesting object in its own right (Preissler & Carey, 2004; Simcock & DeLoache, 2006). And 3-year-olds who can use a model of a room to locate Big Snoopy readily transfer their understanding to a simple map (Marzolf & DeLoache, 1994).

In sum, exposing young children to diverse symbols—picture books, photos, drawings, models, make-believe, and maps—helps them appreciate that one object can stand for another. With age, children come to understand a wide range of symbols that have little physical similarity to what they represent (Liben, 2009). As a result, doors open to vast realms of knowledge.

Limitations of Preoperational Thought

Aside from gains in representation, Piaget described preschoolers in terms of what they *cannot* understand (Beilin, 1992). As the term *pre*operational suggests, he compared them to older, more competent children who have reached the concrete operational stage. According to Piaget, young children are not capable of **operations**—mental representations of actions that obey logical rules. Rather, their thinking is rigid, limited to one aspect of a situation at a time, and strongly influenced by the way things appear at the moment.

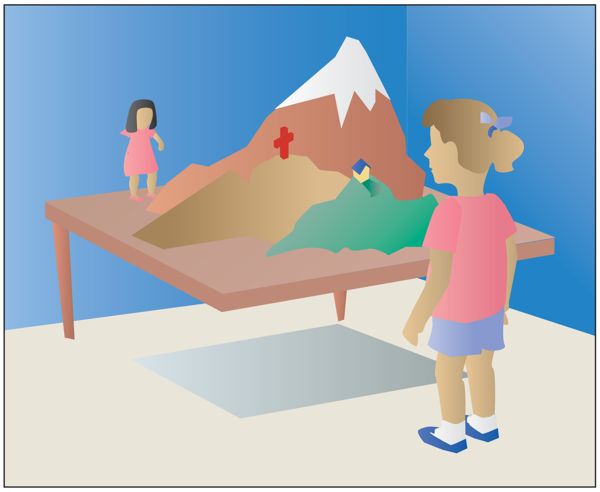


FIGURE 6.8 **Piaget's three-mountains problem.** Each mountain is distinguished by its color and by its summit. One has a red cross, another a small house, and the third a snow-capped peak. Children at the preoperational stage respond egocentrically. They cannot select a picture that shows the mountains from the doll's perspective. Instead, they simply choose the photo that reflects their own vantage point.

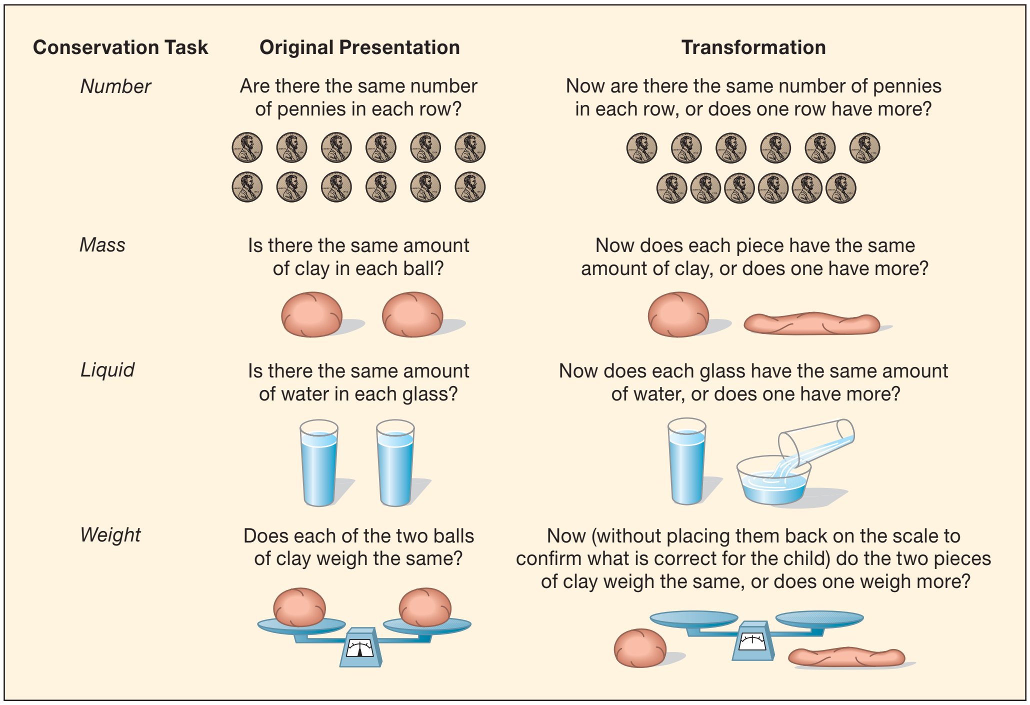
Egocentric and Animistic Thinking For Piaget, the most fundamental deficiency of preoperational thinking is **egocentrism**—failure to distinguish others' symbolic viewpoints from one's own. He believed that when children first mentally represent the world, they tend to focus on their own viewpoint and assume that others perceive, think, and feel the same way they do.

Piaget's most convincing demonstration of egocentrism involves his *three-mountains problem,* described in Figure 6.8. He also regarded egocentrism as responsible for preoperational children's *animistic thinking*—the belief that inanimate objects have lifelike qualities, such as thoughts, wishes, feelings, and intentions (Piaget, 1926/1930). The 3-year-old who charmingly explains that the sun is angry at the clouds and has chased them away is demonstrating this kind of reasoning. According to Piaget, because young children egocentrically assign human purposes to physical events, magical thinking is especially common during the preschool years.

Piaget argued that young children's egocentric bias prevents them from *accommodating,* or reflecting on and revising their faulty reasoning in response to their physical and social worlds. To understand this shortcoming, let's consider some additional tasks that Piaget gave to children.

Inability to Conserve Piaget's famous conservation tasks reveal several deficiencies of preoperational thinking. **Conservation** refers to the idea that certain physical characteristics of objects remain the same, even when their outward appearance changes. For example, in the conservation-of-liquid problem, the child is shown two identical tall glasses of water and asked if they contain equal amounts. Once the child agrees, the water in one glass is poured into a short, wide container, changing the water's appearance but not its amount. Then the child is asked whether the amount of water is the same or has changed. Preoperational children think the quantity has changed. They explain, "There is less now because the water is way down here" (that is, its level is so low) or, "There is more now because it is all spread out." Figure 6.9 illustrates other conservation tasks that you can try with children.

FIGURE 6.9 **Some Piagetian conservation tasks.** Children at the preoperational stage cannot yet conserve. These tasks are mastered gradually over the concrete operational stage. Children in Western nations typically acquire conservation of number, mass, and liquid sometime between 6 and 7 years and of weight between 8 and 10 years.



Conservation Task	Original Presentation	Transformation
Number	Are there the same number of pennies in each row?	Now are there the same number of pennies in each row, or does one row have more?
Mass	Is there the same amount of clay in each ball?	Now does each piece have the same amount of clay, or does one have more?
Liquid	Is there the same amount of water in each glass?	Now does each glass have the same amount of water, or does one have more?
Weight	Does each of the two balls of clay weigh the same?	Now (without placing them back on the scale to confirm what is correct for the child) do the two pieces of clay weigh the same, or does one weigh more?

The inability to conserve highlights several related aspects of preoperational children's thinking. First, their understanding is *centered,* or characterized by **centration.** They focus on one aspect of a situation, neglecting other important features. In conservation of liquid, the child *centers* on the height of the water, failing to realize that changes in width compensate for the changes in height. Second, children are easily distracted by the *perceptual appearance* of objects. Third, children treat the initial and final *states* of the water as unrelated events, ignoring the *dynamic transformation* (pouring of water) between them.

The most important illogical feature of preoperational thought is *irreversibility.* **Reversibility**—the ability to go through a series of steps in a problem and then mentally reverse direction, returning to the starting point—is part of every logical operation. In the case of conservation of liquid, the preoperational child cannot imagine the water being poured back into its original container and so fails to see how the amount must remain the same.

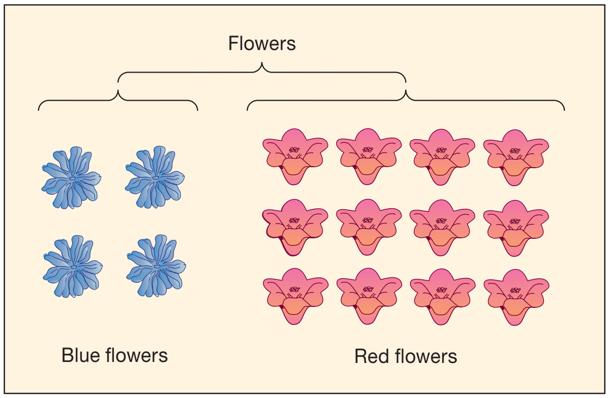


FIGURE 6.10 **A Piagetian class inclusion problem.** Children are shown 16 flowers, 4 of which are blue and 12 of which are red. Asked, "Are there more red flowers or flowers?" the preoperational child responds, "More red flowers," failing to realize that both red and blue flowers are included in the category "flowers."

Lack of Hierarchical Classification Preoperational children have difficulty with **hierarchical classification**—the organization of objects into classes and subclasses on the basis of similarities and differences. Piaget's famous *class inclusion problem,* illustrated in Figure 6.10, demonstrates this limitation. Preoperational children center on the overriding feature, red. They do not think reversibly, moving from the whole class (flowers) to the parts (red and blue) and back again.

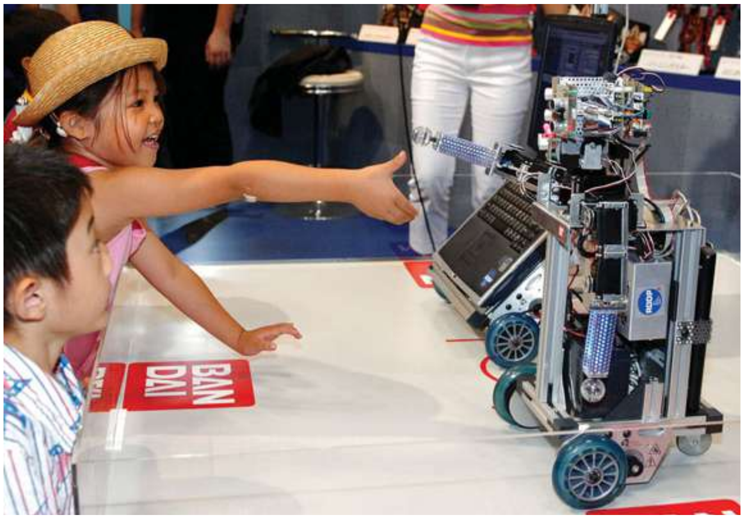
Follow-Up Research on Preoperational Thought

Over the past three decades, researchers have challenged Piaget's account of preschoolers as cognitively deficient. Because many Piagetian problems contain unfamiliar elements or too many pieces of information for young children to handle at once, preschoolers' responses often do not reflect their true abilities. Piaget also missed many naturally occurring instances of effective reasoning by preschoolers. Let's look at some examples.

Egocentric, Animistic, and Magical Thinking Do young children really believe that a person standing elsewhere in a room sees exactly what they see? When researchers adapt Piaget's three-mountains problem to include familiar objects and use methods other than picture selection (which is difficult even for 10-year-olds), 4-year-olds show clear awareness of others' vantage points (Borke, 1975; Newcombe & Huttenlocher, 1992). Even 2-year-olds realize that what they see sometimes differs from what another person sees. When asked to help an adult looking for a lost object, 24-month-olds—but not 18-month-olds—handed her a toy resting behind a bucket that was within the child's line of sight but not visible to the adult (Moll & Tomasello, 2006).

Nonegocentric responses also appear in young children's conversations. For example, preschoolers adapt their speech to fit the needs of their listeners. Four-year-olds use shorter, simpler expressions when talking to 2-year-olds than to agemates or adults (Gelman & Shatz, 1978). And in describing objects, children do not use such words as "big" and "little" in a rigid, egocentric fashion. Instead, they *adjust* their descriptions to allow for context. By age 3, children judge a 2-inch shoe as little when seen by itself (because it is much smaller than most shoes) but as big for a tiny 5-inch-tall doll (Ebeling & Gelman, 1994).

Even toddlers have some appreciation of others' perspectives. In discussing deferred imitation, we saw that they have begun to infer others' intentions (see page 233). And in Chapters 10 and 11, we will encounter evidence that young children have a much greater appreciation of other people's mental states than Piaget's notion of egocentrism implies. In fairness, however, in his later writings Piaget (1945/1951) described preschoolers' egocentrism as a *tendency* rather than an inability. As we revisit the topic of perspective taking, you will see that it develops gradually throughout childhood and adolescence.



© TATSUYUKI TAYAMA/FUJIFOTOS/THE IMAGE WORKS

Although these preschoolers understand that a robot with life-like features is not really alive, they may believe that it has perceptual and psychological capacities, such as seeing and thinking.

Piaget also overestimated preschoolers' animistic beliefs. Even infants and toddlers have begun to distinguish animate from inanimate, as indicated by their remarkable categorical distinctions between living and nonliving things (see page 234). By age 2½, children give psychological explanations ("he likes to" or "she wants to") for people and occasionally for animals, but rarely for objects (Hickling & Wellman, 2001). And 3- to 5-year-olds asked whether a variety of animals and objects can eat, grow, talk, think, remember, see, or feel mostly attribute these capacities to animals, not objects. In addition, they rarely attribute biological properties (like eating and growing) to robots, indicating that they are well aware that even a self-moving object with lifelike features is not alive. But unlike adults, preschoolers often say that robots have perceptual and psychological capacities—for example, seeing, thinking, and remembering (Jipson & Gelman, 2007; Subrahmanyam, Gelman, & Lafosse, 2002). These responses result from incomplete knowledge about certain objects, and they decline with age.

Similarly, preschoolers think that magic accounts for events they cannot otherwise explain, as in 3-year-old Sammy's magical explanation of thunder in the opening to this chapter. Consequently, most 3- and 4-year-olds believe in the supernatural powers of fairies, goblins, and other enchanted creatures (Rosengren & Hickling, 2000). But their notions of magic are flexible and appropriate. For example, older 3-year-olds and 4-year-olds think that violations of physical laws (walking through a wall) and mental laws (turning on the TV just by thinking about it) require magic more than violations of social conventions (taking a bath with shoes on) (Browne & Woolley, 2004). And they are more likely to say that a magical process—wishing—caused an event (an object to appear in a box) when a person made the wish before the event occurred, the event was consistent with the wish (the wished-for object rather than another object appeared in the box), and no alternative causes were apparent (Woolley, Browne, & Boerger, 2006). These features of causality are the same ones preschoolers rely on in ordinary situations.

Between ages 4 and 8, as children gain familiarity with physical events and principles, their magical beliefs decline. They figure out who is really behind Santa Claus and the Tooth Fairy, and they realize that magicians' feats are due to trickery (Subbotsky, 2004). And increasingly, children say that characters and events in fantastical stories aren't real (Wooley & Cox, 2007). Still, because children entertain the possibility that something imaginary might materialize, they may react with anxiety to scary stories, TV shows, and nightmares.

Logical Thought Many studies show that when preschoolers are given tasks that are simplified and made relevant to their everyday lives, they do not display the illogical characteristics that Piaget saw in the preoperational stage. For example, when a conservation-of-number task is scaled down to include only three items instead of six or seven, 3-year-olds perform well (Gelman, 1972). And when preschoolers are asked what happens to substances (such as sugar) after they are dissolved in water, they give accurate explanations. Most 3- to 5-year-olds know that the substance is conserved—that it continues to exist, can be tasted, and makes the liquid heavier, even though it is invisible in the water (Au, Sidle, & Rollins, 1993; Rosen & Rozin, 1993).

Preschoolers' ability to reason about transformations is evident on other problems. They can engage in impressive *reasoning by analogy* about physical changes. When presented with the picture-matching problem "Play dough is to cut-up play dough as apple is to . . . ?," even 3-year-olds choose the correct answer (a cut-up apple) from a set of alternatives, several of which (a bitten apple, a cut-up loaf of bread) share physical features with the right choice (Goswami, 1996). These findings indicate that in familiar contexts, preschoolers can overcome appearances and think logically about cause and effect.

LOOK and LISTEN

Try the conservation of number and mass tasks in Figure 6.9 with a 3- or 4-year-old. Next, simplify conservation of number by reducing the number of pennies, and relate conservation of mass to the child's experience by pretending the clay is baking dough and transforming it into cupcakes. Did the child perform more competently?

Finally, even without detailed biological or mechanical knowledge, preschoolers realize that the insides of animals are responsible for certain cause–effect sequences (such as willing oneself to move) that are impossible for nonliving things, such as machines (Gelman, 2003; Keil & Lockhart, 1999). Preschoolers seem to use illogical reasoning only when they must grapple with unfamiliar topics, too much information, or contradictory facts that they cannot reconcile (Ruffman, 1999).

© LAURA DWIGHT PHOTOGRAPHY

These 4-year-olds understand that a category ("dinosaurs") can be based on underlying characteristics ("cold-blooded"), not just on perceptual features such as upright posture and scaly skin.

Categorization Despite their difficulty with Piagetian class inclusion tasks, preschoolers organize their everyday knowledge into nested categories at an early age. By the beginning of early childhood, children's categories include objects that go together because of their common function, behavior, and natural kind (animate versus inanimate), despite varying widely in perceptual features.

Indeed, 2- to 5-year-olds readily draw inferences about nonobservable characteristics shared by category members. For example, after being told that a bird has warm blood and a stegosaurus (dinosaur) has cold blood, preschoolers infer that a pterodactyl (labeled a dinosaur) has cold blood, even though it closely resembles a bird (Gopnik & Nazzi, 2003). And when shown a set of three characters—two of whom look different but share an inner trait ("outgoing") and two of whom look similar but have different inner traits (one "shy," one "outgoing")—preschoolers rely on the trait category, not physical appearance, to predict similar preferred activities (Heyman & Gelman, 2000).

During the second and third years, and perhaps earlier, children's categories differentiate. They form many *basic-level categories*—ones at an intermediate level of generality, such as "chairs," "tables," "dressers," and "beds." By the third year, preschoolers easily move back and forth between basic-level categories and *general categories,* such as "furniture." And they break down basic-level categories into *subcategories,* such as "rocking chairs" and "desk chairs."

Preschoolers' rapidly expanding vocabularies and general knowledge support their impressive skill at categorizing. As they learn more about their world, they devise theories about underlying characteristics shared by category members, which help them identify new instances (Gelman & Kalish, 2006; Gelman & Koenig, 2003). For example, they realize that animals have an inborn potential for certain physical characteristics and behaviors that determine their identity. In categorizing, they look for causal links among these features. In one study, researchers invented two categories of animals—one with horns, armor, and a spiky tail; the other with wings, large ears, long toes, and a monkeylike tail (see Figure 6.11). Four-year-olds who were given a theory that identified an inner cause for the coexistence of the animals' features—animals in the first category "like to fight"; those in the second category "like to hide in trees"—easily classified new examples of animals. But 4-year-olds for whom animal features were merely pointed out or who were given a separate function for each feature could not remember the categories (Krascum & Andrews, 1998).

As this investigation suggests, adults' explanations are a major source of young children's categorical learning (Gelman & Kalish, 2006). Picture-book reading is an especially rich context for understanding categories.

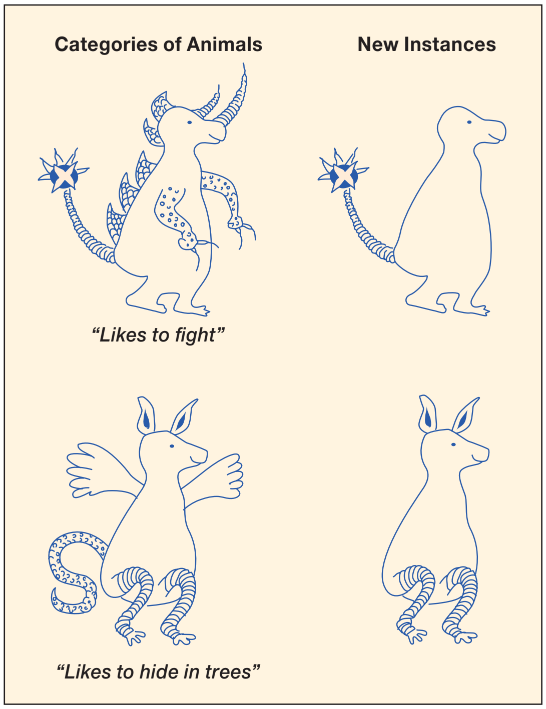


FIGURE 6.11 Categories of imaginary animals shown to preschoolers. When an adult provided a theory about the coexistence of animals' features—"likes to fight" and "likes to hide in trees"—4-year-olds easily classified new instances of animals with only one or two features. Without the theory, preschoolers could not remember the categories. Theories about underlying characteristics support the formation of many categories in early childhood. (From R. M. Krascum & S. Andrews, 1998, "The Effects of Theories on Children's Acquisition of Family-Resemblance Categories," *Child Development, 69,* p. 336. © 1998, John Wiley and Sons. Reprinted with permission of John Wiley and Sons.)

Some Cognitive Attainments of Early Childhood

APPROXIMATE AGE	COGNITIVE ATTAINMENTS
2–4 years 	• Shows a dramatic increase in representational activity, as reflected in language, make-believe play, drawing, understanding of symbol–real-world relations, and categorization • Takes the perspective of others in simplified, familiar situations and in everyday, face-to-face communication • Distinguishes animate beings from inanimate objects; denies that magic can alter everyday experiences • Grasps conservation, notices transformations, reverses thinking, and understands many cause-and-effect relationships in familiar contexts • Categorizes objects on the basis of common function, behavior, and natural kind, not just perceptual features. Devises ideas about underlying characteristics that category members share and uses inner causal features to categorize objects varying widely in external appearance. • Sorts familiar objects into hierarchically organized categories
4–7 years 	• Becomes increasingly aware that make-believe (and other thought processes) are representational activities • Replaces beliefs in magical creatures and events with plausible explanations

Note: These milestones represent overall age trends. Individual differences exist in the precise age at which each milestone is attained.

While looking at books with their preschoolers, parents provide information that guides children's inferences about the structure of categories: "Penguins live at the South Pole, swim, and catch fish," or "Fish breathe by taking water into their mouths." Furthermore, young children ask many questions about their world ("What do crawfish eat? Why does it have claws?") and generally get informative answers, which are particularly well-suited to advancing their conceptual understanding (Chouinard, 2007).

In sum, although preschoolers' category systems are less complex than those of older children and adults, they already have the capacity to classify hierarchically and on the basis of nonobvious properties. And they use logical, causal reasoning to identify the interrelated features that form the basis of a category and to classify new members. Finally, they often rely on language to advance their knowledge of categories.

Evaluation of the Preoperational Stage

The Milestones table above provides an overview of the cognitive attainments of early childhood just considered. **TAKE A MOMENT...** Compare them with Piaget's description of the preoperational child on pages 243–245. The evidence as a whole indicates that Piaget was partly wrong and partly right about young children's cognitive capacities. When given simplified tasks based on familiar experiences, preschoolers show the beginnings of logical thinking. How can we make sense of the contradictions between Piaget's conclusions and the findings of recent research?

That preschoolers have some logical understandings that strengthen with age indicates that they acquire operational reasoning gradually. Over time, children rely on increasingly effective mental (as opposed to perceptual) approaches to solving problems. For example, children who cannot use counting to compare two sets of items do not conserve number. Rather, they rely on perceptual cues to compare the amounts in two sets of items (Rouselle, Palmers, & Noël, 2004; Sophian, 1995). Once preschoolers can count, they apply this skill to conservation-of-number tasks involving just a few items. As counting improves, they extend the strategy to problems with more items. By age 6, they understand that number remains the same after a transformation in the length and spacing of a set of items as long as nothing is added or taken away (Halford & Andrews, 2006). Consequently, they no longer need to count to verify their answer. Thus, children pass through several steps on the way to a full understanding of relationships among variables in conservation problems, although (as Piaget indicated) they do not fully grasp conservation until the school years.

Evidence that preschool children can be trained to perform well on Piagetian problems also supports the idea that operational thought does not emerge all at once (Ping & Goldin-Meadow, 2008; Siegler & Svetina, 2006). Children who possess some understanding would naturally benefit from training, unlike those with none at all.

The gradual development of logical operations poses yet another challenge to Piaget's stage concept. Although the minds of young children still have a great deal of developing to do, research shows that they are considerably more capable than Piaget assumed.

ASK YOURSELF

Review ■ Select two of the following features of preoperational thought: egocentrism, a focus on perceptual appearances, difficulty reasoning about transformations, and lack of hierarchical classification. Present evidence indicating that preschoolers are more capable thinkers than Piaget assumed.

Connect ■ Make-believe play promotes both cognitive and social development (see page 240). Explain why this is so.

Apply ■ Three-year-old Will understands that his tricycle isn't alive and can't feel or move on its own. But watching the setting sun, Will exclaimed, "The sun is tired. It's going to sleep!" Explain this apparent contradiction in Will's reasoning.

Reflect ■ Did you have an imaginary companion as a young child? If so, what was your companion like, and why did you create it? Were your parents aware of your companion? What was their attitude toward it?

The Concrete Operational Stage: 7 to 11 Years

- What are the major characteristics of Piaget's concrete operational stage?
- Discuss follow-up research on concrete operational thought.

According to Piaget, the **concrete operational stage,** extending from about 7 to 11 years, marks a major turning point in cognitive development. Thought becomes far more logical, flexible, and organized, more closely resembling the reasoning of adults than that of younger children.

Concrete Operational Thought

Concrete operations are evident in the school-age child's performance on a wide variety of Piagetian tasks. Let's look closely at these diverse accomplishments.

Conservation The ability to pass *conservation tasks* provides clear evidence of *operations*—mental actions that obey logical rules. In conservation of liquid, for example, children state that the amount of liquid has not changed, and they are likely to offer an explanation something like this: "The water's shorter, but it's also wider. Pour it back—you'll see it's the same amount." Notice how the child is capable of *decentration,* focusing on several aspects of a problem and relating them, rather than centering on only one. This explanation also illustrates *reversibility*—the capacity to imagine the water being returned to the original container as proof of conservation.

© LAURA DWIGHT PHOTOGRAPHY

This 8-year-old carefully sorts and classifies the rocks in his collection. An improved ability to categorize underlies school-age children's interest in collecting objects.

Classification

Between ages 7 and 10, children pass Piaget's *class inclusion problem.* This indicates that they are more aware of classification hierarchies and can focus on relations between a general and two specific categories at the same time—that is, on three relations at once (Hodges & French, 1988; Ni, 1998). Collections—stamps, coins, rocks, bottle caps—become common in middle childhood. At age 10, one boy I know spent hours sorting and resorting his large box of baseball cards, grouping them first by league and team membership, then by playing position and batting average. He easily separated the players into various classes and subclasses and could rearrange them.

Seriation

The ability to order items along a quantitative dimension, such as length or weight, is called **seriation.** To test for it, Piaget asked children to arrange sticks of different lengths from shortest to longest. Older preschoolers can put the sticks in a row to create the series, but they do so haphazardly, making many errors. In contrast, 6- to 7-year-olds create the series efficiently, moving in an orderly sequence from the smallest stick to the next largest, and so on.

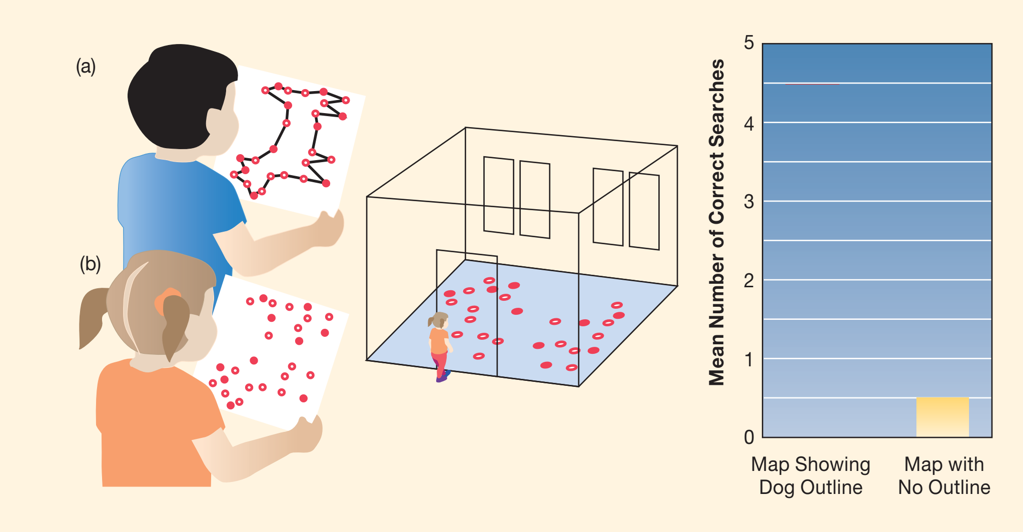
The concrete operational child can also seriate mentally, an ability called **transitive inference.** In a well-known problem, Piaget (1967) showed children pairings of sticks of different colors. From observing that stick *A* is longer than stick *B* and that stick *B* is longer than stick *C,* children must infer that *A* is longer than *C.* Like Piaget's class inclusion task, transitive inference requires children to integrate three relations at once: *A–B, B–C, A–C.* When researchers take steps to ensure that children remember the premises (*A–B* and *B–C*), 7-year-olds grasp transitive inference (Andrews & Halford, 1998; Wright, 2006).

Spatial Reasoning

Piaget found that school-age children's understanding of space is more accurate than that of preschoolers. Let's consider children's **cognitive maps**—mental representations of familiar large-scale spaces, such as their neighborhood or school. Drawing a map of a large-scale space requires considerable perspective-taking skill. Because the entire space cannot be seen at once, children must infer its layout by relating its separate parts.

Preschoolers and young school-age children include *landmarks* on the maps they draw, but their arrangement is not always accurate. They do better when asked to place stickers showing the location of desks and people on a map of their classroom. But if the map is rotated to a position other than the orientation of the classroom, they have difficulty (Liben & Downs, 1993). Their use of a rotated map to find objects hidden in a room improves when the locations form a meaningful pattern, such as the outline of a dog (see Figure 6.12) (Uttal et al., 2001). Pointing out the pattern helps children *reason by analogy* from the rotated map to corresponding locations in the room.

FIGURE 6.12 **Five-year-olds' use of a rotated map to find objects hidden in a room.** In one condition (a), locations on the map were connected to form a meaningful pattern—the outline of a dog. In a second condition (b), the locations on the map were not connected. The map showing the dog outline resulted in more correct searches for a hidden object than the map with no outline. (Adapted from Uttal et al., 2001.)



© ELLEN B. SENISI PHOTOGRAPHY

A 6-year-old's drawing of a neighborhood map depicts familiar buildings and other landmarks, but she does not yet place them accurately along a route of travel.

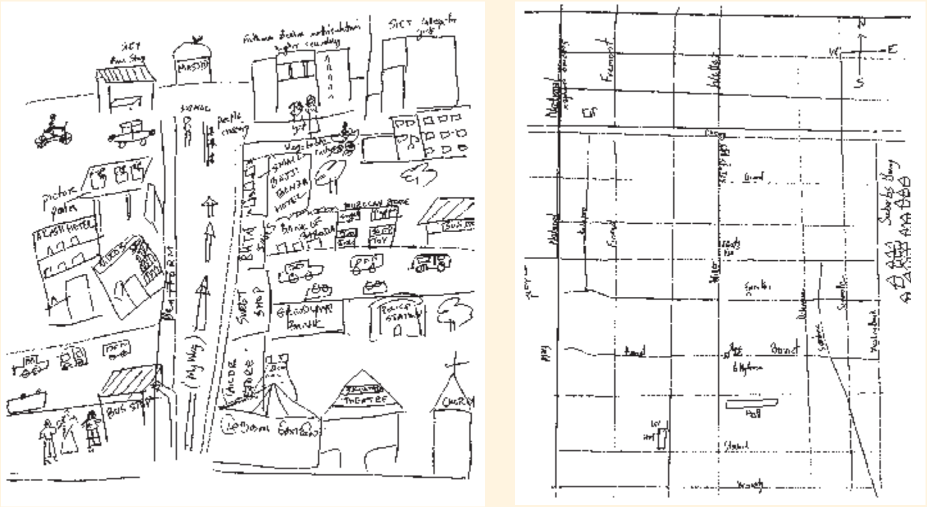
Around age 8 to 10, children's maps become better organized, showing landmarks along an *organized route of travel.* At the same time, children are able to give clear, well-organized directions for getting from place to place by using a "mental walk" strategy—imagining a person's movements along a route (Gauvain & Rogoff, 1989). By the end of middle childhood, children combine landmarks and routes into an *overall view of a large-scale space.* And they readily draw and read maps of extended outdoor environments, even when the orientation of the map and the space it represents do not match (Liben, 2009). Ten- to 12-year-olds also comprehend *scale*—the proportional relation between a space and its representation on a map (Liben, 2006).

Map-related experiences enhance children's map skills. When teachers asked fourth graders to write down the clues they used to decide where stickers (signifying landmark locations) should go on a map of an outdoor space, children's accuracy improved greatly (Kastens & Liben, 2007). Such self-generated explanations seem to induce learners to reflect on and revise their own thinking, sparking gains in many types of problem solving among school-age children and adolescents. And a computer-based curriculum called *Where Are We,* consisting of 12 map-reading and map-making lessons, led to substantial improvements in second to fourth graders' performance on diverse mapping tasks (Liben, Kastens, & Stevenson, 2001).

Cultural frameworks influence children's map making. In many non-Western communities, people rarely use maps for way finding but rely on information from neighbors, street vendors, and shopkeepers. Also, compared to their Western agemates, non-Western children less often ride in cars and more often walk, which results in intimate neighborhood knowledge. When 12-year-olds in small cities in India and in the United States drew maps of their neighborhoods, the Indian children represented many landmarks and aspects of social life, such as people and vehicles, in a small area near their home. The U.S. children drew a more formal, extended space, highlighting main streets and key directions (north–south, east–west) but including few landmarks (see Figure 6.13) (Parameswaran, 2003). Although the U.S. children's maps scored higher in cognitive maturity, this difference reflected cultural interpretations of the task. When asked to create a map to "help people find their way," the Indian children drew spaces as far-reaching and organized as the U.S. children's.

LOOK and LISTEN

Ask a 6- to 8-year-old and a 9- to 12-year-old to draw a neighborhood map showing important landmarks, such as the school, a friend's house, or a shopping area. In what ways do the children's maps differ?



(a) (b)

FIGURE 6.13 Maps drawn by 12-year-olds from India and the United States. (a) The Indian child depicted many landmarks and features of social life in a small area near her home. (b) The U.S. child drew a more extended space and highlighted main streets and key directions. (Reprinted from *Journal of Environmental Psychology,* Vol. 23, No. 4, G. Parameswaran, 2003, "Experimenter Instructions as a Mediator in the Effects of Culture on Mapping One's Neighborhood," pp. 415–416. Copyright 2003, with permission from Elsevier.)

Limitations of Concrete Operational Thought

As the name of this stage suggests, concrete operational thinking suffers from one important limitation: Children think in an organized, logical fashion only when dealing with concrete information they can perceive directly. Their mental operations work poorly with abstract ideas—ones not apparent in the real world. Consider children's solutions to transitive inference problems. When shown pairs of sticks of unequal length, children 7 years and older readily figure out that if stick *A* is longer than stick *B* and stick *B* is longer than stick *C*, then *A* is longer than *C*. But until age 11 or 12, they have difficulty with a hypothetical version of this task: "Susan is taller than Sally and Sally is taller than Mary. Who is the tallest?"

That logical thought is at first tied to immediate situations helps account for a special feature of concrete operational reasoning: Children master concrete operational tasks step by step. For example, they usually grasp conservation of number first, then liquid and mass, and then weight. This *continuum of acquisition* (or gradual mastery) of logical concepts is another indication of the limitations of concrete operational thinking (Fischer & Bidell, 1991). Rather than coming up with general logical principles that they apply to all relevant situations, school-age children seem to work out the logic of each problem separately.

Follow-Up Research on Concrete Operational Thought

According to Piaget, brain development combined with rich and varied experiences should lead children everywhere to reach the concrete operational stage. Yet already we have seen that specific cultural and teaching practices affect children's task performance (Rogoff, 2003).

In tribal and village societies, conservation is often delayed. Among the Hausa of Nigeria, who live in small agricultural settlements and rarely send their children to school, even basic conservation tasks—number, length, and liquid—are not understood until age 11 or later (Fahrmeier, 1978). This suggests that participating in relevant everyday activities helps children master conservation and other Piagetian problems (Light & Perrett-Clermont, 1989). Many children in Western nations, for example, think of fairness in terms of equal distribution—a value emphasized in their culture. They frequently divide materials, such as crayons or treats, equally among their friends. Because they often see the same quantity arranged in different ways, they grasp conservation early.

The very experience of going to school seems to promote mastery of Piagetian tasks. When children of the same age are tested, those who have been in school longer do better on transitive inference problems (Artman & Cahan, 1993). Opportunities to seriate objects, to learn about order relations, and to remember the parts of complex problems are probably responsible.

Yet certain informal, nonschool experiences can also foster operational thought. Brazilian 6- to 9-year-old street vendors, who seldom attend school, do poorly on Piaget's class inclusion tasks. But they perform much better than economically advantaged schoolchildren on versions relevant to street vending—for example, "If you have 4 units of mint chewing gum and 2 units of grape chewing gum, is it better to sell me the mint gum or [all] the gum?" (Ceci & Roazzi, 1994). Similarly, around age 7 to 8, Zinacanteco Indian girls of southern Mexico, who learn to weave elaborately designed fabrics as an alternative to schooling, engage in mental transformations to figure out how a warp strung on a loom will turn out as woven cloth—reasoning expected at the concrete operational stage. American children of the same age, who do much better than Zinacanteco children on Piagetian tasks, have great difficulty with these weaving problems (Maynard & Greenfield, 2003).

On the basis of such findings, some investigators have concluded that the forms of logic required by Piagetian tasks do not emerge spontaneously but are heavily influenced by training, context, and cultural conditions. The Milestones table on the following page summarizes the cognitive attainments of middle childhood discussed in the preceding sections, along with those that will follow in adolescence.

© DAVID FRAZIER/THE IMAGE WORKS

This Brazilian street vendor might do poorly on Piagetian class inclusion tasks, but he is likely to understand that "all the chewing gum" represents a larger quantity than the amount of any one flavor.

Milestones

Some Cognitive Attainments of Middle Childhood and Adolescence

APPROXIMATE AGE		COGNITIVE ATTAINMENTS
Middle childhood **7–11 years**		- Thinks in a more organized, logical fashion about concrete information, as indicated by gradual mastery of Piagetian conservation, class inclusion, and seriation problems, including transitive inference - Displays more effective spatial reasoning, as indicated by ability to construct well-organized cognitive maps and give clear directions
Adolescence **11–18 years**		- Reasons abstractly in situations that offer many opportunities for hypothetico-deductive reasoning and propositional thought - Grasps the logical necessity of propositional thought, permitting reasoning about premises that contradict reality - Displays imaginary audience and personal fable, which gradually decline - Improves in decision-making strategies

Note: These milestones represent overall age trends. Individual differences exist in the precise age at which each milestone is attained.

ASK YOURSELF

Review ■ Children's performance on conservation tasks illustrates a continuum of acquisition of logical concepts. Review the preceding sections, and list additional examples of gradual development of operational reasoning.

Connect ■ Using research on cognitive maps, conservation, and class inclusion, explain how tasks not adapted to children's cultural contexts can underestimate their cognitive competencies.

Apply ■ Nine-year-old Adrienne spends many hours helping her father build furniture in his woodworking shop. How might this experience facilitate Adrienne's advanced performance on Piagetian seriation problems?

Reflect ■ Which aspects of Piaget's description of the concrete operational stage do you accept? Which do you doubt? Explain, citing research evidence.

The Formal Operational Stage: 11 Years and Older

- Describe major characteristics of the formal operational stage and typical consequences of adolescents' advancing cognition.
- What does follow-up research reveal about formal operational thought?

According to Piaget, around age 11 young people enter the **formal operational stage,** in which they develop the capacity for abstract, systematic, scientific thinking. Whereas concrete operational children can "operate on reality," formal operational adolescents can "operate on operations." They no longer require concrete things or events as objects of thought. Instead, they can come up with new, more general logical rules through internal reflection (Inhelder & Piaget, 1955/1958). Let's look at two major features of the formal operational stage.

Hypothetico-Deductive Reasoning

Piaget believed that at adolescence, young people become capable of **hypothetico-deductive reasoning.** When faced with a problem, they start with a *hypothesis,* or prediction about variables that might affect an outcome, from which they *deduce* logical, testable inferences.

Then they systematically isolate and combine variables to see which of these inferences are confirmed in the real world. Notice how this form of problem solving begins with possibility and proceeds to reality. In contrast, concrete operational children start with reality—with the most obvious predictions about a situation. If these are not confirmed, they usually cannot think of alternatives and fail to solve the problem.

Adolescents' performance on Piaget's famous *pendulum problem* illustrates this new approach. Suppose we present several school-age children and adolescents with strings of different lengths, objects of different weights to attach to the strings, and a bar from which to hang the strings (see Figure 6.14). Then we ask each of them to figure out what influences the speed with which a pendulum swings through its arc.

Formal operational adolescents hypothesize that four variables might be influential: (1) the length of the string, (2) the weight of the object hung on it, (3) how high the object is raised before it is released, and (4) how forcefully the object is pushed. By varying one factor at a time while holding the other three constant, they test each variable separately and, if necessary, also in combination. Eventually they discover that only string length makes a difference.

In contrast, concrete operational children cannot separate the effects of each variable. They may test for the effect of string length without holding weight constant—comparing, for example, a short, light pendulum with a long, heavy one. Also, they typically fail to notice variables that are not immediately suggested by the concrete materials of the task—for example, how high the object is raised or how forcefully it is released.

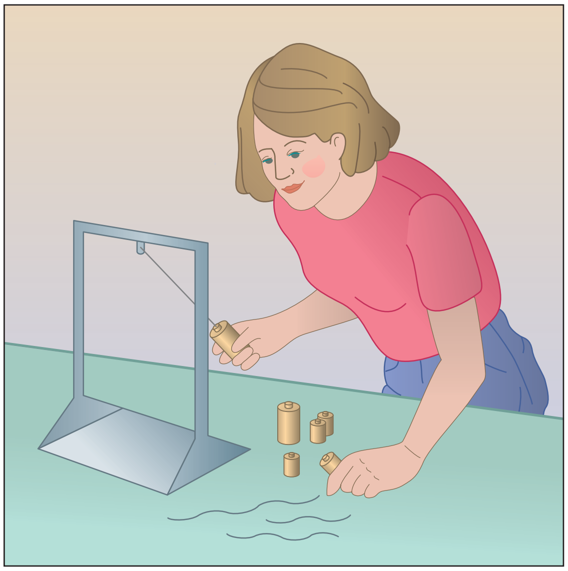

FIGURE 6.14 **Piaget's pendulum problem.** Adolescents who engage in hypothetico-deductive reasoning think of variables that might possibly affect the speed with which a pendulum swings through its arc. Then they isolate and test each variable, as well as testing the variables in combination. Eventually they deduce that the weight of the object, the height from which it is released, and how forcefully it is pushed have no effect. Only string length makes a difference.

Propositional Thought

A second important characteristic of Piaget's formal operational stage is **propositional thought**—adolescents' ability to evaluate the logic of propositions (verbal statements) without referring to real-world circumstances. In contrast, children can evaluate the logic of statements only by considering them against concrete evidence in the real world.

In a study of propositional reasoning, an adult showed children and adolescents a pile of poker chips and asked whether statements about the chips were true, false, or uncertain (Osherson & Markman, 1975). In one condition, the adult hid a chip in her hand and then presented the following propositions:

> "*Either* the chip in my hand is green *or* it is not green."
> "The chip in my hand is green *and* it is not green."

In another condition, the researcher made the same statements while holding either a red or a green chip in full view.

School-age children focused on the concrete properties of the poker chips. When the chip was hidden, they replied that they were uncertain about both statements. When it was visible, they judged both statements to be true if the chip was green and false if it was red. In contrast, adolescents analyzed the logic of the statements. They understood that the "either-or" statement is always true and the "and" statement is always false, regardless of the poker chip's color.

Although Piaget did not view language as playing a central role in cognitive development, he acknowledged its importance in adolescence. Formal operations require language-based and other symbolic systems that do not stand for real things, such as those in higher mathematics. Secondary school students use such systems in algebra and geometry. Formal operational thought also involves

© CINDY CHARLES/PHOTOEDIT

In Piaget's formal operational stage, adolescents engage in propositional thought. As these students discuss problems in a social studies class, they reason logically with propositions that do not refer to real-world circumstances.

APPLYING WHAT WE KNOW

Handling Consequences of Teenagers' New Cognitive Capacities

ABSTRACT THOUGHT EXPRESSED AS . . .	SUGGESTION
Sensitivity to public criticism	Refrain from finding fault with the adolescent in front of others. If the matter is important, wait until you can speak to the teenager alone.
Exaggerated sense of personal uniqueness	Acknowledge the adolescent's unique characteristics. At opportune times, encourage a more balanced perspective by pointing out that you had similar feelings as a young teenager.
Idealism and criticism	Respond patiently to the adolescent's grand expectations and critical remarks. Point out positive features of targets, helping the teenager see that all societies and people are blends of virtues and imperfections.
Difficulty making everyday decisions	Refrain from deciding for the adolescent. Model effective decision making, and offer diplomatic suggestions about the pros and cons of alternatives, the likelihood of various outcomes, and learning from poor choices.

verbal reasoning about abstract concepts. Adolescents show that they can think in this way when they ponder the relations among time, space, and matter in physics or wonder about justice and freedom in philosophy.

Consequences of Adolescent Cognitive Changes

The development of increasingly complex, effective thinking leads to dramatic revisions in the way adolescents see themselves, others, and the world in general. But just as adolescents are occasionally awkward in using their transformed bodies, so they initially falter in their more advanced thinking. Teenagers' self-concern, idealism, criticism, and indecisiveness, though perplexing to adults, are usually beneficial in the long run. Applying What We Know above suggests ways to handle the everyday consequences of teenagers' newfound cognitive capacities.

Self-Consciousness and Self-Focusing Adolescents' ability to reflect on their own thoughts, combined with physical and psychological changes they are undergoing, leads them to think more about themselves. Piaget believed that a new form of egocentrism arises, in which adolescents again have difficulty distinguishing their own and others' perspectives (Inhelder & Piaget, 1955/1958). Piaget's followers suggest that two distorted images of the relationship between self and others appear.

The first is called the **imaginary audience,** adolescents' belief that they are the focus of everyone else's attention and concern (Elkind & Bowen, 1979). As a result, they become extremely self-conscious, often going to great lengths to avoid embarrassment. The imaginary audience helps explain the long hours adolescents spend inspecting every detail of their appearance and why they are so sensitive to public criticism. To teenagers, who believe that everyone is monitoring them, a critical remark from a parent or teacher can be mortifying.

A second cognitive distortion is the **personal fable.** Certain that others are observing and thinking about them, teenagers develop an inflated opinion of their own importance—a feeling that they are special and unique. Many adolescents view themselves as reaching great heights of omnipotence and also sinking to unusual depths of despair—experiences others cannot possibly understand (Elkind, 1994). One teenager wrote in her diary, "My parents' lives are so ordinary, so stuck in a rut. Mine will be different. I'll realize my hopes and ambitions." Another, upset when a boyfriend failed to return her affections, rebuffed her mother's comforting words: "Mom, you don't know what it's like to be in love!"

© ANTONIO MO/GETTY IMAGES/PHOTODISC

This teenager's swagger reflects self-confidence and delight that all eyes are on him. As long as the personal fable engenders a view of oneself as highly capable and influential, it may help young people cope with the challenges of adolescence.

Although imaginary-audience and personal-fable ideation is common in adolescence, these distorted visions of the self do not result from egocentrism, as Piaget suggested. Rather, they are partly an outgrowth of advances in perspective taking, which cause young teenagers to be more concerned with what others think (Vartanian & Powlishta, 1996).

In fact, certain aspects of the imaginary audience may serve positive, protective functions. In a study in which adolescents were asked why they worry about the opinions of others, they responded that they do so because others' evaluations have important *real* consequences—for self-esteem, peer acceptance, and social support (Bell & Bromnick, 2003). The idea that others care about their appearance and behavior also has emotional value, helping teenagers hold onto important relationships as they struggle to separate from parents and establish an independent sense of self (Vartanian, 1997).

With respect to the personal fable, in an investigation of sixth through tenth graders, sense of omnipotence predicted self-esteem and overall positive adjustment. Viewing the self as highly capable and influential helps young people cope with the challenges of adolescence. In contrast, sense of personal uniqueness was modestly associated with depression and suicidal thinking (Aalsma, Lapsley, & Flannery, 2006). Focusing on the distinctiveness of one's own experiences may interfere with forming close, rewarding relationships, which provide social support in stressful times. And when combined with a sensation-seeking personality, the personal fable seems to contribute to adolescent risk taking by reducing teenagers' sense of vulnerability (Alberts, Elkind, & Ginsberg, 2007). Young people with high personal-fable and sensation-seeking scores tend to take more sexual risks, more often use drugs, and commit more delinquent acts than their agemates (Greene et al., 2000).

Idealism and Criticism

Because abstract thinking permits adolescents to think about possibilities, it opens up the world of the ideal. Teenagers can imagine alternative family, religious, political, and moral systems, and they want to explore them. They often construct grand visions of a world with no injustice, discrimination, or tasteless behavior. The disparity between teenagers' idealism and adults' more realistic view creates tension between parent and child. Envisioning a perfect family against which their parents and siblings fall short, adolescents become fault-finding critics.

Overall, however, teenage idealism and criticism are advantageous. Once adolescents come to see other people as having both strengths and weaknesses, they are better able to work for social change and to form positive, lasting relationships (Elkind, 1994).

Decision Making

Adolescents handle many cognitive tasks more effectively than they did when younger. But recall from Chapter 5 that changes in the brain's emotional/social network outpace development of the prefrontal cortex's cognitive-control network. Consequently, teenagers perform less well than adults in planning and decision making, where they must inhibit emotion and impulses in favor of thinking rationally.

Good decision making involves: (1) identifying pros and cons of each alternative, (2) assessing the likelihood of various outcomes, (3) evaluating one's choice in terms of whether one's goals were met, and, if not, (4) learning from the mistake and making a better future decision. When researchers modified a card game to trigger strong emotion by introducing immediate feedback about gains and losses after each choice, teenagers behaved more irrationally, taking far greater risks than adults in their twenties (Figner et al., 2009). In a second condition, in which players were merely asked what they would do at each step of the game but were not given feedback, adolescents and adults did not differ in quality of decision making. Additional evidence confirms that adolescents, relative to adults, are more influenced by the possibility of immediate reward—more willing to take risks and less likely to avoid potential harm (Cauffman et al., 2010; Ernst & Spear, 2009; Steinberg et al., 2009).

Nevertheless, other research indicates that teenagers are less effective than adults at decision making even under "cool," unemotional conditions (Huizenga, Crone, & Jansen, 2007). In one study, participants were given challenging hypothetical real-world dilemmas—whether to have cosmetic surgery, which parent to live with after divorce—and asked to explain how they would decide. Adults outperformed adolescents, more often considering alternatives, weighing benefits and risks, and suggesting advice seeking, especially in areas (such as medical decisions) where they had little experience (Halpern-Felsher & Cauffman, 2001).

Furthermore, in making decisions, adolescents, more often than adults (who also have difficulty), fall back on well-learned intuitive judgments (Jacobs & Klaczynski, 2002). Consider a hypothetical problem requiring a choice, on the basis of two arguments, between taking a traditional lecture class and taking a computer-based class. One argument contains large-sample information: course evaluations from 150 students, 85 percent of whom liked the computer class. The other argument contains small-sample personal reports: complaints of two honor-roll students who both hated the computer class and enjoyed the traditional class. Many adolescents, even though they knew that selecting the large-sample argument was "more intelligent," still based their choice on the small-sample argument, which resembled the informal opinions they depend on in everyday life (Klaczynski, 2001).

In sum, the heat of the moment, when making a good decision depends on inhibiting "feel-good" behavior and the appeal of immediate rewards, the brain's emotional/social network tends to prevail, and adolescents are far more likely than adults to emphasize short-term over long-term goals. In Chapter 5, we also noted that processing skills governed by the prefrontal cognitive-control system develop gradually, into the early twenties. Like other aspects of brain development, the cognitive-control system is affected by experience (Kuhn, 2009). As "first-timers" in many situations, adolescents do not have sufficient knowledge to consider pros and cons and predict likely outcomes. After engaging in risky behavior without negative consequences, teenagers rate its benefits higher and its risks lower than peers who have not tried it (Halpern-Felsher et al., 2004).

Over time, young people learn from their successes and failures, gather information from others about factors that affect decision making, and reflect on the decision-making process (Byrnes, 2003; Reyna & Farley, 2006). But because engaging in risk taking without experiencing harm can heighten adolescents' sense of invulnerability, they need supervision and protection from high-risk experiences until their decision making improves.

Follow-Up Research on Formal Operational Thought

Research on formal operational thought poses questions similar to those we discussed with respect to Piaget's earlier stages: Does formal operational thinking appear earlier than Piaget expected? Do all individuals reach formal operations during their teenage years?

Are Children Capable of Hypothetico-Deductive and Propositional Thinking?

School-age children show the glimmerings of hypothetico-deductive reasoning. In simplified situations involving no more than two possible causal variables, 6-year-olds understand that hypotheses must be confirmed by appropriate evidence. They also realize that once a hypothesis is supported, it shapes predictions about what might happen in the future (Ruffman et al., 1993). But school-age children cannot sort out evidence that bears on three or more variables at once. And as we will see when we take up information-processing research on scientific reasoning in Chapter 7, children have difficulty explaining why a pattern of observations supports a hypothesis, even when they recognize the connection between the two.

With respect to propositional thought, when a simple set of premises defies real-world knowledge ("All cats bark. Rex is a cat. Does Rex bark?"), 4- to 6-year-olds can reason logically in make-believe play. In justifying their answer, they are likely to say, "We can pretend cats bark!" (Dias & Harris, 1988, 1990). But in an entirely verbal mode, children have great difficulty reasoning from premises that contradict reality or their own beliefs.

Consider this set of statements: "If dogs are bigger than elephants and elephants are bigger than mice, then dogs are bigger than mice." Children younger than age 10 judge this reasoning to be false because not all of the relations specified occur in real life (Moshman & Franks, 1986; Pillow, 2002). They have more trouble than adolescents inhibiting activation of well-learned knowledge ("Elephants are larger than dogs") that impedes effective reasoning (Klaczynski, Schuneman, & Daniel, 2004; Simoneau & Markovits, 2003). Partly for this reason, they fail to grasp the **logical necessity** of propositional thought—that the accuracy of conclusions drawn from premises rests on the rules of logic, not on real-world confirmation.

Furthermore, in reasoning with propositions, school-age children rarely think carefully about the major premise and, therefore, violate the most basic rules of logic (Markovits, Schleifer, & Fortier, 1989). For example, when given the following problem, they almost always draw an incorrect conclusion:

> *Major premise:* If Susan hits a tambourine, then she will make a noise.
> *Second premise:* Suppose that Susan does not hit a tambourine.
> *Question:* Did Susan make a noise?
> *Wrong conclusion:* No, Susan did not make a noise.

Notice that the major premise did *not* state that Susan makes a noise *if, and only if,* she hits a tambourine. Adolescents generally detect that Susan could make noise in other ways, partly because they are better at searching their knowledge for examples that contradict wrong conclusions (Klaczynski, 2004; Markovits & Barrouillet, 2002).

As with hypothetico-deductive reasoning, in early adolescence young people become better at analyzing the *logic* of propositions, regardless of their *content.* And as they get older, they handle problems requiring increasingly complex mental operations. In justifying their reasoning, they move from giving a concrete example ("She could have hit a drum instead of a tambourine") to explaining the logical rules on which it is based ("We can be certain that Susan did not hit a tambourine. But we cannot be certain that Susan did not make a noise; she might have done so in many other ways") (Müller, Overton, & Reese, 2001; Venet & Markovits, 2001). These capacities, however, do not appear suddenly at puberty. Rather, gains occur gradually from childhood on—findings that call into question the emergence of a new stage of cognitive development at adolescence (Kuhn, 2009; Moshman, 2005).

Do All Individuals Reach the Formal Operational Stage?

TAKE A MOMENT... Try giving one or two of the formal operational tasks just described to your friends. How well do they do? Even well-educated adults often have difficulty (Kuhn, 2009; Markovits & Vachon, 1990)!

Why are so many adults not fully formal operational? One reason is that people are most likely to think abstractly and systematically on tasks in which they have had extensive guidance and practice in using such reasoning. This conclusion is supported by evidence that taking college courses leads to improvements in formal reasoning related to course content. Math and science prompt gains in propositional thought, social science in methodological and statistical reasoning (Lehman & Nisbett, 1990). Like concrete reasoning in children, formal operations do not emerge in all contexts at once but are specific to situation and task (Keating, 2004).

Individuals in tribal and village societies rarely do well on tasks typically used to assess formal operational reasoning (Cole, 1990). For example, people in nonliterate societies often refuse requests to engage in propositional thought. Take this hypothetical proposition: "In the North, where there is snow, all bears are white. Novaya Zemlya is in the Far North, and it always has snow. What color are the bears there?" In response, a Central Asian peasant explains that he must see the event to discern its logical implications. Yet the peasant uses

These adolescents of Indonesia's highland rainforests would probably have difficulty with Piaget's formal operational tasks. But in familiar situations, they exhibit complex reasoning, coordinating multiple variables as they construct a tree house.

propositions to defend his point of view: "*If* a man . . . had seen a white bear and had told about it, [*then*] he could be believed, *but* I've never seen one and *hence* I can't say" (Luria, 1976, pp. 108–109). Although he rarely displays it in everyday life, the peasant is clearly capable of formal operational thought!

Piaget acknowledged that without the opportunity to solve hypothetical problems, people in some societies might not display formal operations. Still, researchers ask, Does formal operational thinking result largely from children's and adolescents' independent efforts to make sense of their world, as Piaget claimed? Or is it a culturally transmitted way of thinking that is specific to literate societies and is taught in school? In an Israeli study of seventh to ninth graders, after controlling for participants' age, researchers found that years of schooling fully accounted for early adolescent gains in propositional thought (Artman, Cahan, & Avni-Babad, 2006). School tasks, the investigators speculated, provide crucial experiences in setting aside the "if . . . then" logic of everyday conversations that is often used to convey intentions, promises, and threats ("If you don't do your chores, then you won't get your allowance") but that conflicts with the logic of academic reasoning. In school, then, adolescents encounter rich opportunities to realize their neurological potential to think more effectively.

Piaget and Education

▶ Describe educational implications of Piaget's theory.

Three educational principles derived from Piaget's theory continue to influence teacher training and classroom practices, especially during early childhood:

- *Discovery learning.* In a Piagetian classroom, children are encouraged to discover for themselves through spontaneous interaction with the environment. Instead of presenting ready-made knowledge verbally, teachers provide a rich variety of activities designed to promote exploration and discovery, including art, puzzles, table games, dress-up clothing, building blocks, books, measuring tools, natural science tasks, and musical instruments.
- *Sensitivity to children's readiness to learn.* In a Piagetian classroom, teachers introduce activities that build on children's current thinking, challenging their incorrect ways of viewing the world. But they do not try to speed up development by imposing new skills before children indicate they are interested and ready.
- *Acceptance of individual differences.* Piaget's theory assumes that all children go through the same sequence of development, but at different rates. Therefore, teachers must plan activities for individual children and small groups, not just for the whole class. In addition, teachers evaluate educational progress in relation to the child's previous development, rather than on the basis of normative standards, or average performance of same-age peers.

Like his stages, educational applications of Piaget's theory have met with criticism, especially his insistence that young children learn mainly through acting on the environment and his neglect of other important avenues, such as verbal teaching and corrective feedback (Brainerd, 2003). Nevertheless, Piaget's influence on education has been powerful. He gave teachers new ways to observe, understand, and enhance young children's development and offered strong theoretical justification for child-oriented approaches to teaching.

▶ Summarize contributions and shortcomings of Piaget's theory.

Overall Evaluation of Piaget's Theory

Piaget's contributions to the field of child development are greater than those of any other theorist. He awakened psychologists and educators to a view of children as curious knowledge seekers who contribute actively to their own development. And his pioneering efforts to both describe and explain development inspired the current focus on *mechanisms of cognitive change*—precise accounts of biological, psychological, and environmental factors that lead children to modify their thinking, which we will encounter in Chapter 7 (McClelland & Siegler, 2001). Finally, Piaget's theory offers a useful "road map" of development that is accurate in many respects, though incorrect in others. His cognitive milestones remain powerful aids to understanding emotional, social, and moral development.

Nevertheless, the wealth of research that Piaget's theory inspired has uncovered weaknesses in his theory. Let's consider two major challenges posed by his critics.

Is Piaget's Account of Cognitive Change Clear and Accurate?

Piaget's explanation of cognitive change focuses on broad transformations in thinking through equilibration and its attendant processes of adaptation and organization. But exactly what the child does to equilibrate is vague. Recall our description of *organization*—that the structures of each stage form a coherent whole. Piaget was not explicit about how the diverse achievements of each stage are bound together by a single, underlying form of thought—and efforts to confirm this coherence have not succeeded. On a variety of tasks, infants and young children appear more competent, and adolescents and adults less competent, than Piaget assumed. Today, researchers agree that the child's efforts to assimilate, accommodate, and reorganize structures cannot adequately explain these patterns of change.

Furthermore, Piaget's belief that infants and young children must act on the environment to revise their thinking is too narrow a notion of how learning takes place. We have seen that as early as 2 to 3 months, babies group objects into categories and have some awareness of hidden objects—findings inconsistent with manual activity as the principal means of cognitive change (Johnson, 2010). And without explicit adult teaching, including verbal explanations, children may not always notice or come to understand aspects of a situation necessary for building more effective schemes. With its overemphasis on the child's initiative, Piaget's theory has been of limited practical value in devising teaching strategies that foster children's optimum learning.

© ELLEN SENISI/THE IMAGE WORKS

Piaget believed that young children learn mainly by acting on the environment, but adult teaching is also essential. In this hands-on science lesson, children look to their teacher for guidance.

Does Cognitive Development Take Place in Stages?

We have seen that many cognitive changes proceed slowly and gradually. Also, periods of cognitive equilibrium are rare. Instead, children are constantly modifying structures and acquiring new skills. Today, virtually all experts agree that children's cognition is less broadly stagelike than Piaget believed (Bjorklund, 2012). Furthermore, contemporary researchers disagree on how general or specific cognitive development actually is.

Some theorists agree with Piaget that development is a *general process,* following a similar course across the diverse cognitive domains of physical, numerical, and social knowledge. But they reject the existence of stages, believing instead that thought processes are alike at all ages—just present to a greater or lesser extent—and that variations in children's knowledge and experience largely account for uneven performance across domains. These assumptions form the basis of the *information-processing perspective,* discussed in Chapter 7.

Other researchers think that the stage notion is valid but that it must be modified. They point to strong evidence for certain stagelike changes, such as the flourishing of representation around age 2 and the move toward abstract, systematic thinking in adolescence. Yet they also recognize many smaller developments that lead up to these transformations. In Chapter 7, we will consider a *neo-Piagetian perspective* that combines Piaget's stage approach with information-processing ideas (Case, 1996, 1998; Halford, 2002; Halford & Andrews, 2006). In this view, Piaget's strict definition of stage is modified into a less tightly knit concept, in which related competencies develop over an extended period, depending on brain development and specific experiences.

Still others deny not only Piaget's stages but also his belief that the human mind is made up of general reasoning abilities that can be applied to any cognitive task. They argue that the remarkable competencies of infants and young children indicate that cognitive development begins with far more than sensorimotor reflexes. Rather, infants come into the world with several basic, built-in types of knowledge, each of which jump-starts vital aspects of cognition. We will take up this *core knowledge* perspective in the next section.

Piaget's Legacy

Although Piaget's description of development is no longer fully accepted, researchers are far from consensus on how to modify or replace it. Some have begun to search for points of contact among the alternative perspectives just mentioned. Others blend Piaget's emphasis on the child as an active agent with a stronger role for context—the objects, events, and people in children's lives. For example, followers of Vygotsky's theory are intensively studying social and cultural influences on children's thinking—an area Piaget neglected.

Diverse theories and lines of investigation leave research into children's thinking far more fragmented today than several decades ago, when Piaget's theory held sway. Nevertheless, researchers continue to draw inspiration from Piaget's vision of the child as an active, constructive learner and his lifelong quest to understand how children acquire new capacities. Piaget's findings have served as the starting point for virtually every major contemporary line of research on cognitive development.

The Core Knowledge Perspective

- Explain the core knowledge perspective on cognitive development, noting research that supports its assumptions.
- What are the strengths and limitations of the core knowledge perspective?

According to the **core knowledge perspective,** infants begin life with innate, special-purpose knowledge systems referred to as *core domains of thought.* Each of these "prewired" understandings permits a ready grasp of new, related information and therefore supports early, rapid development of certain aspects of cognition. Each core domain has a long evolutionary history and is essential for survival (Carey & Markman, 1999; Leslie, 2004; Spelke, 2004; Spelke & Kinzler, 2007). Core knowledge theorists argue that infants could not make sense of the multifaceted stimulation around them without having been genetically "set up" in the course of evolution to comprehend its crucial aspects.

Two core domains have been studied extensively in infancy. The first is *physical knowledge*—in particular, understanding of objects and their effects on one another. The second is *numerical knowledge*—the capacity to keep track of multiple objects and to add and subtract small quantities. Physical and numerical knowledge enabled our ancestors to secure food and other resources from the environment.

The core knowledge perspective asserts that an inherited foundation makes possible remarkably advanced knowledge systems early in development. In Chapter 9, we will consider a nativist (or inborn) view of preschoolers' amazing language skill that regards *linguistic knowledge* as etched into the structure of the human brain. Furthermore, infants' early orientation toward people (see Chapter 4) provides the foundation for rapid development of *psychological knowledge*—in particular, understanding of people as agents who have mental states (such as emotions, intentions, desires, beliefs, and perspectives) that influence their behavior, which is vital for surviving in human groups. And young children demonstrate impressive *biological knowledge,* including ideas about inheritance of characteristics and about bodily processes, such as birth, growth, illness, and death.

Rather than regarding development as a general process, core knowledge theorists see it as *domain-specific* and uneven, with each core domain developing independently. And although initial knowledge is assumed to be innate, that knowledge becomes more elaborate as children explore, play, and interact with others (Geary & Bjorklund, 2000; Leslie, 2004; Spelke & Kinzler, 2007). Children are viewed as *naïve theorists,* building on core knowledge concepts to explain their everyday experiences in the physical, psychological, and biological realms. Let's examine a sampling of findings that shed light on the existence of core domains of thought.

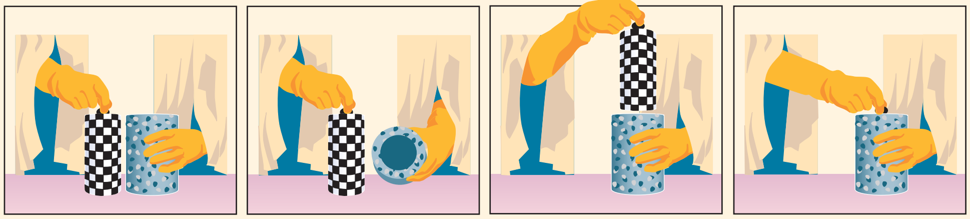
Infancy: Physical and Numerical Knowledge

Do infants display impressive physical and numerical understandings so early that some knowledge must be innate? Again, the violation-of-expectation method has been used to answer this question. Besides research on early awareness of object permanence (see page 231), core knowledge theorists point to evidence indicating that young infants are aware of basic object properties and that they build on this knowledge quickly, acquiring more detailed understandings as they are exposed to relevant outcomes in their everyday experiences (Baillargeon, 2004; Baillargeon et al., 2009; Luo & Baillargeon, 2005).

For example, 2½-month-olds seem to recognize that one solid object cannot move through another solid object. In one study, some infants saw an object lowered into a container with an opening, whereas others saw an object lowered into a container with no opening (see Figure 6.15). Babies in the closed-container condition looked longer, suggesting that this impossible event violated their notions of physical reality (Hespos & Baillargeon, 2001). By 6½ months, infants look longer when an object much wider than an opening appears to pass through that opening than they do at an appropriately sized object passing through (Aguiar & Baillargeon, 2003). Around 7½ months, infants spend more time looking at an object too tall to fit inside a container that disappears into the container than they do at an object that is the right height (Hespos & Baillargeon, 2001, 2006). And at 9½ months, they expect an object placed inside a transparent container to be visible through that container (Baillargeon et al., 2009).

Furthermore, in the first half-year, infants are sensitive to basic principles of object support. Babies as young as 4½ months stare intently at a box resting in midair, with nothing to hold it in place (Needham & Baillargeon, 1993). And 6½-month-olds' attention increases and their reaching behavior decreases when an object is placed on top of another object with most of its bottom surface not in contact with the lower object—conditions that would cause the top object to fall (Baillargeon, 1994; Hespos & Baillargeon, 2008). Around 8 months, infants are sensitive to position of contact: When a large, oblong box rests horizontally on a small, square box, babies expect the large box to be centered over the small box so it is adequately supported (Huettel & Needham, 2000).

Expected Event: Open-Container Condition



Unexpected Event: Closed-Container Condition

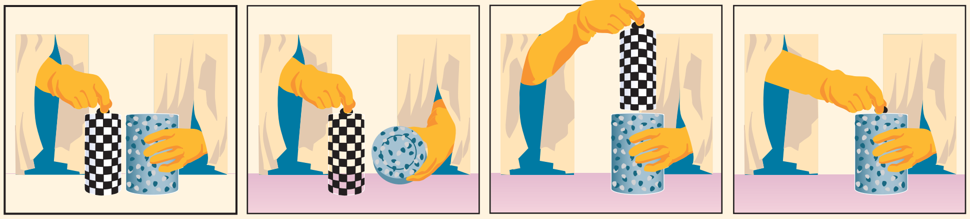


FIGURE 6.15 Testing infants for understanding of object solidity using the violation-of-expectation method. Infants in the *expected event: open-container condition* saw a tall object and a tall container standing a short distance apart. An adult's right hand grasped a knob attached to the top of the object, while her left hand rotated the container forward so infants could see its opening. After a few seconds, the container was returned to its original position. Then the right hand lifted the object and lowered it into the container. Finally, the hand lifted the object out of the container and set it down. Infants in the *unexpected event: closed-container condition* saw the same event, with one exception: The container's top was closed, so it should have been impossible for the object to be lowered into the container. (In fact, the container had a false, magnetic top that adhered to the bottom of the object, which could be lowered into it.) Infants as young as 2½ months looked longer at the unexpected, closed-container event, suggesting awareness of object solidity. (Adapted from S. J. Hespos & R. Baillargeon, "Reasoning About Containment Events in Very Young Infants," *Cognition, 78,* p. 213. © Elsevier. Reprinted with permission.)

Research also suggests that young infants have basic number concepts (Spelke, 2004; Spelke & Kinzler, 2007). In the best-known study, 5-month-olds saw a screen raised to hide a single toy animal, then watched a hand place a second toy behind the screen. Finally the screen was removed to reveal either one or two toys. As Figure 6.16 on page 264 reveals, infants looked longer at the impossible, one-toy display, suggesting that they kept track of the two objects, which would require them to add one object to another. In additional experiments using this task, 5-month-olds looked longer at three objects than two. These findings and those of similar investigations suggest that babies can discriminate quantities up to three and use that knowledge to perform simple arithmetic—both addition and subtraction (in which two objects are covered and one object is removed) (Kobayashi et al., 2004; Kobayashi, Hiraki, & Hasegawa, 2005; Wynn, Bloom, & Chiang, 2002).

Other research shows that 6-month-olds can distinguish among large sets of items when the difference between those sets is very great—at least a factor of two. For example, they can tell the difference between 8 and 16 dots but not between 6 and 12 (Lipton & Spelke, 2004; Xu, Spelke, & Goddard, 2005). Six-month-olds can also discriminate ratios—for example, several scenes in which the ratio of blue pellets to yellow Pac-Men is 2 to 1 from several scenes in which the ratio is 4 to 1 (McCrink & Wynn, 2007). And like the experiment in Figure 6.16, 9-month-olds can perform operations on sets of items, adding and subtracting (McCrink & Wynn, 2004). As a result, some researchers believe that infants can represent approximate large-number values, in addition to small-number discriminations.

These impressive findings suggest that some notion of quantity is present in the first year. But like other violation-of-expectation results, they are controversial (Bremner, 2010). Critics question whether other aspects of object displays, rather than numerical sensitivity, are responsible for the findings (Cohen &

If another duck is added or one is taken away, will this baby know that the quantity has changed? Research suggests that young infants can discriminate quantities up to three and use that knowledge to perform simple addition and subtraction.

© LESLEY HOWLING/AMANAIMAGES/CORBIS

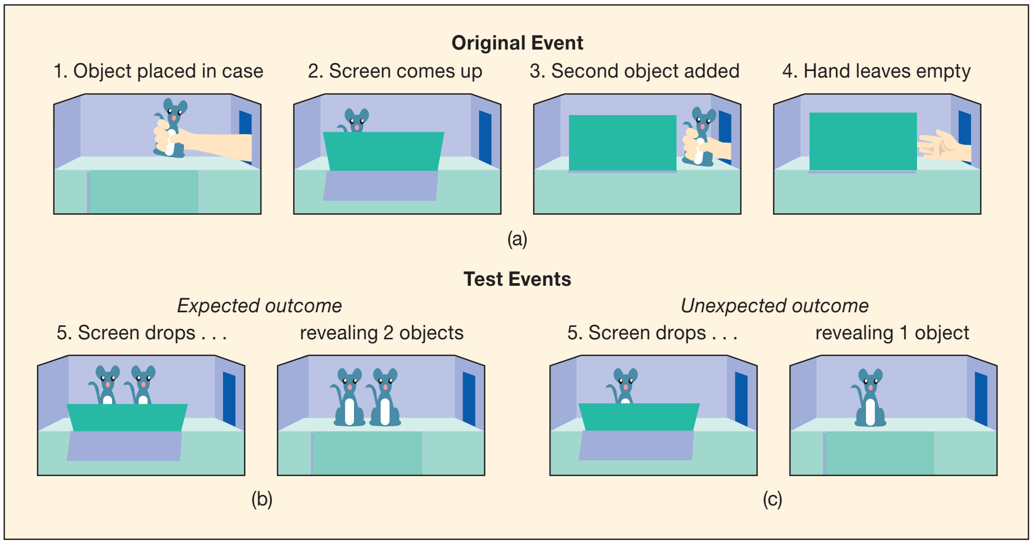

FIGURE 6.16 Testing infants for basic number concepts. (a) First, infants saw a screen raised in front of a toy animal. Then an identical toy was added behind the screen. Next, the researchers presented two outcomes. (b) In the *expected outcome,* the screen dropped to reveal two toy animals. (c) In the *unexpected outcome,* the screen dropped to reveal one toy animal. Five-month-olds shown the unexpected outcome looked longer than 5-month-olds shown the expected outcome. The researchers concluded that infants can discriminate the quantities "one" and "two" and use that knowledge to perform simple addition: 1 + 1 = 2. A variation of this procedure suggested that 5-month-olds could also do simple subtraction: 2 – 1 = 1. (From K. Wynn, 1992, "Addition and Subtraction by Human Infants." Adapted with permission of Macmillan Publishers Ltd., *Nature, 358,* p. 749.)

Marks, 2002; Langer, Gillette, & Arriaga, 2003; Mix, Huttenlocher, & Levine, 2002; Wakeley, Rivera, & Langer, 2000). According to these investigators, claims for infants' knowledge of number concepts are surprising, given other research indicating that before 14 to 16 months, toddlers have difficulty making less-than and greater-than comparisons between small sets. And as we will see in Chapter 7, not until the preschool years do children answer correctly when asked to add and subtract small sets of items.

Core knowledge theorists respond that infant looking behaviors may be a more reliable indicator of understanding than older children's verbal and motor behaviors, which may not always display their true competencies (Wynn, 2002). And ERP brain-wave recordings taken while babies view correct and incorrect solutions to simple arithmetic equations reveal a response pattern identical to the pattern adults show when they detect errors (Berger, Tzur, & Posner, 2006).

Finally, proponents of the core knowledge perspective point to studies of two peoples living in Brazil's remote Amazon regions, whose cultures have no verbal counting routines: the Piraha, who lack number words beyond "two" in their language; and the Munduruku, who have number words only up to "three." Despite this numerical language deprivation (which impedes learning about number through social communication), Piraha and Munduruku adults demonstrate primitive number knowledge that resembles findings on infants: They can accurately discriminate and compare numerical quantities only up to three (Gordon, 2004; Pica et al., 2004). Still, critics continue to argue that such knowledge is not built-in but, rather, constructed over an extended time period.

Children as Naïve Theorists

A growing number of researchers believe that children form naïve theories, or explanations of events, that differ among core domains. According to this **theory theory** (meaning *theory of children as theorists*), after children observe an event, they draw on innate concepts to explain, or theorize about, its cause. Then they test their naïve theory against experience, revising it when it cannot adequately account for new information (Gelman, 2003; Gelman & Kalish, 2006; Gopnik & Nazzi, 2003). These revisions often lead to stagelike changes—dramatic, qualitative shifts in the complexity of concepts and explanations. Although this account of cognitive change is similar to Piaget's, theory theorists claim that because children start with innate knowledge, their reasoning advances quickly, with sophisticated cause-and-effect explanations evident much earlier than Piaget proposed.

The most extensively investigated naïve theory is children's *theory of mind*—the psychological knowledge of self and others that forms rapidly during the first few years, which we will consider in Chapter 11. Preschoolers also have naïve physical and biological theories.

When researchers asked 3- and 4-year-olds to explain events that had either a psychological, a physical, or a biological cause, the children reasoned about each event in ways consistent with its core domain. For a child who pours orange juice instead of milk on his cereal, they offered mostly psychological explanations ("He *thought* it was milk"). But for a boy who tries to float in the air by jumping off a stool but falls, they gave mostly physical explanations ("He's too *heavy* to float"). And a girl who tries to hang from a tree branch "forever" but lets go elicited biological explanations ("Her arms got *hurting*"). In everyday conversation, too, preschoolers typically offer psychological, physical, and biological explanations that are linked appropriately to the behaviors of humans, animals, and objects (Hickling & Wellman, 2001; Wellman, Hickling, & Schultz, 1997).

Although young children are impressive theorists, their reasoning in different domains develops at different rates. Physical and psychological explanations are prevalent at age 2, probably because these understandings originate in infancy. But because grasping biological processes is difficult, young preschoolers frequently use psychological concepts to explain biological events (Carey, 1995, 1999; Inagaki & Hatano, 2002). For example, when asked whether they can tell a pain to go away or a heartbeat to stop, many 3-year-olds say yes!

In contrast, 4-year-olds know that they cannot control biological processes (Inagaki, 1997). And by age 6, children interpret biological processes, especially those of humans, in terms of a "life force" derived from food and water that enables living things to grow, energizes their activity, and prevents them from becoming ill. When asked what will happen if a child eats very little, they are likely to say, "If we don't eat food, we lose energy and die" (Inagaki & Hatano, 2004, p. 359). Nevertheless, psychological accounts of biological events persist into the early school years.

Biological knowledge emerges later in children from widely varying cultures, suggesting that unlike other core domains, it may have only a weak innate foundation. Alternatively, it may depend entirely on a lengthy process of construction based on experience. For example, when told stories about a child born to one parent and raised by another, not until ages 5 to 7 do North American and European children show knowledge of biological inheritance, consistently predicting that an adopted child will resemble her birth parents in physical characteristics (such as hair type and skin color) but resemble her adoptive parents in beliefs and skills (Gimenez & Harris, 2002; Solomon et al., 1996; Weissman & Kalish, 1999).

In some non-Western village societies, this distinction between the influence of biology and that of social learning on human traits is not attained until adolescence or adulthood (Bloch, Solomon, & Carey, 2001; Mahalingham, 1999). The Vezo of Madagascar hold certain folk beliefs that make it harder for their children to grasp biological inheritance—for example, that a pregnant mother who spends much time thinking about another person can cause her baby to look like that person! Because Vezo children do not go to school, they are not exposed to biology lessons that contradict such folk beliefs (Astuti, Solomon, & Carey, 2004). They must, instead, notice and gradually make sense of the fact that children and their biological parents resemble each other physically—a challenging task that is not mastered until ages 14 to 20.

© DAVID YOUNG-WOLFF/PHOTOEDIT

Preschoolers' biological reasoning develops slowly, suggesting no more than a weak innate foundation. But by age 6, children interpret biological processes—such as what makes these chicks hatch and grow—in terms of a "life force" energized by food and water.

Evaluation of the Core Knowledge Perspective

Core knowledge theorists offer a fascinating evolutionary account of why certain cognitive skills emerge early and develop rapidly. And more seriously than other perspectives, they have addressed the question, What allows learning to get off the ground? As a result, they have enriched our understanding of infants' and young children's thinking.

Nevertheless, critics take issue with the core knowledge assumption, based on violation-of-expectation evidence, that infants are endowed with *knowledge* (Bremner, 2010). And indisputable evidence for built-in core knowledge requires that it be demonstrated in all core domains in the absence of any relevant opportunities to learn—at birth or close to it

(Johnson, 2010). Currently, debate continues over just what babies start out with—domain-specific understandings or minimal perceptual biases that combine with powerful, general learning strategies to permit rapid discovery of various types of knowledge.

While emphasizing native endowment, the core knowledge perspective acknowledges that experience is essential for children to elaborate this initial knowledge. So far, however, it has not offered greater clarity than Piaget's theory about how heredity and environment jointly produce cognitive change. It does not tell us just what children do to revise their innate structures. And it says little about which experiences are most important in each domain and how those experiences advance children's thinking.

Finally, the core knowledge perspective, like Piaget's theory, views children as building more adequate structures largely through their own activity. It pays little attention to children's learning in interaction with others—the unique strength of Vygotsky's theory, which we take up next. Despite these limitations, the ingenious studies and provocative findings of core knowledge research have sharpened the field's focus on specifying the starting point for human cognition and carefully tracking the changes that build on it.

ASK YOURSELF

Review ■ What are core domains of thought? Cite examples of innate knowledge in the physical and numerical domains. Why do some researchers question the existence of innate knowledge?

Connect ■ Describe similarities and differences between Piaget's theory and the theory theory.

- Explain Vygotsky's view of cognitive development, noting the importance of social experience and language.
- According to Vygotsky, what is the role of make-believe play in cognitive development?

Vygotsky's Sociocultural Theory

Piaget's theory and the core knowledge perspective emphasize the biological side of cognitive development. Both identify the most important source of cognition as the child himself—a busy, self-motivated explorer who forms ideas and tests them against the world. Lev Vygotsky, while also viewing children as active seekers of knowledge, emphasized the profound effects of rich social and cultural contexts on their thinking.

Early events in Vygotsky's life contributed to his vision of human cognition as inherently social and language-based. As a university student, he was interested primarily in a verbal field—literature. After graduating, he first became a teacher and only later turned to psychology. Because Vygotsky died of tuberculosis at age 37, his theory is not as complete as Piaget's. Nevertheless, the field of child development has experienced a burst of interest in Vygotsky's sociocultural perspective. His appeal lies mainly in his rejection of an individualistic view of the developing child in favor of a socially formed mind (Bakhurst, 2007; Tudge & Scrimsher, 2003).

According to Vygotsky, infants are endowed with basic perceptual, attention, and memory capacities that they share with other animals. These develop during the first two years through direct contact with the environment. Then rapid growth of language leads to a profound change in thinking. It broadens preschoolers' participation in social dialogues with more knowledgeable individuals, who encourage them to master culturally important tasks. Soon young children start to communicate with themselves much as they converse with others. As a result, basic mental capacities are transformed into uniquely human, higher cognitive processes.

Children's Private Speech

TAKE A MOMENT... Watch preschoolers as they play and explore the environment, and you will see that they frequently talk out loud to themselves. For example, as a 4-year-old worked a puzzle at preschool one day, I heard him say, "Where's the red piece? I need the red one. Now a blue one. No, it doesn't fit. Try it here."

Piaget (1923/1926) called these utterances *egocentric speech,* reflecting his belief that young children have difficulty taking the perspectives of others. Their talk, he said, is often "talk for self" in which they express thoughts in whatever form they happen to occur, regardless of whether a listener can understand. Piaget believed that cognitive development and certain social experiences eventually bring an end to egocentric speech. Specifically, through disagreements with peers, children see that others hold viewpoints different from their own. As a result, egocentric speech declines in favor of social speech, in which children adapt what they say to their listeners.

Vygotsky (1934/1986) disagreed strongly with Piaget's conclusions. Because language helps children think about mental activities and behavior and select courses of action, Vygotsky saw it as the foundation for all higher cognitive processes, including controlled attention, deliberate memorization and recall, categorization, planning, problem solving, abstract reasoning, and self-reflection. In Vygotsky's view, children speak to themselves for self-guidance. As they get older and find tasks easier, their self-directed speech is internalized as silent, *inner speech*—the internal verbal dialogues we carry on while thinking and acting in everyday situations.

Over the past three decades, almost all studies have supported Vygotsky's perspective (Berk & Harris, 2003; Winsler, 2009). As a result, children's self-directed speech is now called **private speech** instead of egocentric speech. Children use more of it when tasks are appropriately challenging (neither too easy nor too hard), after they make errors, or when they are confused about how to proceed. Figure 6.17 shows how 5- and 6-year-olds' private speech increased as researchers made a problem-solving task moderately difficult, then decreased as the task became very difficult (Fernyhough & Fradley, 2005).

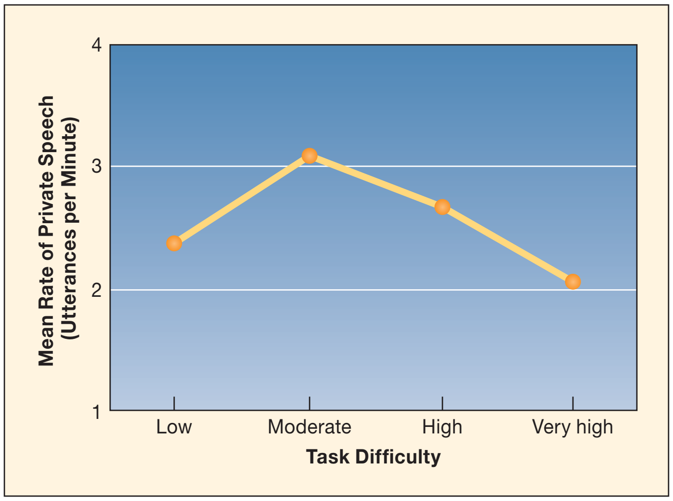

FIGURE 6.17 **Relationship of private speech to task difficulty among 5- and 6-year-olds.** Researchers increased the difficulty of a problem-solving task. Private speech rose as the task became moderately difficult, then declined as it became highly difficult. Children are more likely to use private speech for self-guidance when tasks are within their zone of proximal development, or range of mastery. (Adapted from Fernyhough & Fradley, 2005.)

With age, as Vygotsky predicted, private speech goes underground, changing into whispers and silent lip movements. Furthermore, children who freely use self-guiding private speech during a challenging activity are more attentive and involved and show better task performance than their less talkative agemates (Al-Namlah, Fernyhough, & Meins, 2006; Lidstone, Meins, & Fernyhough, 2010; Winsler, Naglieri, & Manfra, 2006).

Finally, compared with their agemates, children with learning and behavior problems engage in higher rates of private speech over a longer period of development (Berk, 2001b; Ostad & Sorensen, 2007; Paladino, 2006; Winsler et al., 2007). They seem to use private speech to help compensate for impairments in attention and cognitive processing that make many tasks more difficult for them.

Private speech helps this preschooler explore possibilities in a handful of bubbles. As Vygotsky theorized, children use self-directed speech to guide their thinking and behavior.

© LAURA DWIGHT PHOTOGRAPHY

Social Origins of Cognitive Development

Where does private speech come from? Vygotsky (1930–1935/1978) believed that children's learning takes place within the **zone of proximal development**—a range of tasks too difficult for the child to do alone but possible with the help of adults and more skilled peers. Consider the joint activity of 3-year-old Sammy and his mother as she helps him put together a difficult puzzle:

> *Sammy:* I can't get this one in. [*Tries to insert a piece in the wrong place.*]
> *Mother:* Which piece might go down here? [*Points to the bottom of the puzzle.*]
> *Sammy:* His shoes. [*Looks for a piece resembling the clown's shoes but tries the wrong one.*]
> *Mother:* Well, what piece looks like this shape? [*Points again to the bottom of the puzzle.*]
> *Sammy:* The brown one. [*Tries it, and it fits; then attempts another piece and looks at his mother.*]

Mother: Try turning it just a little. [*Gestures to show him.*]
Sammy: There! [*Puts in several more pieces while his mother watches.*]

By questioning, prompting, and suggesting strategies, Sammy's mother keeps the puzzle within his zone of proximal development, at a manageable level of difficulty.

To promote cognitive development, social interaction must have certain features. One is **intersubjectivity,** the process whereby two participants who begin a task with different understandings arrive at a shared understanding (Newson & Newson, 1975). Intersubjectivity creates a common ground for communication, as each partner adjusts to the other's perspective. Adults try to promote it when they translate their own insights in ways that are within the child's grasp. As the child stretches to understand the adult, she is drawn into a more mature approach to the situation.

The capacity for intersubjectivity is present early, in parent–infant mutual gaze, exchange of vocal and emotional signals, imitation, and joint play with objects, and in toddlers' capacity to infer others' intentions (Csibra, 2010; Feldman, 2007c). Later, language facilitates intersubjectivity. As conversational skills improve, preschoolers increasingly seek others' help and direct that assistance to ensure that it is beneficial. Between ages 3 and 5, children strive for intersubjectivity in dialogues with peers, as when they affirm a playmate's message, add new ideas, and contribute to ongoing play to sustain it. They may say, "I think [this way]. What do you think?"—evidence for a willingness to share viewpoints (Berk, 2001a). In these ways, children create zones of proximal development for one another.

© DAVID YOUNG-WOLFF/PHOTOEDIT

A father engages in scaffolding by breaking the task of preparing rice balls into manageable units, suggesting strategies, and gradually turning over responsibility to the child.

A second important feature of social interaction is **scaffolding**—adjusting the support offered during a teaching session to fit the child's current level of performance. When the child has little notion of how to proceed, the adult uses direct instruction, breaking the task into manageable units, suggesting strategies, and offering rationales for using them. As the child's competence increases, effective scaffolders—like Sammy's mother—gradually and sensitively withdraw support, turning over responsibility to the child. Then children take the language of these dialogues, make it part of their private speech, and use this speech to organize their independent efforts.

Scaffolding captures the form of teaching interaction that occurs as children work on school or school-like tasks, such as puzzles, model building, picture matching, and (later) academic assignments. It may not apply to other contexts that are equally vital for cognitive development—for example, play or everyday activities, during which adults usually support children's efforts without deliberately teaching. To encompass children's diverse opportunities to learn through involvement with others, Barbara Rogoff (1998, 2003) suggests the term **guided participation,** a broader concept than scaffolding. It refers to shared endeavors between more expert and less expert participants, without specifying the precise features of communication. Consequently, it allows for variations across situations and cultures.

What evidence supports Vygotsky's ideas on the social origins of cognitive development? A wealth of research indicates that when adults promote intersubjectivity by being stimulating, responsive, and supportive, they foster many competencies—attention, language, complex play, and understanding of others' perspectives (Bornstein et al., 1992; Charman et al., 2001; Morales et al., 2000). Furthermore, children whose parents are effective scaffolders use more private speech, are more successful when attempting difficult tasks on their own, and are advanced in overall cognitive development (Berk & Spuhl, 1995; Conner & Cross, 2003; Mulvaney et al., 2006). Among Caucasian-American parent–child pairs, adult cognitive support—teaching in small steps and offering strategies—predicts children's mature thinking and academic competence (Stright et al., 2001). And adult emotional support—offering encouragement and transferring responsibility to the child—predicts children's effort (Neitzel & Stright, 2003).

LOOK and LISTEN

Ask a preschooler to join you in working a difficult puzzle or other challenging task. How did you scaffold the child's progress? Did the child display any self-guiding private speech?

Nevertheless, effective scaffolding can take different forms in different cultures. In an investigation of Hmong families who had emigrated from Southeast Asia to the United States, once again, parental cognitive support was associated with children's advanced reasoning skills. But unlike Caucasian-American parents, who emphasize independence by encouraging their children to think of ways to approach a task, Hmong parents—who highly value interdependence and child obedience—frequently tell their children what to do (for example, "put this block piece here, then this piece on top of it") (Stright, Herr, & Neitzel, 2009). Among Caucasian-American children, such directive scaffolding is associated with kindergartners' lack of self-control and behavior problems (Neitzel & Stright, 2003). Among the Hmong children, however, it predicted favorable kindergarten adjustment—capacity to follow rules, be organized, and finish assignments.

Vygotsky's View of Make-Believe Play

In accord with his emphasis on social experience and language as vital forces in cognitive development, Vygotsky (1933/1978) regarded make-believe play as a unique, broadly influential zone of proximal development in which *children advance themselves* as they try out a wide variety of challenging skills. In Vygotsky's theory, make-believe is the central source of development during the preschool years, leading development forward in two ways.

First, as children create imaginary situations, they learn to act in accord with internal ideas, not just in response to external stimuli. While pretending, children continually use one object to stand for another—a stick for a horse, a folded blanket for a sleeping baby—and, in doing so, change the object's usual meaning. Gradually they realize that thinking (or the meaning of words) is separate from objects and that ideas can be used to guide behavior.

Second, the rule-based nature of make-believe strengthens children's capacity to think before they act. Pretend play, Vygotsky pointed out, constantly demands that children act against their impulses because they must follow the rules of the play scene. For example, a child pretending to go to sleep obeys the rules of bedtime behavior. A child imagining himself as a father and a doll as his child conforms to the rules of parental behavior (Bodrova & Leong, 2007). Through enacting rules in make-believe, children better understand social norms and expectations and strive to follow them.

Much evidence fits with Vygotsky's conclusion that make-believe play serves as a zone of proximal development, supporting many competencies. Turn back to pages 240–241 to review evidence that make-believe enhances a diverse array of cognitive and social skills. Pretending is also rich in private speech—a finding that supports its role in helping children bring action under the control of thought (Krafft & Berk, 1998). And preschoolers who spend more time engaged in sociodramatic play are better at following classroom rules and regulating their emotions and behavior (Berk, Mann, & Ogan, 2006; Lemche et al., 2003).

Finally, Vygotsky questioned Piaget's belief that make-believe arises spontaneously in the second year of life. Vygotsky argued that, like other higher cognitive processes, the elaborate pretending of the preschool years has social origins. Research reviewed in the Cultural Influences box on page 270 supports the view that children learn to pretend under the guidance of experts.

Vygotsky and Education

- Describe educational implications of Vygotsky's theory.

Vygotsky's theory offers new visions of teaching and learning—ones that emphasize the importance of social context and collaboration. Like Piagetian classrooms, Vygotskian classrooms accept individual differences and provide opportunities for children's active participation. But a Vygotskian classroom goes beyond independent discovery to promote *assisted discovery*. Teachers guide children's learning with explanations, demonstrations, and verbal prompts, tailoring their interventions to each child's zone of proximal development. Assisted discovery is aided by *peer collaboration*, as children work in groups, teaching and helping one another.

CULTURAL INFLUENCES

Social Origins of Make-Believe Play

One of the activities my husband, Ken, used to do with our two sons when they were young was to bake pineapple upside-down cake, a favorite treat. One day as a cake was in the making, 21-month-old Peter stood on a chair at the kitchen sink, busily pouring water from one cup to another.

"He's in the way, Dad!" complained 4-year-old David, trying to pull Peter away from the sink.

"Maybe if we let him help, he'll give us some room," Ken suggested. As David stirred the batter, Ken poured some into a small bowl for Peter, moved his chair to the side of the sink, and handed him a spoon.

"Here's how you do it, Petey," instructed David, with a superior air. Peter watched David stir, then tried to copy his motion. When it was time to pour the batter, Ken helped Peter hold and tip the small bowl.

"Time to bake it," said Ken.

"Bake it, bake it," repeated Peter, watching Ken slip the pan into the oven.

Several hours later, we observed one of Peter's earliest instances of make-believe play. He got his pail from the sandbox and, after filling it with a handful of sand, carried it into the kitchen and set it on the floor in front of the oven. "Bake it, bake it," Peter called to Ken. Together, father and son placed the pretend cake in the oven.

Piaget and his followers concluded that toddlers discover make-believe independently, once they are capable of representational schemes. Vygotsky challenged this view, pointing out that society provides children with opportunities to represent culturally meaningful activities in play. Make-believe, like other complex mental activities, is first learned under the guidance of experts. In the example just described, Peter extended his capacity to represent daily events when Ken drew him into the baking task and helped him act it out in play.

Current evidence supports the idea that early make-believe is the combined result of children's readiness to engage in it and social experiences that promote it. In one observational study of U.S. middle-class toddlers, 75 to 80 percent of make-believe involved mother–child interaction (Haight & Miller, 1993). At 12 months, almost all play episodes were initiated by mothers. But by the end of the second year, half of pretend episodes were initiated by each.

During make-believe, mothers offer toddlers a rich array of cues that signal they are pretending—looking and smiling at the child more, making more exaggerated movements, and using more "we" talk (acknowledging that pretending is a joint endeavor) than they do during the same real-life event (Lillard, 2007). These maternal cues encourage toddlers to join in and probably facilitate their ability to distinguish pretend from real acts, which strengthens over the second and third years (Lillard & Witherington, 2004; Ma & Lillard, 2006).

Also, when adults participate, toddlers' make-believe is more elaborate (Keren et al., 2005). They are more likely to combine pretend acts into complex sequences, as Peter did when he put the sand in the bucket ("making the batter"), carried it into the kitchen, and (with Ken's help) put it in the oven ("baking the cake"). The more parents pretend with their toddlers, the more time their children devote to make-believe.

In some cultures, such as those of Indonesia and Mexico, where extended-family households and sibling caregiving are common, make-believe is more frequent and complex with older siblings than with mothers. As early as age 3 to 4, children provide rich, challenging stimulation to their younger brothers and sisters, take these teaching responsibilities seriously, and, with age, become better at them (Zukow-Goldring, 2002). In a study of Zinacanteco Indian children of southern Mexico, by age 8, sibling teachers were highly skilled at showing 2-year-olds how to play at everyday tasks, such as washing and cooking (Maynard, 2002). They often guided toddlers verbally and physically through the task and provided feedback.

© CAROLINE PENN/PANOS PICTURES

A Kenyan child guides his younger brother in pretend play. In cultures where sibling caregiving is common, make-believe with older siblings is more frequent and complex than with mothers.

In Western middle-class families, older siblings less often teach deliberately but still serve as influential models of playful behavior. In a study of New Zealand families of Western European descent, when both a parent and an older sibling were available, toddlers more often imitated the actions of the sibling, especially when siblings engaged in make-believe (Barr & Hayne, 2003).

Make-believe play is a major means through which children extend their cognitive skills and learn about important activities in their culture. Vygotsky's theory, and the findings that support it, tell us that providing a stimulating environment is not enough to promote early cognitive development. In addition, toddlers must be invited and encouraged by more skilled members of their culture to participate in the social world around them. Parents and teachers can enhance early make-believe by playing often with toddlers, guiding and elaborating their make-believe themes.

Vygotsky's educational message for the preschool years is to provide socially rich, meaningful activities in children's zones of proximal development and a wealth of opportunities for make-believe play—the ultimate means of fostering the self-discipline required for later academic learning. Once formal schooling begins, Vygotsky emphasized literacy activities (Scrimsher & Tudge, 2003). As children talk about literature, mathematics, science, and social studies, their teachers inform, correct, and ask them to explain. As a result, children reflect on their own thought processes and shift to a higher level of cognitive activity in which they think about how to symbolize ideas in socially useful ways. Gradually they become proficient in manipulating and controlling the symbol systems of their culture.

Let's look at two Vygotsky-based educational innovations, each of which incorporates assisted discovery and peer collaboration.

Reciprocal Teaching

Originally designed to improve reading comprehension in poorly achieving students, this teaching method has been extended to other subjects and all schoolchildren. In **reciprocal teaching,** a teacher and two to four students form a collaborative group and take turns leading dialogues on the content of a text passage. Within the dialogues, group members apply four cognitive strategies: questioning, summarizing, clarifying, and predicting.

The dialogue leader (at first a teacher, later a student) begins by *asking questions* about the content of the text passage. Students offer answers, raise additional questions, and, in case of disagreement, reread the original text. Next, the leader *summarizes* the passage, and children discuss the summary and *clarify* unfamiliar ideas. Finally, the leader encourages students to *predict* upcoming content based on clues in the passage.

Elementary and middle school students exposed to reciprocal teaching show impressive gains in reading comprehension compared to controls taught in other ways (Rosenshine & Meister, 1994; Sporer, Brunstein, & Kieschke, 2009; Takala, 2006). Notice how reciprocal teaching creates a zone of proximal development in which children gradually learn to scaffold one another's progress and assume more responsibility for comprehending text passages. Also, by collaborating with others, children forge group expectations for high-level thinking and acquire skills vital for learning and success in everyday life.

Cooperative Learning

Although reciprocal teaching uses peer collaboration, a teacher guides it, helping to ensure its success. According to Vygotsky, more expert peers can also spur children's development, as long as they adjust the help they provide to fit the less mature child's zone of proximal development. Recall that Piaget, too, thought that peer interaction could contribute to cognitive change. He asserted that peers' clashing viewpoints—arguments jarring the child into noticing an agemate's viewpoint—were necessary for peer interaction to foster logical thought.

Today, peer collaboration is widely used, but evidence is mounting that it promotes development only under certain conditions. A crucial factor is **cooperative learning,** in which small groups of classmates work toward common goals. Conflict and disagreement seem less important than the extent to which peers achieve intersubjectivity—by resolving differences of opinion, sharing responsibilities, and providing one another with sufficient explanations to correct misunderstandings. And in line with Vygotsky's theory, children profit more when their peer partner is an "expert"—especially capable at the task. When older or more expert students assist younger or less expert students, both benefit in achievement and self-esteem, with stronger effects for low-income, minority students (Ginsburg-Block, Rohrbeck, & Fantuzzo, 2006: Renninger, 1998).

Because working in groups comes more easily to children reared in collectivist than in individualistic cultures, Western children usually require extensive guidance for cooperative learning to succeed. When teachers prompt, explain, model, and have children role-play how to work together effectively, cooperative learning results in higher-level explanations, greater enjoyment of learning, and achievement gains across a wide range of school subjects (Gillies, 2000, 2003; Terwel et al., 2001; Webb et al., 2008). It also enhances peer relationships generally, leading students to cooperate more in future group activities within and outside the classroom (Blatchford

Children reared in individualistic cultures typically need extensive teacher guidance to engage in cooperative learning. For these first graders, teacher support promotes pleasure, higher-level explanations, and achievement gains.

© ELLEN B. SENISI/THE IMAGE WORKS

et al., 2006; Tolmie et al., 2010). Teaching through cooperative learning broadens Vygotsky's concept of the zone of proximal development, from a single child in collaboration with an expert partner (adult or peer) to multiple partners with diverse forms of expertise stimulating and encouraging one another.

Evaluation of Vygotsky's Theory

In granting social experience a fundamental role in cognitive development, Vygotsky's theory helps us understand the wide cultural variation in cognitive skills. Whereas Piaget emphasized universal cognitive change, Vygotsky's theory leads us to expect highly diverse paths of development. The reading, writing, and mathematical activities of children who attend school in literate societies generate cognitive capacities different from those in tribal and village cultures, where children receive little formal schooling. But the elaborate spatial skills of Australian Aborigines, whose food-gathering missions require that they find their way through barren desert regions, and the proportional reasoning of Brazilian fishermen, promoted by their navigational experiences, are just as advanced (Carraher, Schliemann, & Carraher, 1988; Kearins, 1981). Each is a unique form of symbolic thinking required by activities that make up that culture's way of life.

Vygotsky's (1934/1986) theory also underscores the vital role of teaching in cognitive development. According to Vygotsky, from communicating with more expert partners, children engage in "verbalized self-observation," reflecting on, revising, and controlling their own thought processes. In this way, parents' and teachers' engagement with children prompts profound advances in the complexity of children's thinking.

Vygotsky's theory has not gone unchallenged. Although he acknowledged the role of diverse symbol systems (such as pictures, maps, and mathematical expressions) in the development of higher cognitive processes, he elevated language to highest importance. But in some cultures, verbal dialogues are not the only—or even the most important—means through which children learn. When Western parents help children with challenging tasks, they assume much responsibility for children's motivation by frequently giving verbal instructions and conversing with the child. Their communication resembles the teaching that occurs in school, where their children will spend years preparing for adult life. But in cultures that place less emphasis on schooling and literacy, parents often expect children to take greater responsibility for acquiring new skills through keen observation and participation in community activities (Paradise & Rogoff, 2009; Rogoff, 2003). The Cultural Influences box on the following page illustrates this difference.

Finally, in focusing on social and cultural influences, Vygotsky said little about biological contributions to children's cognition. His theory does not address how basic motor, perceptual, memory, and problem-solving capacities spark changes in children's social experiences, from which more advanced cognition springs. Nor does it tell us just how children internalize social experiences to advance their mental functioning (Miller, 2009; Moll, 1994). Consequently, like the other perspectives addressed in this chapter, Vygotsky's theory is vague in its explanation of cognitive change. It is intriguing to imagine the broader theory that might exist today had Piaget and Vygotsky—the two twentieth-century giants of cognitive development—had a chance to weave together their extraordinary accomplishments.

ASK YOURSELF

Review ■ Describe features of social interaction that support children's cognitive development. How does such interaction create a one of proximal development?

Connect ■ Explain how Piaget's and Vygotsky's theories complement each other. How would classroom practices inspired by these theories be similar? How would they be different?

Apply ■ Tanisha sees her 5-year-old son Toby talking aloud to himself as he plays. She wonders whether she should discourage this behavior. Use Vygotsky's theory and related research to explain why Toby talks to himself. How would you advise Tanisha?

Reflect ■ When do you use private speech? Does it serve a self-guiding function for you, as it does for children? Explain.

CULTURAL INFLUENCES

Children in Village and Tribal Cultures Observe and Participate in Adult Work

In Western societies, children are largely excluded from participating in adult work, which generally takes place outside the home. The role of equipping children with the skills they need to become competent workers is assigned to school. In early childhood, middle-class parents' interactions with children emphasize child-focused activities designed to prepare children to succeed in school—especially adult–child conversations and play that enhance language, literacy, and other school-related knowledge. In village and tribal cultures, children receive little or no schooling, spend their days in contact with or participating in adult work, and start to assume mature responsibilities in early childhood (Rogoff et al., 2003). Consequently, parents have little need to rely on conversation and play to teach children.

A study comparing 2- and 3-year-olds' daily lives in four cultures—two U.S. middle-class suburbs, the Efe hunters and gatherers of the Republic of Congo, and a Mayan agricultural town in Guatemala—documented these differences (Morelli, Rogoff, & Angelillo, 2003). In the U.S. communities, young children had little access to adult work and spent much time conversing and playing with adults. In contrast, the Efe and Mayan children rarely engaged in these child-focused activities. Instead, they spent their day close to—and frequently observing—adult work, which often took place in or near the Efe campsite or the Mayan family home.

An ethnography of a remote Mayan village in Yucatán, Mexico, shows that when young children are legitimate onlookers and participants in a daily life structured around adult work, their competencies differ from those of Western preschoolers (Gaskins, 1999; Gaskins, Haight, & Lancy, 2007). Yucatec Mayan adults are subsistence farmers. Men tend cornfields, aided by sons age 8 and older. Women prepare meals, wash clothes, and care for the livestock and garden, assisted by daughters and by sons too young to work in the fields. Children join in these activities from the second year on. When not participating, they are expected to be self-sufficient. Young children make many nonwork decisions for themselves—how much to sleep and eat, what to wear, when to take their daily bath, and even when to start school. As a result, Yucatec Mayan preschoolers are highly competent at self-care. In contrast, their make-believe play is limited; when it occurs, they usually imitate adult work. Otherwise, they watch others—for hours each day.

Yucatec Mayan parents rarely converse or play with preschoolers or scaffold their learning. Rather, when children imitate adult tasks, parents conclude that they are ready for more responsibility. Then they assign chores, selecting tasks the child can do with little help so that adult work is not disturbed. If a child cannot do a task, the adult takes over and the child observes, reengaging when able to contribute.

Expected to be autonomous and helpful, Yucatec Mayan children seldom display attention-getting behaviors or ask others for something interesting to do. From an early age, they can sit quietly for long periods—through a lengthy religious service or a three-hour truck ride. And when an adult interrupts their activity and directs them to do a chore, they respond eagerly to the type of command that Western children frequently avoid or resent. By age 5, Yucatec Mayan children spontaneously take responsibility for tasks beyond those assigned.

SUMMARY

Piaget's Cognitive-Developmental Theory (p. 226)

According to Piaget, how does cognition develop?

- Piaget's **constructivist approach** assumes that children discover knowledge through their own activity, moving through four invariant, universal stages. According to Piaget, newborn infants have little in the way of built-in structures; only at the end of the second year are they capable of a cognitive approach to the world through **mental representations**.
- In Piaget's theory, psychological structures, or **schemes**, change with age in two ways: through **adaptation**, which consists of two complementary activities—**assimilation** and **accommodation**; and through **organization**, the internal rearrangement of schemes to form a strongly interconnected cognitive system. **Equilibration** describes the changing balance of assimilation and accommodation that gradually leads to more effective schemes.

The Sensorimotor Stage: Birth to 2 Years (p. 228)

Describe major cognitive attainments of Piaget's sensorimotor stage.

- In the **sensorimotor stage**, the **circular reaction** provides a means of adapting first schemes, and the newborn baby's reflexes transform into the older infant's more flexible action patterns. Eight- to 12-month-olds develop **intentional**, or **goal-directed, behavior** and begin to master **object permanence**.

Twelve- to 18-month-olds become better problem solvers and no longer make the **A-not-B search error**. Between 18 and 24 months, mental representation is evident in sudden solutions to problems, mastery of object permanence tasks involving invisible displacement, **deferred imitation**, and **make-believe play**.

What does follow-up research reveal about infant cognitive development and the accuracy of Piaget's sensorimotor stage?

- Many studies suggest that infants display various understandings earlier than Piaget believed. Some awareness of object permanence, as revealed by the **violation-of-expectation method**, may be evident in the first few months, although searching for hidden objects is a true cognitive advance. Young infants also display deferred imitation, categorization, and **analogical problem solving**, and toddlers imitate rationally, by inferring others' intentions—attainments that require mental representation.

© LAURA DWIGHT/PHOTOEDIT

- **Displaced reference**—the realization that words can be used to cue mental images of things not physically present—is a major symbolic advance that occurs around the first birthday. The capacity to use language to modify mental representations improves from the end of the second into the third year. By the middle of the second year, toddlers treat realistic-looking pictures symbolically.
- Today, most researchers believe that newborns have more built-in cognitive equipment for making sense of experience than Piaget assumed, although they disagree on how much initial understanding infants have.

The Preoperational Stage: 2 to 7 Years (p. 239)

Describe advances in mental representation and cognitive limitations during the preoperational stage.

- Rapid advances in mental representation—notably, language, make-believe play, and drawing—occur during Piaget's **preoperational stage**. With age, make-believe becomes increasingly complex, evident in **sociodramatic play**. Children's drawings increase in complexity and realism.
- **Dual representation** improves during the third year as children realize that photographs, drawings, models, and simple maps correspond to circumstances in the real world.

© ARIEL SKELLEY/CORBIS

- Piaget described preschoolers as not yet capable of **operations**. Because **egocentrism** prevents children from accommodating, it contributes to animistic thinking, **centration**, and lack of **reversibility**—difficulties that cause preschoolers to fail **conservation** and **hierarchical classification** tasks.

What does follow-up research reveal about preschoolers' cognitive development and the accuracy of Piaget's preoperational stage?

- When preschoolers are given familiar and simplified problems, their performance is more mature than Piaget assumed. They recognize differing perspectives, appreciate that animals (but not inanimate objects) have biological properties, have flexible and appropriate notions of magic, and reason about transformations and cause-and-effect relations.
- Preschoolers also show impressive skill at categorizing on the basis of nonobservable characteristics, revealing that their thinking is not dominated by appearances. Rather than being absent in the preschool years, operational thinking develops gradually.

The Concrete Operational Stage: 7 to 11 Years (p. 249)

What are the major characteristics of Piaget's concrete operational stage?

- During the **concrete operational stage**, thought becomes more logical, flexible, and organized. Mastery of conservation requires decentration and reversibility. Children also become proficient at hierarchical classification and **seriation**, including **transitive inference**. Spatial reasoning improves, as indicated by children's **cognitive maps**.
- Concrete operational thought is limited in that children have difficulty reasoning about abstract ideas. Mastery of Piaget's concrete operational tasks takes place gradually.

Discuss follow-up research on concrete operational thought.

- Cultural practices and schooling affect children's mastery of Piagetian tasks. Concrete operations are heavily influenced by training, context, and cultural conditions.

The Formal Operational Stage: 11 Years and Older (p. 253)

Describe major characteristics of the formal operational stage and typical consequences of adolescents' advancing cognition.

- In Piaget's **formal operational stage**, adolescents become capable of **hypothetico-deductive reasoning**. When faced with a problem, they start with a hypothesis about variables that might affect an outcome; deduce logical, testable inferences; and systematically isolate and combine variables to see which inferences are confirmed.
- Adolescents also develop **propositional thought**—the ability to evaluate the logic of verbal statements without referring to real-world circumstances.
- As adolescents reflect on their own thoughts, two distorted images of the relationship between self and other appear: the **imaginary audience** and the **personal fable**. Both result from gains in perspective taking.
- Adolescents' capacity to think about possibilities prompts idealistic visions at odds with everyday reality, and they often become fault-finding critics.
- Compared with adults, adolescents are less effective at decision making. They take greater risks under emotionally charged conditions, less often weigh alternatives, and more often fall back on well-learned intuitive judgments.

What does follow-up research reveal about formal operational thought?

- On tasks requiring hypothetico-deductive reasoning, school-age children cannot evaluate evidence that bears on three or more variables at once. They also do not grasp the **logical necessity** of propositional thought.

© ANDERS RYMAN/CORBIS

- Adolescents and adults are most likely to think abstractly and systematically in situations in which they have had extensive guidance and practice in using such reasoning. Individuals in tribal and village societies rarely do well on tasks typically used to assess formal operational reasoning. Learning activities in school provide adolescents with rich opportunities to acquire formal operations.

Piaget and Education (p. 259)

Describe educational implications of Piaget's theory.

- A Piagetian classroom promotes discovery learning, sensitivity to children's readiness to learn, and acceptance of individual differences.

Overall Evaluation of Piaget's Theory (p. 260)

Summarize contributions and shortcomings of Piaget's theory.

- Piaget emphasized children's active contributions to their own development, inspired the contemporary focus on mechanisms of cognitive change, and provided a useful "road map" of cognitive development. However, he offered only a vague account of how cognition changes. Children's cognitive attainments are less coherent and more gradual than Piaget's stages indicate.
- Some researchers reject Piaget's stages while retaining his view of cognitive development as an active, constructive process. Others support a less tightly knit stage concept. Still others deny both Piaget's stages and his belief in the existence of general reasoning abilities.

The Core Knowledge Perspective (p. 261)

Explain the core knowledge perspective on cognitive development, noting research that supports its assumptions.

- According to the **core knowledge perspective**, infants are innately equipped with core domains of thought that support rapid cognitive development. Each core domain is essential for survival and develops independently, resulting in uneven, domain-specific changes. Violation-of-expectation research suggests that young infants have impressive physical and numerical knowledge.
- The **theory theory** regards children as naïve theorists who draw on innate concepts to explain their everyday experiences and then test their theory, revising it to account for new information. In support of this view, children reason about everyday events in ways consistent with the event's core domain. Physical and psychological explanations emerge earlier than biological explanations, suggesting that biological knowledge may have little or no innate foundation.

What are the strengths and limitations of the core knowledge perspective?

- Core knowledge researchers are testing intriguing ideas about why certain cognitive skills emerge early and develop rapidly. But critics believe that violation-of-expectation studies are not adequate to show that infants are endowed with knowledge. The core knowledge perspective has not offered clarity on how cognition changes.

Vygotsky's Sociocultural Theory (p. 266)

Explain Vygotsky's view of cognitive development, noting the importance of social experience and language.

- Vygotsky viewed human cognition as inherently social and saw language as the foundation for all higher cognitive processes. According to Vygotsky, **private speech**, or language used for self-guidance, emerges out of social communication as adults and more skilled peers help children master challenging tasks within their **zone of proximal development**. Eventually, private speech is internalized as inner, verbal thought.
- **Intersubjectivity** and **scaffolding** are two features of social interaction that promote transfer of cognitive processes to children. **Guided participation** recognizes cultural and situational variations in adult support of children's efforts.

According to Vygotsky, what is the role of make-believe play in cognitive development?

- Vygotsky viewed make-believe play as a unique, broadly influential zone of proximal development in which children learn to act in accord with internal ideas rather than on impulse.

Vygotsky and Education (p. 269)

Describe educational implications of Vygotsky's theory.

- A Vygotskian classroom emphasizes assisted discovery through teachers' guidance and peer collaboration. When formal schooling begins, literacy activities prompt children to shift to a higher level of cognitive activity, in which they proficiently manipulate and control their culture's symbol systems.
- Vygotsky-based educational innovations include **reciprocal teaching** and **cooperative learning**, in which multiple partners stimulate and encourage one another.

Evaluation of Vygotsky's Theory (p. 272)

Cite strengths and limitations of Vygotsky's theory.

- Vygotsky's theory helps us understand wide cultural variation in cognitive skills and underscores the vital role of teaching in cognitive development. But in some cultures, verbal dialogues are not the only or most important means through which children learn. Vygotsky said little about biological contributions to cognition and about how children internalize social experiences to advance their thinking.

Evaluation of the Information-Processing Approach

“Finally!” 6-year-old Margarita explained the day she entered first grade. “Now I get to go to real school just like Victor!” Holding her 9-year-old brother's hand, Margarita walked confidently through the school doors, ready for a more disciplined approach to learning than she had experienced in early childhood.

Margarita had entered a new world of challenging mental activities. In a single morning, she and her classmates met in reading groups, worked on single-digit addition and subtraction, painted a mural depicting tropical plants and animals to complement their study of rainforests, and wrote in journals about what they liked best about a field trip to a botanical garden. Meanwhile, in Victor's fourth-grade class, Mr. Sharp reminded the children of the inverse relationship between addition and subtraction and asked them to estimate the size of solutions to three-digit subtraction problems. After recess, he drew their attention to this week's list of spelling words: “Fourth graders, why is it easy to remember these words and use them all in the essays we're going to write?” Victor's hand shot up. “They're all related to our unit on electricity,” he exclaimed. “See—battery, magnetism, circuit. . . .”

Information-processing research sheds light on how children develop the attention, memory, and self-management skills and knowledge to succeed at these diverse tasks. Unlike the perspectives covered in Chapter 6, information processing is not a unified theory of cognitive development. Rather, it is an approach followed by researchers who thoroughly study specific aspects of cognition in an effort to uncover *mechanisms of change*—how children and adults operate on information, detecting, transforming, storing, accessing, and modifying it further as it makes its way through the cognitive system.

In this chapter, we review basic assumptions of the information-processing approach along with models of the human cognitive system that are major forces in child development research. As we do so, we will consider several general cognitive changes—in processing capacity, processing speed, and “executive” processing (purposeful management of cognitive activities)—that contribute vitally to children's increasingly complex, effective thinking with age. Next, we delve into two basic processes involved in all human thinking: attention and memory. We also consider how children's expanding knowledge of the world and awareness of their own mental activities enhance their cognitive processing.

As we examine these topics, we will return to a familiar theme: the impact of task demands and cultural contexts on children's thinking. We pay special attention to how schooling, with its emphasis on literacy, mathematics, scientific reasoning, and retention of discrete pieces of information, channels cognitive development in culturally specific ways. Although information-processing theorists are especially interested in internal, self-generated cognitive changes, they also want to find out how external influences—teaching techniques, the design of learning environments and tasks, and cultural values and practices—affect children's thinking. We conclude with an evaluation of information processing as a framework for understanding cognitive development. ■

The Information-Processing Approach

Most information-processing theorists view the mind as a complex symbol-manipulating system through which information from the environment flows, often using the metaphor of a computer. First, information is *encoded*—taken in by the system and retained in symbolic form. Then a variety of internal processes operate on it, *recoding* it, or revising its symbolic structure into a more effective representation, and then *decoding* it, or interpreting its meaning by comparing and combining it with other information in the system. When these cognitive operations are complete, individuals use the information to make sense of their experiences and to solve problems.

Notice the clarity and precision of the computer analogy of human mental functioning. Researchers use computer-like diagrams and flowcharts to try to map the exact series of steps children and adults follow when faced with a task or problem (Miller, 2009). Some researchers do this in such detail that the same mental operations can be programmed into a computer. Then the researcher conducts *simulations* to see if the computer responds as children and adults do on certain tasks. Other investigators intensively study children's and adults' thinking by tracking eye movements, analyzing error patterns, and examining self-reports of mental activity. Regardless of approach, all share a strong commitment to explicit models of thinking that guide the questions they raise about components of cognitive development and thorough testing of each component.

- Describe the store model of the human information processing system, noting implications for cognitive development and related findings.

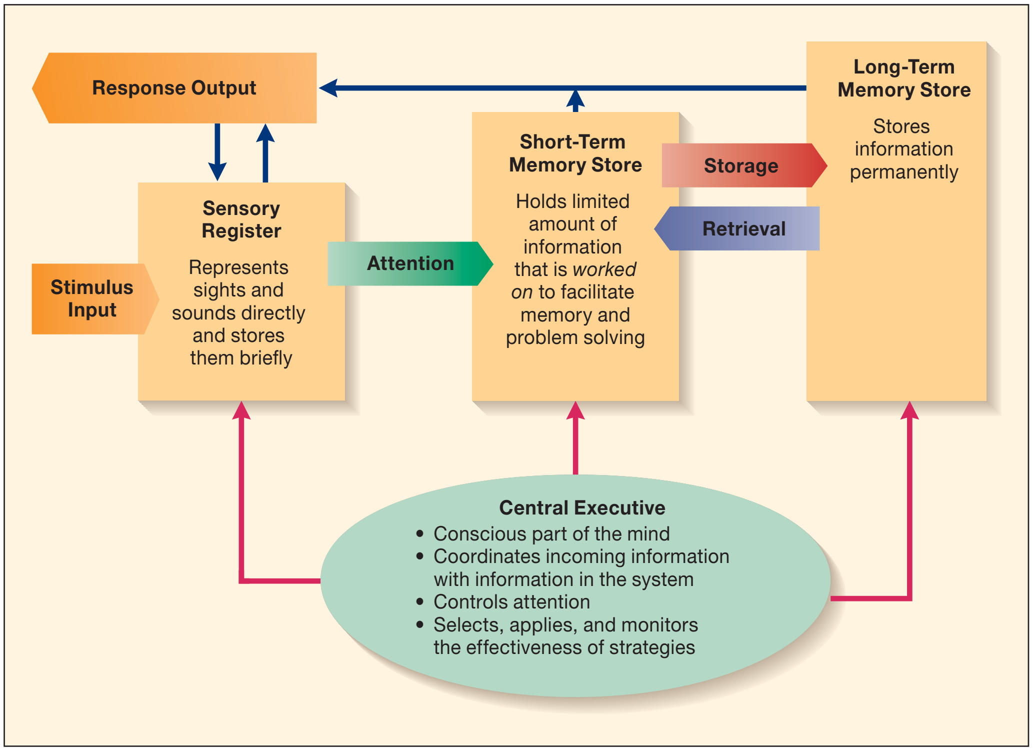
A General Model of Information Processing

The computer-like view of the cognitive system adopted, either directly or indirectly, by most information-processing researchers emerged in the late 1960s and early 1970s. Called the *store model*, it focuses on general units of cognitive functioning, assuming that we hold, or store, information in three parts of the mental system for processing: the *sensory register;* the *short-term memory store;* and the *long-term memory store* (see Figure 7.1) (Atkinson & Shiffrin, 1968). As information flows sequentially through each, we can use *mental strategies* to operate on and transform it, increasing the chances that we will retain information, use it efficiently, and think flexibly, adapting the information to changing circumstances. To understand this more clearly, let's look at each component of the mental system.

Components of the Mental System

First, information enters the **sensory register.** Here, a broad panorama of sights and sounds are represented directly but stored only momentarily. **TAKE A MOMENT...** Look around you, and then close your eyes. An image of what you saw persists for a few seconds but then decays, or disappears, unless you use mental strategies to preserve it. For example, by *attending to* some information more carefully than to other information, you increase the chances that it will transfer to the next step of the information-processing system.

In the second part of the mind, the **short-term memory store,** we retain attended-to information briefly so we can actively "work" on it to reach our goals. One way of looking at the short-term store is in terms of its *basic capacity,* often referred to as *short-term memory:* how many pieces of information can be held at once for a few seconds. Suppose you were asked to perform an operation on the following numerals: 1, 4, 2, 3, 6. If you could not briefly hold onto the digits, you would be unable solve the problem. In line with this example, a commonly used basic short-term memory task measures *verbatim digit span*—the longest sequence of items (such as a list of randomly ordered numerical digits) a person can repeat back in exact order. Among adults, average digit span is about seven items (Cowan, 2001).



Response Output
Long-Term Memory Store
Stores information permanently
Short-Term Memory Store
Holds limited amount of information that is *worked on* to facilitate memory and problem solving
Storage
Retrieval
Sensory Register
Represents sights and sounds directly and stores them briefly
Attention
Stimulus Input
Central Executive
• Conscious part of the mind
• Coordinates incoming information with information in the system
• Controls attention
• Selects, applies, and monitors the effectiveness of strategies

FIGURE 7.1 **Model of the human information-processing system.** Information flows through three parts of the mental system: the *sensory register, short-term memory store,* and *long-term memory store*. In each, mental strategies can be used to manipulate information, increasing the efficiency and flexibility of thinking and the chances that information will be retained. The *central executive* is the conscious, reflective part of the mental system. It coordinates incoming information with information already in the system, decides what to attend to, and oversees the use of strategies.

But we must almost always go beyond passively maintaining verbatim information to actively thinking about that information. Consequently, most researchers endorse a contemporary view of the short-term store, which offers a more meaningful indicator of its capacity, called **working memory**—the number of items that can be briefly held in mind while also engaging in some effort to monitor or manipulate those items. Working memory can be thought of as a "mental workspace" that we use to accomplish many activities in everyday life.

Researchers use a variety of tasks to assess working-memory capacity. A *verbal memory-span task* might ask children to repeat a sequence of numerical digits backward; memorize a list of words while also verifying the accuracy of simple math computations; or listen to a set of short sentences, remember the final word in each, and then repeat the words in correct order. In a *visual/spatial-span task,* researchers might present children with a set of distinctly colored circles in an arrangement on a screen and then ask them to point to the spot in an identical empty grid where each circle was located. Working-memory span is typically about two items fewer than short-term memory span. As we will soon see, children's performance on working-memory tasks is a good predictor of their capacity to learn.

Recall that the sensory register, though limited, can take in a wide panorama of information. The capacity of working memory is far more restricted. But by engaging in a variety of basic cognitive procedures, such as focusing attention on relevant items and repeating (rehearsing) them rapidly, we increase the chances that information will be retained and accessible to ongoing thinking (Cowan & Alloway, 2009).

To manage the cognitive system's activities, the **central executive** directs the flow of information, implementing the basic procedures just mentioned and also engaging in more sophisticated activities that enable complex, flexible thinking. For example, the central executive coordinates incoming information with information already in the system, and it selects, applies, and monitors strategies that facilitate memory storage, comprehension, reasoning, and problem solving (Baddeley, 2000; Pressley & Hilden, 2006). The central executive is the conscious, reflective part of our mental system. It ensures that we harness our cognitive processes purposefully, to attain our goals.

The more effectively the central executive joins with working memory to process information, the better learned those cognitive activities will be and the more *automatically* we can apply them. Consider the richness of your thinking while you automatically drive a car.

Automatic processes are so well-learned that they require no space in working memory and, therefore, permit us to focus on other information while simultaneously performing them. Furthermore, the more information we process in working memory and the more effectively we process it, the more likely it will transfer to the third and largest storage area—**long-term memory,** our permanent knowledge base, which is unlimited. In fact, we store so much in long-term memory that *retrieval*—getting information back from the system—can be problematic. To aid retrieval of information, we apply strategies, just as we do in working memory. Information in long-term memory is *categorized* by its contents, much like a library shelving system that allows us to retrieve items by following the same network of associations used to store them in the first place.

Implications for Development

When applied to development, the store model suggests that several aspects of the cognitive system improve with age: (1) the *basic capacity* of its stores, especially working memory; (2) the *speed* with which children work on information in the system; and (3) *executive function*—applying basic procedures and higher-level strategies in the service of goal-oriented behavior.

Working-Memory Capacity Short-term and working-memory spans increase steadily with age—on a verbatim digit span task tapping short-term memory, from about two digits at 2½ years, to 4 or 5 digits at 7 years, to 6 or 7 digits in adolescence and early adulthood; and on working-memory tasks, from 2 to about 4 to 5 items from early childhood to early adulthood (Cowan, 2005; Cowan & Alloway, 2009). Still, individual differences are evident at all ages, and they are of particular concern because working-memory capacity predicts intelligence test scores and academic achievement in diverse subjects in middle childhood and adolescence (Colom et al., 2007; Gathercole et al., 2005; St Clair-Thompson & Gathercole, 2006).

Indeed, children with persistent learning difficulties in reading and math are often deficient in working-memory capacity. And the poorer they perform on working-memory span tasks, the more severe their achievement problems, even after controlling for individual differences in intelligence (Alloway, 2009; Gathercole et al., 2006; Geary et al., 2007). Reduced working-memory capacity creates a bottleneck for learning. In an observational study of 5- and 6-year-olds who scored very low in working-memory capacity, the children often failed at school assignments that made heavy memory demands (Gathercole, Lamont, & Alloway, 2006). They were unable to follow complex instructions, lost their place in tasks with multiple steps, and frequently abandoned work before finishing it. The children struggled because they could not hold in mind sufficient information to complete their assignments.

Compared to their economically advantaged agemates, children from poverty-stricken families are more likely to score low on working-memory span tasks—an important contributor to their generally poorer academic achievement (Farah et al., 2006; Noble, McCandiliss, & Farah, 2007). In one study, years of childhood spent in poverty predicted reduced working-memory capacity in early adulthood (Evans & Schamberg, 2009). Childhood physiological measures of stress (elevated blood pressure and stress hormone levels, including cortisol) largely explained this poverty–work-memory association. Chronic stress, as we saw in Chapter 4, can impair brain structure and function, especially the prefrontal cortex and its connections with the hippocampus, which govern working-memory capacity.

In a large British sample of over 3,000 5- to 11-year-olds, nearly 10 percent were identified as having very low working-memory scores, the majority of whom were struggling in school (Alloway et al., 2009). Clearly, interventions are needed that reduce memory loads so these children can learn. Effective approaches include communicating in short sentences with familiar vocabulary, repeating task instructions, asking children to repeat back crucial information to ensure they remember, breaking complex tasks into manageable parts, and encouraging children to use external memory aids (such as lists of useful spellings when writing, number lines when doing math) (Gathercole & Alloway, 2008). **TAKE A MOMENT...** Do these techniques remind you of *scaffolding,* a style of teaching discussed in Chapter 6 (see page 268) known to promote cognitive development?

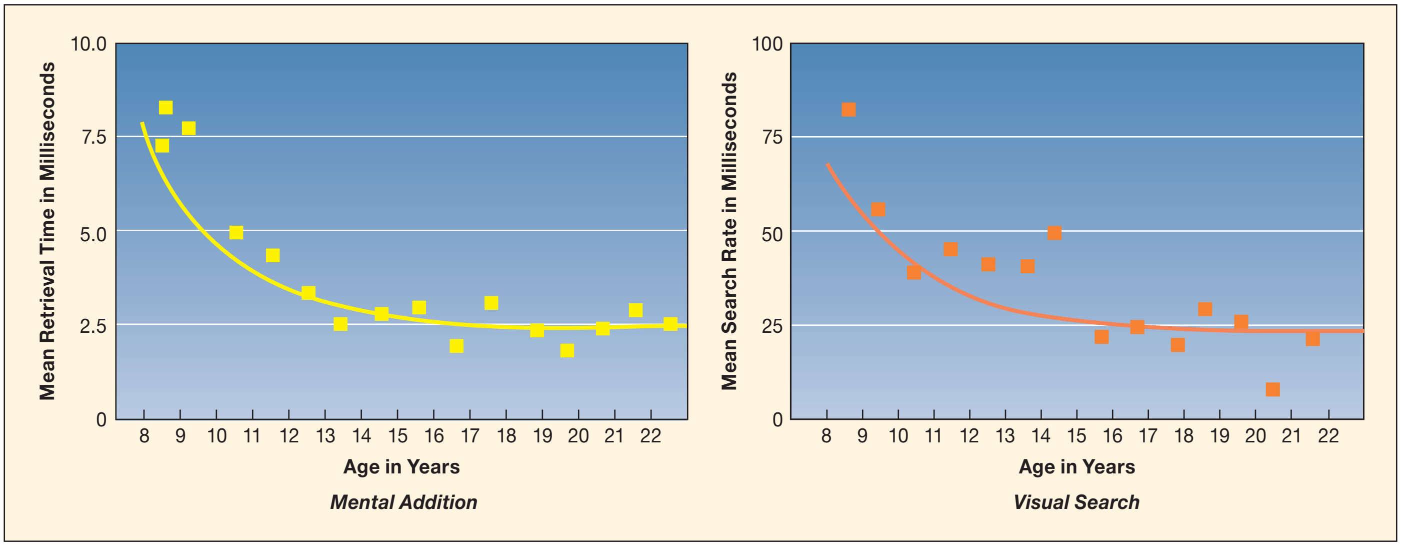


FIGURE 7.2 **Age-related decline in processing time, illustrated for mental addition and visual search.** Processing speed improves similarly across many tasks. This common trend implies an age-related gain in basic processing capacity. (*Left:* Reprinted from *Journal of Experimental Child Psychology,* Vol. 45, No. 3, R. Kail, "Developmental Functions for Speeds of Cognitive Processes," p. 361, copyright 1988, with permission from Elsevier. *Right:* From R. Kail, "Processing Time Declines Exponentially During Childhood and Adolescence," *Developmental Psychology, 27,* p. 265. Copyright © 1991 by the American Psychological Association. Adapted with permission of the American Psychological Association.)

Speed of Processing Developmental increases in working-memory capacity in part reflect gains in processing speed. Efficient processing releases working-memory resources to support storage of information. The faster children can repeat to-be-learned information either out loud or silently to themselves, the larger their memory spans (Cowan & Alloway, 2009; Luna et al., 2004).

Research confirms that with age, children process information more efficiently. In a series of studies, Robert Kail (1991, 1993, 1997) gave 7- to 22-year-olds a variety of cognitive tasks in which they had to respond as quickly as possible. For example, in a name-retrieval task, they had to judge whether pairs of pictures were physically identical or had the same name (for instance, two umbrellas, one opened and one closed). In a mental addition task, they were given addition problems and answers, and they had to indicate whether the solutions were correct. And in a visual search task, they were shown a single digit and asked to signal if it was among a set of digits that appeared on a screen. On all tasks, processing time decreased with age. More important, the rate of change—a fairly rapid decline in processing time, trailing off around age 12—was similar across many activities (see Figure 7.2).

The changes in processing speed shown in Figure 7.2 have been found in Canada, Korea, and the United States (Fry & Hale, 1996; Kail & Park, 1992). Similarity in development across diverse tasks in several cultures implies a fundamental change in efficiency of the information-processing system, perhaps due to myelination or synaptic pruning in the brain (Kail, 2003). Increased processing speed enables older children and adults to scan information more quickly, to transform it more rapidly, and therefore to hold more information in working memory at once. Efficient cognitive processing influences academic achievement indirectly—by augmenting working-memory resources and, thus, supporting many complex cognitive activities (Rinderman & Neubauer, 2004).

Executive Function The central executive, as noted earlier, is the overall supervisor of the cognitive system, managing its activities to ensure that we attain our goals. After observing that adults with damage to the prefrontal cortex were deficient in diverse executive skills, researchers became interested in studying the development of **executive function**—the set of cognitive operations and strategies necessary for self-initiated, purposeful behavior in relatively novel, challenging situations. These include controlling attention, suppressing impulses in favor of adaptive responses, coordinating information in working memory, and planning, organizing, monitoring, and flexibly redirecting thought and behavior.

© LAURA DWIGHT PHOTOGRAPHY

While collaborating on a complex map-making project, these 4th-graders must focus their attention, inhibit inappropriate responses, think flexibly, and coordinate information in working memory. These skills are aspects of executive function, which develops rapidly in middle childhood.

As we will see in later sections when we take up children's attention, strategy use, and self-regulation in complex cognitive activities, researchers have investigated each of the component processes of executive function. But they still have much to discover about how those components work together. And whereas some investigators view executive function as a unitary capacity (Brookshire et al., 2004; Zelazo et al., 2003), others see it as made up of multiple, distinct cognitive abilities that collaborate in goal-directed action (Welsh, Friedman, & Spieker, 2008). Indeed, research suggests that executive skills are, at best, weakly correlated with one another (Anderson, 2002; Welsh, Pennington, & Groisser, 1991).

As our discussion will reveal, early childhood is a vital time for laying the foundations of executive function: Preschoolers make strides in focusing attention, inhibiting inappropriate responses, and thinking flexibly—developments that parallel rapid synapse formation followed by synaptic pruning in the prefrontal cortex (see Figure 5.9 on page 186). During the school years—a time of continued synaptic pruning and maturing of the prefrontal cortex—executive function undergoes its most energetic period of development (Welsh, 2002). Children handle increasingly difficult tasks that require the integration of working memory, inhibition, planning, flexible use of strategies, and self-monitoring and self-correction of behavior (Luciana, 2003; Welsh, Pennington, & Groisser, 1991). And executive function improves further in adolescence, when the prefrontal cortex attains an adult level of synapses.

Heritability evidence suggests substantial genetic contributions to individual differences in working-memory capacity and attentional processing, including inhibiting inappropriate responses (Hansell et al., 2001; Polderman et al., 2009; Young et al., 2009). And molecular genetic analyses are identifying specific genes related to severely deficient functioning of executive components, such as control of attention and impulses, which (as we will soon see) contributes to learning and behavior disorders, such as attention-deficit hyperactivity disorder (ADHD).

But in both typically and atypically developing children, heredity combines with environmental contexts to influence executive function. In Chapter 2, we saw how prenatal iron deficiency places children at risk for lasting memory deficits (see page 49). And in Chapter 3, we reviewed evidence indicating that prenatal teratogens can compromise executive function by impairing attention, impulse control, and memory. Finally, our discussion in this chapter will confirm that supportive parenting and educational experiences are essential for optimal development of executive components and their eventual synthesis into planning, flexible strategic thinking, and self-regulation.

▶ How do Case's neo-Piagetian theory and Siegler's model of strategy choice explain changes in children's thinking?

Developmental Theories of Information Processing

Although the store model has implications for development, it began with the aim of explaining adult information processing, not how children's thinking changes. Next, we consider two *developmental* approaches to information processing. The first, Case's *neo-Piagetian perspective,* uses Piaget's theory as a starting point, recasting his stage sequence in information-processing terms to construct an overall vision of cognitive development. The second, Siegler's *model of strategy choice,* highlights children's experimentation with and selection of mental strategies to account for the diversity and ever-changing nature of children's cognition.

Case's Neo-Piagetian Theory

Robbie Case's (1992, 1998) **neo-Piagetian theory** accepts Piaget's stages but attributes change within each stage, and movement from one stage to the next, to increases in the efficiency with which children use their limited working-memory capacity. Each stage involves a distinct type of cognitive structure: in infancy, sensory input and physical actions; in early childhood, internal representations of events and actions; in middle childhood, simple transformations of representations; and in adolescence, complex transformations of representations. As children become more efficient processors, the amount of information they can hold and combine in working memory expands, making movement to a higher stage possible. Three factors contribute to cognitive change:

- *Brain development.* Neurological changes, including myelination, synaptic growth, and synaptic pruning, improve the efficiency of thought, leading to readiness for each stage. According to Case, biology imposes a systemwide ceiling on cognitive development. At any given time, the child cannot exceed a certain upper limit of processing speed. (Refer back to age-related gains in speed of processing on page 281.)
- *Practice with schemes and automization.* In Case's theory, Piagetian schemes are the child's mental strategies. Within each stage, through repeated use, the child's schemes become automatic, freeing working-memory resources for combining existing schemes and generating new ones. Notice how Case's mechanisms of cognitive change offer a clarified view of Piaget's concepts of assimilation and accommodation. *Practicing schemes* (assimilation) leads to *automization,* which *releases working memory* for other activities, permitting *scheme combination and construction* (accommodation).
- *Formation of central conceptual structures.* Once the schemes of a Piagetian stage become automatic and brain development further increments processing speed, enough space in working memory is available to consolidate schemes into an improved representational form. As a result, children generate **central conceptual structures**—networks of concepts and relations that permit them to think about a wide range of situations in more advanced ways. Consequently, processing efficiency expands further (Case, 1996, 1998). When children form new central conceptual structures, they move to the next stage of development.

Let's take a familiar set of tasks—conservation—to illustrate Case's ideas. Imagine a 5-year-old who cannot yet conserve liquid but who has some isolated schemes: (1) After water is poured from a tall glass into a short glass, the height of the water level is reduced. (2) After water is poured from a thin into a wide glass, the width of the water increases. As the child gains experience in transferring liquids from one container to another, these schemes become automatic, and she combines them into a conserving response. A similar sequence occurs in other conservation situations—involving, for example, mass and weight. Eventually the child coordinates several task-specific conserving responses into a new, broadly applicable principle: a central conceptual structure. When this happens, cognition moves from simple to complex transformations of representations, or from concrete to formal operational thought.

Case and his colleagues have applied his theory to many tasks: solving arithmetic word problems, understanding stories, drawing pictures, sight-reading music, handling money, and interpreting social situations (Case, 1992, 1998; Case & Okamoto, 1996). In each case, children coordinate an increasing number of task dimensions with age. In understanding stories, for example, preschoolers grasp only a single story line. By the early school years, they combine two story lines into a single plot. Around age 9 to 11, central conceptual structures integrate multiple dimensions: Children tell coherent stories with a main plot and several subplots.

Case's (1998) theory offers an information-processing account of the *continuum of acquisition*—that many understandings appear in specific situations at different times rather than being mastered all at once (see page 252 in Chapter 6). First, different forms of the same logical insight, such as the various conservation tasks, vary in their processing demands; those acquired later

As she practices counting money, this 6-year-old becomes a more efficient processor, coordinating an increasing number of task dimensions into a central conceptual structure—a general representation that she can apply in many situations.

© JGI/GETTY IMAGES/BLEND IMAGES

require that more information be held and combined in working memory. Second, children's experiences vary widely. A child who often listens to and tells stories displays more advanced central conceptual structures in storytelling than in other activities. And children who do not show central conceptual structures expected for their age can usually be trained to attain them (Case, Griffin, & Kelly, 2001). Therefore, Case's theory is better able than Piaget's to account for unevenness in cognitive development. Although Case's ideas remain to be tested with many more tasks, his theory is unique in offering an integrated picture of how children's processing efficiency, practice with strategies, and efforts to reorganize their thinking interact to produce development.

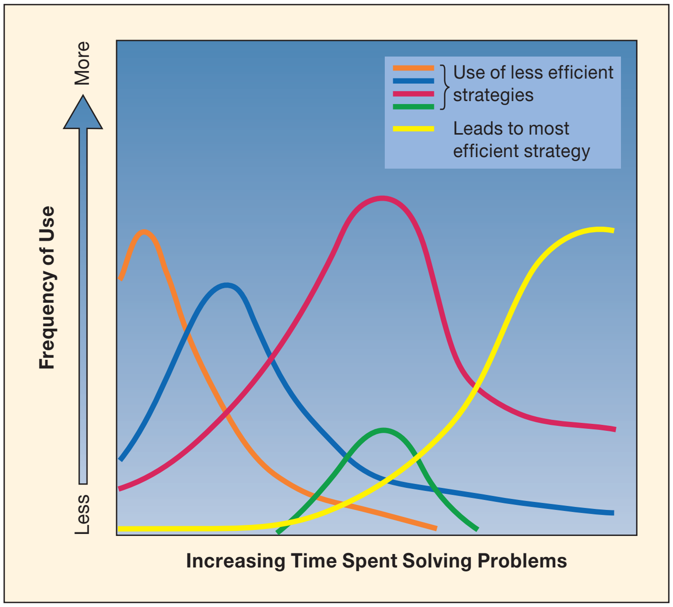
Siegler's Model of Strategy Choice

Robert Siegler's (1996, 2006) **model of strategy choice** uses an evolutionary metaphor—"natural selection"—to help us understand cognitive change. When given challenging problems, children generate a *variety* of strategies, testing the usefulness of each. With experience, some strategies are *selected*; they become more frequent and "survive." Others become less frequent and "die off." Like the evolution of physical traits, children's mental strategies display *variation* and *selection,* yielding adaptive problem-solving techniques—ones best suited to solving the problems at hand.

To study children's strategy use, Siegler used the microgenetic research design (see Chapter 2, pages 64–65), presenting children with problems over an extended time period. He found that children experiment with diverse strategies on many types of problems—basic math facts, numerical estimation, conservation, memory for lists of items, reading first words, telling time, spelling, and even tic-tac-toe. Consider 5-year-old Darryl, who was adding marbles tucked into pairs of small bags that his kindergarten teacher had set out on a table. As Darryl dealt with each pair, his strategies varied. Sometimes he guessed, not applying any strategy. At other times, he counted from 1 on his fingers. For example, for bags containing 2 + 4 marbles, his fingers popped up one by one as he exclaimed, "1, 2, 3, 4, 5, 6!" Occasionally he started with the lower digit, 2, and "counted on" ("2, 3, 4, 5, 6"). Or he began with the higher digit, 4, and counted on ("4, 5, 6"), a strategy called *min* because it minimizes the work. Sometimes he retrieved the answer from memory.

Siegler found that strategy use for basic math facts—and many other types of problems—follows an *overlapping-waves pattern* (see Figure 7.3). Performance tends to progress from a single incorrect approach, to a highly variable state in which children try different strategies, to use of a more advanced procedure. Even 2-year-olds solving simple problems, such as how to use a tool to obtain an out-of-reach toy, display this sequence (Chen & Siegler, 2000; Siegler, 2007). While trying strategies, children observe which work best, which work less well, and which are ineffective. Gradually they select strategies on the basis of two adaptive criteria: *accuracy* and *speed*—for basic addition, the *min* strategy. As children home in on effective strategies, they learn more about the problems at hand. As a result, correct solutions become more strongly associated with problems, and children display the most efficient strategy—automatic retrieval of the answer.

FIGURE 7.3 **Overlapping-waves pattern of strategy use in problem solving.** When given challenging problems, a child generates a variety of strategies, each represented by a wave. The waves overlap because the child tries several different strategies at the same time. Use of each strategy, depicted by the height of the wave, is constantly changing. As the child observes which strategies work best, which work less well, and which are ineffective, the one that results in the most rapid, accurate solutions wins out. (From R. S. Siegler, *Emerging Minds: The Process of Change in Children's Thinking.* Copyright © 1996 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.)



How do children move from less to more effective strategies? Often they discover faster, more accurate strategies by using more time-consuming techniques. For example, by repeatedly counting on fingers, Darryl began to recognize the number of fingers he held up. And by alternating between counting from the lower digit and using *min,* Darryl directly observed *min*'s greater speed and accuracy (Siegler & Jenkins, 1989). Indeed, when given the same problems repeatedly over a short time interval, children regress from more advanced to less advanced approaches on as many as 40 percent of the trials! The more variable their strategies, the better their eventual

SOCIAL ISSUES: EDUCATION

Speech–Gesture Mismatches: Using the Hand to Read the Mind

Mr. Beal introduced his fourth-grade class to the concept of equivalence—that the quantity on one side of an equals sign is the same as the quantity on the other side. Then he watched as several children stepped up to the blackboard to work the following problem: 5 + 3 + 4 = ____ + 4.

"I added 5 + 3 + 4 + 4 equals 16," Kerry said, pointing to each number as she mentioned it and then to the blank as she gave her answer, ignoring the placement of the equals sign. Kerry's speech and gestures were consistent: Both revealed an incorrect strategy.

Noelle, who went next, gave the same incorrect explanation. But her gestures sent a different message. As she spoke, she pointed to each number on the left, then touched the equals sign, then the 4 on the right, and finally rested her finger on the blank. Noelle showed a *speech–gesture mismatch:* Her hand movements suggested she knew more than she could say. Over the next few weeks, Noelle mastered equivalence problems more rapidly than Kerry. How can we account for Noelle's faster progress?

Children who produce speech–gesture mismatches seem to be in a transitional state. Their behavior indicates that they are considering two contradictory strategies at once, a sign of readiness to learn. In a microgenetic study, two groups of children who did not have a full understanding of addition-based equivalence problems were identified: speech–gesture matched and speech–gesture mismatched. As the children worked more problems, some in each group received feedback about the accuracy of their answers along with instruction explaining the equivalence principle; others received no intervention. Finally, the children's learning was assessed as they worked problems on their own (Goldin-Meadow, 2003a, 2006b).

Children who received instruction following a speech–gesture mismatch were more likely than others to move out of that state to a correct answer, based on a speech–gesture match. They also more often generalized their new knowledge to multiplication-based equivalence problems (5 × 3 × 4 = 5 × ____). Interestingly, the few speech–gesture match children who improved with instruction generalized what they learned only if they first passed through a speech–gesture mismatch phase. Correct strategies appeared first in gesture and only later in speech.

This second grader's hand gesture suggests that he understands more than he can articulate. Such speech–gesture mismatches provide opportune moments for instruction.

© ELLEN B. SENISI PHOTOGRAPHY

Children on the verge of learning appear to have strategies that are accessible to gesture but not to speech (Goldin-Meadow, 2002). Perhaps expressing a strategy in gesture that differs from one in speech facilitates awareness of conflicting ideas, encouraging the child to resolve the discrepancy in favor of the more effective strategy. Children in a mismatch state are particularly open to teaching.

Parents and teachers can use children's gestures to provide instruction at the most opportune moment. Indeed, many adults are attuned to children's speech–gesture mismatches, and others can be taught to notice them (Goldin-Meadow, 2005a). In one study, adults were more likely to teach a variety of problem-solving strategies to children who displayed mismatches than to children who did not (Goldin-Meadow & Singer, 2003). In doing so, they encouraged the "mismatchers" to try out many strategies, which—as Siegler's model of strategy choice makes clear—facilitates learning.

Finally, adults who gesture while teaching encourage students to use their hands to support learning, which leads to improved performance (Goldin-Meadow, Cook, & Mitchell, 2009). How does gesturing contribute to advances in understanding? By enabling children (and adults) to represent thoughts they cannot yet express in words, it lightens demands on working memory (Ping & Goldin-Meadow, 2010). As a result, learners can allocate additional cognitive resources to grappling with the task.

performance (Siegler, 2007). Even on a single item, children may generate varying procedures, as indicated by occasions in which their words and gestures differ (see the Social Issues: Education box above for the significance of these mismatches for readiness to learn).

Problems with certain features help children discover a better strategy (Luwel, Siegler, & Verschaffel, 2008). When Darryl opened a pair of bags, one containing ten marbles, the other two marbles, he realized that *min* would be best. Teaching children to reason logically with concepts relevant to the problems at hand also helps (Alibali, Phillips, & Fischer, 2009; Siegler & Svetina, 2006). First graders more often use *min* after realizing that regardless of the order in which two sets are combined, they yield the same results (2 + 4 = 6 and 4 + 2 = 6). Finally, when children are taught an effective strategy, they usually adopt it, abandoning less successful techniques (Siegler & Booth, 2004). Sometimes, however, children do not immediately take advantage of new, more adaptive strategies. As we will see in later sections, using a new strategy taxes working memory, and children may resist giving up a well-established, nearly automatic procedure for a new one because gains in speed of thinking are small at first.

Siegler's model reveals that no child thinks in just one way, even on a single task. A child given the same problem on two occasions often uses different approaches. Strategy variability is vital for devising new, more adaptive ways of thinking, which "evolve" through extensive experience solving problems.

The model of strategy choice offers a powerful image of development that overcomes deficiencies of the stage approach in accounting for both diversity and continuous change in children's thinking. By exploiting the microgenetic method, researchers have captured periods of high variability in children's strategy use that contribute vitally to cognitive advances. Typical cross-sectional and longitudinal studies, which easily miss such periods, make cognitive change appear more abrupt (and therefore stagelike) than it actually is.

LOOK and LISTEN

Over 2 to 3 days, present a 5- to 7-year-old with a set of math problems just ahead of his or her current level of mastery, noting the child's solution strategies. (If you can't tell by observing, ask the child, "How did you do that?"). Could you see the child experimenting with diverse strategies?

ASK YOURSELF

Review ■ Summarize evidence indicating that speed of information processing increases with age, contributing to gains in working-memory capacity. In Case's neo-Piagetian theory, how do gains in processing efficiency contribute to development?

Connect ■ Recall the dynamic systems perspective, which assumes that periods of instability precede a reorganized, more effectively functioning, stable system (see pages 30–31 in Chapter 1 and pages 148–149 in Chapter 4). How are findings on children's strategy development consistent with this idea?

Apply ■ Five-year-old Kayla used several strategies to solve conservation-of-number problems involving rows of pennies. On one, she said, "The rows aren't the same." On the next, she said, "The rows have the same number because you didn't add any." On the third, she said, "I counted the pennies. The rows have the same number." Did she move from a more to a less mature strategy? Explain. Why is it beneficial for Kayla to experiment with strategies?

Reflect ■ Think of a challenging task that you recently completed successfully. Describe executive skills you implemented, explaining how each contributed to your success.

- Describe the development of attention, including sustained, selective, and adaptable strategies.

Attention

The following sections address children's processing in major parts of the cognitive system—how children encode information, hold and transform it in working memory so it will transfer to long-term memory, and retrieve it so they can think and solve problems. We begin with research on the development of attention. Attention is fundamental to human thinking because it determines which information will be considered in any task. Parents and teachers are well aware that young children spend only a short time involved in tasks, have difficulty focusing on relevant details, and find it difficult to switch mental sets (usually persist in one way of doing something). During early and middle childhood, attention improves greatly, becoming more sustained, selective, and adaptable.

Sustained, Selective, and Adaptable Attention

During the first year, infants attend to novel and eye-catching events, orienting to them more quickly and tracking their movements more effectively. They also spend more time focused on complex stimuli, such as toys and videos, and display greater slowing of heart rate while engaged—a physiological indicator of *sustained attention* (Richards, 2008). In toddlerhood, children become increasingly capable of intentional, or goal-directed, behavior (see Chapter 6, page 229). Consequently, attraction to novelty declines (but does not disappear), and sustained attention improves further, especially during play. A toddler who engages in goal-directed behavior even in a limited way, such as stacking blocks or putting them in a container, must sustain attention to reach the goal. In a study of toddlers and young preschoolers, sustained attention during play with toys increased sharply between ages 2 and 3½ years (Ruff & Capozzoli, 2003).

Rapid growth of the prefrontal cortex, the capacity to generate increasingly complex play goals (children must concentrate to attain them), and adult scaffolding of attention are jointly responsible for this gain in sustained attention (Ruff & Capozzoli, 2003). When parents help toddlers and young preschoolers maintain a focus of attention by offering suggestions, questions, and comments about the child's current interest, sustained attention improves. More attentive children are better developed, cognitively and socially (Bono & Stifter, 2003; Murphy et al., 2007; Pérez-Edgar et al., 2010). Many skills, including language, exploration, problem solving, academic learning, social interaction, cooperation, and complex play, benefit from an improved ability to concentrate.

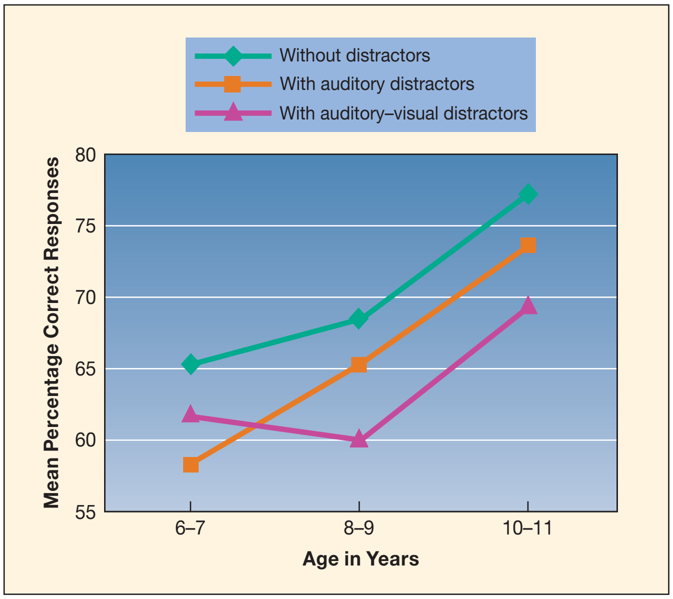


FIGURE 7.4 **Gains in selective attention from age 6 to 11 years on a task requiring children to distinguish safe from dangerous road-crossing scenes.** Children viewed computer images of road-crossing scenes, pushing a green key to indicate a safe scene and a red key to indicate an unsafe scene. On some sets of scenes, researchers introduced visual and auditory distractors, such as a dog barking, a train whistling, or a boy shouting. Accuracy increased with age, even under distracting conditions. (Adapted from Tabibi & Pfeffer, 2007.)

As sustained attention increases, children become better at focusing on only those aspects of a situation that are relevant to their goals. To study this increasing selectivity of attention, researchers introduce irrelevant stimuli into a task and see how well children respond to its central elements. For example, they might present a stream of numbers on a computer screen and ask children to press a button whenever a particular sequence of two digits (such as "1" and then "9") appears. Findings show that selective attention improves sharply between ages 6 and 10, with gains continuing through adolescence (Gomez-Perez & Ostrosky-Solis, 2006; Tabibi & Pfeffer, 2007; Vakil et al., 2009). Tasks tapping everyday requirements for selective attention reveal similar trends. In one study, researchers showed 6- to 11-year-olds computer images of safe and dangerous road-crossing scenes, sometimes with and sometimes without visual and auditory distractors (Tabibi & Pfeffer, 2007). Ability to distinguish safe from dangerous sites increased with age, even in the presence of distractors (see Figure 7.4), and also correlated positively with scores on laboratory attention tasks.

Older children are also better at flexibly adapting their attention to task requirements, switching mental sets within a task. When asked to sort a deck of cards with pictures that vary in both color and shape, children age 5 and older readily switch their basis of sorting from color to shape when asked to do so. Younger children persist in sorting in just one way, even though they know the rule system relevant to the task (pre-switch: *red* goes in this box, *blue* in that box; post-switch: *circles* go in this box, *triangles* in that box) (Brooks et al., 2003; Zelazo, Carlson, & Kesek, 2008).

Furthermore, with age, children adapt their attention to changes in their own learning. When given lists of items to learn and allowed to select half for further study, first graders do not choose systematically, but third graders select those they had previously missed (Masur, McIntyre, & Flavell, 1973). In research presenting complex information, such as prose passages, the ability to allocate attention based on previous performance continues to improve into the college years (Brown, Smiley, & Lawton, 1978).

How do children acquire selective, adaptable attention? Gains in two components of executive function—inhibition and attentional strategies—play vital roles.

© DAVID GROSSMAN/ALAMY

Amid the distractions of a subway car, these readers remain engrossed in their books. Gains in inhibition between ages 6 and 10 contribute to a dramatic improvement in selective attention—the capacity to focus on a task, ignoring irrelevant stimuli.

Inhibition Sustained, selective, and adaptable attention requires **inhibition**—the ability to control internal and external distracting stimuli. Individuals who are skilled at inhibition can prevent the mind from straying to alternative attractive thoughts and can keep stimuli unrelated to a current goal from capturing their attention (Dempster & Corkill, 1999). By controlling irrelevant stimuli, inhibition frees working-memory resources for the task at hand and, therefore, supports many information-processing skills (Bjorklund & Harnishfeger, 1995; Handley et al., 2004; Klenberg, Korkman, & Lahti-Nuuttila, 2001).

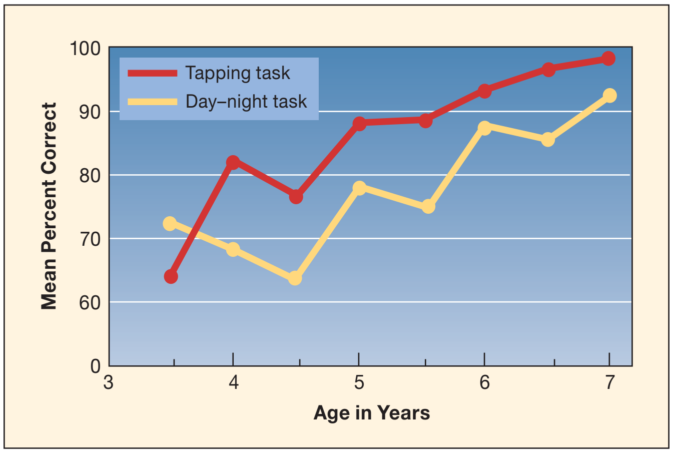

FIGURE 7.5 Gains between ages 3 and 7 in performance on tasks requiring children to inhibit an impulse and focus on a competing goal. In the tapping task, children had to tap once when the adult tapped twice and tap twice when the adult tapped once. In the day–night task, children had to say "night" to a picture of the sun and "day" to a picture of the moon with stars. (From A. Diamond, 2004, "Normal Development of Prefrontal Cortex from Birth to Young Adulthood: Cognitive Functions, Anatomy, and Biochemistry," as appeared in D. T. Stuss & R. T. Knight [Eds.], *Principles of Frontal Lobe Function.* New York: Oxford University Press, p. 474. Reprinted by permission of Adele Diamond.)

Besides helping children remember, reason, and solve problems, it assists them in managing their behavior in social situations. As we will see in later chapters, to get along with others, children must learn to restrain impulses and keep negative emotions in check.

The ability to inhibit thoughts and behavior improves from infancy on. Between ages 3 and 4, for example, preschoolers perform considerably better in situations in which they must follow some commands but not others, as in the game "Simon Says" (Jones, Rothbart, & Posner, 2003). On more complex tasks requiring children to inhibit distracting stimuli, marked gains occur from early to middle childhood. Consider, for example, a task in which the child must tap once after the adult taps twice and tap twice after the adult taps once, or must say "night" to a picture of the sun and "day" to a picture of the moon. As Figure 7.5 shows, 3- and 4-year-olds make many errors. But by age 6 to 7, children find such tasks easy (Johnson, Im-Bolter, & Pascual-Leone, 2003; Kirkham, Cruess, & Diamond, 2003). They can resist the "pull" of their attention toward a dominant stimulus—a skill that predicts social maturity as well as subsequent reading and math achievement, from kindergarten through high school (Blair & Razza, 2007; Duncan et al., 2007; Rhoades, Greenberg, & Domitrovich, 2009). ERP and fMRI measures reveal a steady age-related increase in activation of the prefrontal cortex while children engage in these inhibitory tasks (Bartgis, Lilly, & Thomas, 2003; Diamond, 2004; Luna et al., 2001).

High-quality preschool education can enhance inhibition and other attentional components of executive function. In *Tools of the Mind*—a preschool curriculum inspired by Vygotsky's theory—scaffolding of attention is woven into virtually all classroom activities (Bodrova & Leong, 2007). For example, teachers provide external aids to support attention: A child might hold a drawing of an ear as a reminder to listen and not interrupt a classmate who is telling a story. Teachers also lead games requiring frequent inhibition and rule-switching. And they encourage make-believe play, which helps children suppress impulses and use thought to guide behavior (see page 269 in Chapter 6). When preschoolers from low-income families, who often show deficits in attention, were randomly assigned to either Tools or comparison classrooms, the Tools children performed substantially better on end-of-year tasks assessing inhibition and other attentional capacities (Diamond et al., 2007). Nurturing attention through the Tools curriculum may prove powerful in early prevention of academic and behavior problems.

In sum, by clearing unnecessary stimuli, inhibition increases available space in working memory. This, in turn, opens the door to higher-level strategy use—working more effectively with information held in mind.

Attentional Strategies

Patricia Miller and her colleagues gave 3- to 9-year-olds a task requiring a selective attentional strategy—a large box with rows of doors that could be opened. On half the doors were pictures of cages, indicating that behind each was an animal. On the other half were pictures of houses, indicating that they contained household objects. Children were asked to remember the location of each object in one group, then given a study period in which they could open any doors they wished. Next they were shown pictures of each relevant object, one at a time, and asked to point to the object's location (DeMarie-Dreblow & Miller, 1988; Miller et al., 1986; Woody-Ramsey & Miller, 1988). The most efficient attentional strategy—opening only doors with relevant pictures on them—emerged and became refined in the following sequence:

1. **Production deficiency.** Preschoolers rarely engage in attentional strategies. In other words, they usually fail to *produce* strategies when they could be helpful. On the task just described, they simply opened all the doors.
2. **Control deficiency.** Young elementary school children sometimes produce strategies, but not consistently. They have difficulty *controlling*, or executing, strategies effectively. For example, 5-year-olds began to apply a selective attentional strategy—opening only relevant doors—but, at times, reverted to opening irrelevant doors.

3. **Utilization deficiency.** Slightly later, children execute strategies consistently, but their performance either does not improve or improves less than that of older children. For many 6- and 7-year-olds, opening only the relevant doors did not increase memory for object locations after the pictures were removed from the doors.
4. **Effective strategy use.** By the mid-elementary school years, children use strategies consistently, and performance improves (Miller, 2000).

As we will soon see, this sequence also characterizes children's use of memory strategies. Why, when children first use a strategy, does it not work well? Applying a new strategy generally requires so much effort and attention that little space in working memory remains to perform other parts of the task well (Woody-Dorning & Miller, 2001). Another reason a new strategy may not lead to performance gains is that young children are not good at monitoring their task performance (Schneider & Bjorklund, 2003). Because they fail to keep track of how well a strategy is working, they do not apply it consistently or refine it in other ways.

© LAURA DWIGHT PHOTOGRAPHY

While following a recipe, an 11-year-old provides her 7-year-old sister with guidance in planning, first gathering the ingredients and then combining them in correct sequence. With many everyday opportunities to practice, planning improves with age.

Planning

With age, children's attention undergoes a profound advance that contributes greatly to executive function: **Planning** involves thinking out a sequence of acts ahead of time and allocating attention accordingly to reach a goal (Scholnick, 1995). The seeds of effective planning are present in infancy. When researchers showed 2- and 3-month-olds a series of pictures that alternated in a predictable left–right sequence, the babies quickly learned to shift their focus to the location of the next stimulus before it appeared (Wentworth & Haith, 1998). And recall 4-month-olds' ability to engage in predictive tracking of objects' movements (see page 165 in Chapter 4). Even young infants' attention seems to be "future-oriented."

But on relatively simple tasks requiring children to reason about how best to implement a future action, preschoolers have great difficulty generating a plan. In one study, 3- to 5-year-olds were shown a doll named Molly, a camera, and a miniature zoo with a path, along which were three animal cages. The first and third cages had storage lockers next to them; the middle cage, with no locker, housed a kangaroo (see Figure 7.6). The children were told that Molly could follow the path only once and that she wanted to take a picture of the kangaroo, but there was no locker beside the kangaroo's cage in which to store the camera. Then they were asked, "What locker could you leave the camera in so Molly can get

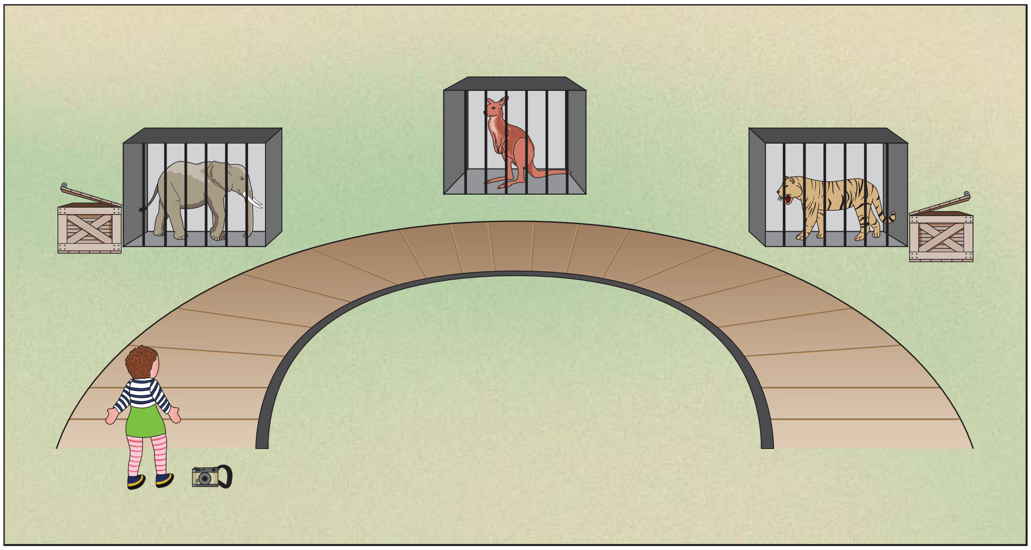

FIGURE 7.6 Miniature zoo used to assess preschoolers' planning. After being told that Molly wanted to take a picture of the kangaroo but could follow the path only once, preschoolers were asked to indicate which locker the camera should be left in so Molly could get it and take the photo. Not until age 5 did children plan, more often selecting the first locker; younger children chose the two lockers equally often. (Adapted from McColgan & McCormack, 2008.)

BIOLOGY and ENVIRONMENT

Children with Attention-Deficit Hyperactivity Disorder

While the other fifth graders worked quietly at their desks, Calvin squirmed, dropped his pencil, looked out the window, fiddled with his shoelaces, and talked aloud. "Hey Joey," he yelled over the heads of several classmates, "wanna play ball after school?" But the other children weren't eager to play with Calvin, who was physically awkward and failed to follow the rules of the game. He had trouble taking turns at bat. In the outfield, he tossed his mitt in the air and looked elsewhere when the ball came his way. Calvin's desk was a chaotic mess. He often lost his books, pencils, and other school materials, and he had trouble remembering assignments or deadlines.

Symptoms of ADHD

Calvin is one of 3 to 7 percent of U.S. school-age children with **attention-deficit hyperactivity disorder (ADHD),** which involves inattention, impulsivity, and excessive motor activity resulting in academic and social problems (American Psychiatric Association, 2000; Goldstein, 2011). Boys are diagnosed about four times as often as girls. However, many girls with ADHD seem to be overlooked, either because their symptoms are less flagrant or because of a gender bias: A difficult, disruptive boy is more likely to be referred for treatment (Abikoff et al., 2002; Biederman et al., 2005).

Children with ADHD cannot stay focused on a task that requires mental effort for more than a few minutes. They often act impulsively, ignoring social rules and lashing out with hostility when frustrated. Many, though not all, are *hyperactive,* exhausting parents and teachers and irritating other children with their excessive motor activity. For a child to be diagnosed with ADHD, these symptoms must have appeared before age 7 as a persistent problem.

Because of their difficulty concentrating, children with ADHD score 7 to 15 points lower than other children on intelligence tests (Barkley, 2002). Researchers agree that executive-function deficiencies underlie ADHD symptoms. According to one view, children with ADHD are impaired in capacity to inhibit action in favor of thought—a basic difficulty that results in wide-ranging inadequacies in executive processing and, therefore, in impulsive, disorganized behavior (Barkley, 2003). Another hypothesis is that ADHD is the direct result of a cluster of executive-processing problems that interfere with the ability to guide one's own actions (Brown, 2005, 2006). Research confirms that children with ADHD do poorly on tasks requiring sustained attention; find it hard to ignore irrelevant information; have difficulty with memory, planning, reasoning, and problem solving in academic and social situations; and often fail to manage frustration and intense emotion (Barkley, 2003, 2006).

Origins of ADHD

ADHD runs in families and is highly heritable: Identical twins share it far more often than fraternal twins (Freitag et al., 2010; Rasmussen et al., 2004). Children with ADHD show abnormal brain functioning, including reduced electrical and blood-flow activity and structural abnormalities in the prefrontal cortex and in other areas involved in attention, inhibition of behavior, and additional aspects of motor control (see page 186 in Chapter 5) (Mackie et al., 2007; Sowell et al., 2003). Also, the brains of children with ADHD grow more slowly and are about 3 percent smaller in overall volume, with a thinner cerebral cortex, than the brains of unaffected agemates (Narr et al., 2009; Shaw et al., 2007). Several genes that disrupt functioning of the neurotransmitters serotonin (involved in inhibition and self-control) and dopamine (required for effective cognitive processing) have been implicated in the disorder (Bobb et al., 2006; Faraone & Mick, 2010).

At the same time, ADHD is associated with environmental factors. Prenatal teratogens, such as tobacco, alcohol, and environmental pollutants, are linked to inattention and

it and take a photo of the kangaroo?" (McColgan & McCormack, 2008). Below age 5, children were unable to plan effectively; they selected the two lockers with equal frequency. Yet in a task with the same elements that asked children to reason about the past—Molly took the kangaroo's picture, stored the camera in a locker, and after traveling the path can't find it, so at which location is she likely to recover it?—4-year-olds often succeeded.

These findings—and others—indicate marked gains in planning around 5 years of age (Hudson, Sosa, & Shapiro, 1997). Apparently, reasoning about a sequence of future events, which the child has never before experienced, is more difficult than reasoning about a sequence of past events, which the child has directly observed.

On more complex planning tasks, further improvement occurs during middle childhood. When 5- to 9-year-olds were given lists of items to obtain from a play grocery store, older children more often took time to scan the store before shopping and also paused more often to look for each item before moving to get it. Consequently, they followed shorter routes through the aisles (Gauvain & Rogoff, 1989; Szepkouski, Gauvain, & Carberry, 1994).

Planning in most everyday tasks requires children to coordinate attention skills with other cognitive processes. To solve problems involving multiple steps, children must imagine future possibilities, postpone action in favor of evaluating alternatives, organize task materials (such as items on a grocery list), and remember the steps of their plan so they can attend to each one in sequence. Along the way, they must monitor how well the plan works and revise it if necessary. Clearly, planning places heavy demands on working memory. Not

For the 7-year-old on the right, who has ADHD, a classroom offering many opportunities for active learning may combine with other interventions to help her sustain attention.

hyperactivity (see Chapter 3). Furthermore, children with ADHD are more likely to come from homes in which marriages are unhappy and family stress is high. But a stressful home life rarely causes ADHD. Rather, these children's behaviors can contribute to family problems, which intensify the child's preexisting difficulties.

Treating ADHD

Calvin's doctor eventually prescribed stimulant medication, the most common treatment for ADHD. As long as dosage is carefully regulated, these drugs reduce activity level and improve attention, academic performance, and peer relations for about 70 percent of children who take them (Greenhill, Halperin, & Abikoff, 1999). Stimulant medication seems to increase activity in the frontal lobes, thereby improving the child's capacity to sustain attention and to inhibit off-task and self-stimulating behavior.

In 2006, an advisory panel convened by the U.S. Food and Drug Administration warned that stimulants might impair heart functioning, even causing sudden death in a few individuals, and advocated warning labels describing these potential risks. Debate over the safety of medication for ADHD is likely to intensify. In any case, medication is not enough. Drugs cannot teach children to compensate for inattention and impulsivity. The most effective treatment approach combines medication with interventions that model and reinforce appropriate academic and social behavior (American Academy of Pediatrics, 2005a; Smith, Barkley, & Shapiro, 2006).

Family intervention is also important. Inattentive, overactive children strain the patience of parents, who are likely to react punitively and inconsistently—a child-rearing style that strengthens defiant, aggressive behavior. In fact, in 50 to 75 percent of adolescent cases, these two sets of behavior problems occur together (Goldstein, 2011).

Some media reports suggest that the number of U.S. children diagnosed with ADHD has increased greatly. But two large surveys yielded similar overall prevalence rates 25 years ago and today. Nevertheless, the incidence of ADHD is much higher in some communities than in others. At times, children are overdiagnosed and unnecessarily medicated because their parents and teachers are impatient with inattentive, active behavior that is within normal range (Mayes, Bagwell, & Erkulwater, 2008). In Hong Kong, where academic success is particularly prized, children are diagnosed at more than twice the rate in the United States. But in Great Britain, where doctors are hesitant to label children with ADHD or to prescribe medication, children are underdiagnosed and often do not receive the treatment they need (Taylor, 2004).

ADHD is usually a lifelong disorder. Adults with ADHD continue to need help—in structuring their environments, regulating negative emotion, selecting appropriate careers, and understanding their condition as a biological deficit rather than a character flaw.

surprisingly, even when young children do plan, they succeed only on tasks with a small number of steps.

Children learn much from cultural tools that support planning—directions for playing games, patterns for construction, recipes for cooking—especially when they collaborate with more expert planners. When 4- to 7-year-olds were observed jointly constructing a toy with their mothers, the mothers provided basic information about the usefulness of plans and how to implement specific steps: "Do you want to look at the picture and see what goes where? What piece do you need first?" After working with their mothers, younger children more often referred to the plan when building on their own (Gauvain, 2004; Gauvain, de la Ossa, & Hurtado-Ortiz, 2001).

Having many opportunities to practice planning helps children understand its components and use that knowledge. Parents can foster planning by encouraging it in everyday activities, from loading the dishwasher to planning for a vacation. In one study, parent–child discussions involving planning at ages 4 to 9 predicted planning competence in adolescence (Gauvain & Huard, 1999). The demands of academic tasks—and teachers' explanations of how to plan—also contribute to gains in planning.

The attentional strategies we have just considered are crucial for both school and life success. Unfortunately, some children have grave difficulties paying attention. See the Biology and Environment box on the following page for a discussion of the serious learning and behavior problems of children with attention-deficit hyperactivity disorder.

ASK YOURSELF

Review ■ How does inhibition support development of attention and other information-processing skills?

Connect ■ What other components of executive function likely contribute to improved planning in middle childhood? What can adults do to scaffold children's planning skills?

Apply ■ At age 7, Jonah played his piano pieces from beginning to end instead of spending extra time on the hard sections. Around age 8, he devoted more time to sections he knew least well, but his performance did not improve for several months. What explains Jonah's gradual gains in strategy use and performance?

Reflect ■ Describe an instance in which you applied a strategy for the first time but experienced a utilization deficiency. Why do you think the deficiency occurred, and how did you overcome it?

- Describe the development of strategies for storing and retrieving information from memory.
- Explain the development of episodic memory and its relationship to semantic memory.
- How does eyewitness memory change with age, and what factors influence the accuracy of children's reports?

Memory

As attention improves, so do *memory strategies*—deliberate mental operations we use to increase the likelihood of retaining information in working memory and transferring it to our long-term knowledge base. In Chapters 4 and 6, we saw that during the first two years, memory for objects, people, and events—as assessed in operant conditioning, habituation, and deferred-imitation studies—undergoes dramatic gains. With age, babies remember more information over longer periods (see pages 141 and 233).

But relative to children and adults, infants and toddlers engage in little effortful, strategic memorizing. For the most part, they remember unintentionally, as part of their ongoing activities (Bjorklund, 2012). And when memory strategies emerge in early childhood, they are not very successful at first (Schneider, 2002). Not until middle childhood do these executive techniques take a giant leap forward.

Strategies for Storing Information

Researchers have studied the development of three strategies that enhance memory for new information: rehearsal, organization, and elaboration.

Rehearsal, Organization, and Elaboration

TAKE A MOMENT... Next time you have a list of things to learn, such as major cities in your state or country, or items to buy at the supermarket, notice your behavior. You are likely to repeat the information to yourself, a memory strategy called **rehearsal**—a procedure mentioned earlier that holds information in working memory. And you will probably group related items (for example, all the cities in the same part of the country), a strategy called **organization.**

Why are young children not adept at rehearsal and organization? Memory strategies require extra space in working memory and time and effort to perfect. Even when school-age children use these strategies more often—around age 7 for rehearsal and age 8 for organization—many show *control* and *utilization deficiencies* (Bjorklund, Dukes, & Brown, 2009). For example, 7- to 8-year-olds often rehearse in a piecemeal fashion. When given the word *cat* in a list of items, they say, "*Cat, cat, cat.*" In contrast, older children combine previous words with each new item, saying "*Desk, man, yard, cat, cat.*" This more active rehearsal approach, in which neighboring words create contexts for one another that trigger recall, yields much better memory (Lehman & Hasselhorn, 2007, 2010). Similarly, younger children usually organize items by their everyday association: "*hat–head,*" "*carrot–rabbit.*" Older children group such items into *taxonomic categories,* based on common properties—clothing, body parts, food, animals. Placing more items in a few categories permits more efficient organization, dramatically improving memory (Bjorklund et al., 1994). Experience with materials that form clear categories and adult demonstration and prompting to organize helps children use organization and, eventually, apply the strategy to less clearly related materials (Güller et al., 2010; Schlagmüller & Schneider, 2002).

SOCIAL ISSUES: EDUCATION

Media Multitasking Disrupts Learning

“Mom, I’m going to study for my biology test now,” called 16-year-old Ashley while shutting her bedroom door. Sitting down at her desk, she accessed a popular social-networking website on her laptop, donned headphones and began listening to a favorite song on her MP3 player, and placed her cell phone next to her elbow so she could hear it chime if any text messages arrived. Only then did she open her textbook and begin to read.

In a survey of a nationally representative sample of U.S. 8- to 18-year-olds, more than two-thirds reported engaging in two or more media activities at once, some or most of the time (Rideout, Foehr, & Roberts, 2010). Their most frequent type of media multitasking is listening to music while doing homework, but many also report watching TV or using the Internet while studying (Jeong & Fishbein, 2007). The presence of a television or computer in the young person’s bedroom is a strong predictor of this behavior (Foehr, 2006). And it extends into classrooms, where students can be seen text-messaging under their desks or surfing the Internet on cell phones.

Research confirms that media multitasking greatly reduces learning. In one experiment, participants were given two tasks: learning to predict the weather in two different cities using colored shapes as cues and keeping a mental tally of how many high-pitched beeps they heard through headphones. Half the sample performed the tasks simultaneously, the other half separately. Both groups learned to predict the weather in the two-city situation, but the multitaskers were unable to apply their learning to new weather problems (Foerde, Knowlton, & Poldrack, 2006).

fMRI evidence revealed that the participants working only on the weather task activated the hippocampus, which plays a vital role in *explicit memory*—conscious, strategic recall, which enables new information to be used flexibly and adaptively in contexts outside the original learning situation (see page 190 in Chapter 5). In contrast, the multitaskers activated subcortical areas involved in *implicit memory*—a shallower, automatic form of learning that takes place unconsciously.

© LAURA DWIGHT PHOTOGRAPHY

Checking phone and text messages while studying may seem harmless—and irresistible. But research suggests that the attention shifting involved in media multitasking interferes with learning.

As early as 1980, studies linked heavy media use with executive-function difficulties (Nunez-Smith et al., 2008). Frequent media multitaskers, who are accustomed to continuously shifting their attention between tasks, have a harder time filtering out irrelevant stimuli when they are not multitasking (Ophir, Nass, & Wagner, 2009).

Beyond superficial preparation for her biology test, Ashley is likely to have trouble concentrating and strategically processing new information after turning off her computer and MP3 player. Experienced teachers often complain that compared to students of a generation ago, today’s teenagers are more easily distracted and learn less thoroughly. One teacher reflected, “It’s the way they’ve grown up—working short times on many different things at one time” (Clay, 2009, p. 40).

Furthermore, older children are more likely to apply several memory strategies at once, rehearsing, organizing, and stating category names. The more strategies they use, the better they remember (Coyle & Bjorklund, 1997; Schwenck, Bjorklund, & Schneider, 2007). Although younger children’s use of multiple memory strategies may have little impact on performance, their tendency to experiment is adaptive, allowing them to discover which strategies work best on different tasks and how to combine them effectively. For example, second to fourth graders know that a good way to study lists is to organize the items first, next rehearse category names, and then rehearse individual items (Hock, Park, & Bjorklund, 1998).

By the end of middle childhood, children start to use a third memory strategy, **elaboration.** It involves creating a relationship, or shared meaning, between two or more pieces of information that do not belong to the same category. For example, to learn the words *fish* and *pipe,* you might generate the verbal statement or mental image, “The fish is smoking a pipe.” This highly effective memory technique becomes more common during adolescence as young people improve at holding two or more items in mind while generating complex, meaningful associations (Schneider & Pressley, 1997).

In sum, older-school-age children and adolescents have become adept at strategic memorizing. But while doing schoolwork, they frequently engage in other pursuits—most often, media activities, such as text messaging and e-mailing friends, listening to music, and watching TV or videos. To find out what happens to knowledge acquisition when students engage in this “media multitasking,” consult the Social Issues: Education box above.

This child of the U'wa people of Colombia, who have no written tradition, would have trouble recalling isolated bits of information, as school tasks require. But she demonstrates keen memory for the steps involved in making traditional cocara leaf hats.

Culture, Schooling, and Memory Strategies

People usually employ memory strategies when they need to remember information for its own sake. On many other occasions, memory occurs as a natural byproduct of participation in daily activities (Rogoff, 2003). In a study illustrating this idea, 4- and 5-year-olds were told either to *play with* a set of toys or to *remember* them. The play condition produced far better recall because the children engaged in many spontaneous organizations. These included using objects in typical ways (putting a shoe on a doll's foot) and narrating their activities: "I'm squeezing this lemon," or "Fly away in this helicopter, doggie" (Newman, 1990).

A repeated finding is that people in non-Western cultures who lack formal schooling rarely use or benefit from instruction in memory strategies because they see no practical reason to use these techniques (Rogoff & Mistry, 1985). Tasks that require children to remember isolated bits of information, which are common in school, strongly motivate use of memory strategies. In fact, Western children get so much practice with this type of learning that they do not refine techniques that rely on cues available in every life, such as spatial location and arrangement of objects (Mistry, 1997). For example, Guatemalan Mayan 9-year-olds do slightly better than their U.S. agemates when told to remember the placement of 40 familiar objects in a play scene. U.S. children often rehearse object names when it would be more effective to keep track of spatial relations (Rogoff & Waddell, 1982). The development of memory strategies, then, is not just a matter of a more competent information-processing system. It is also a product of task demands and cultural circumstances.

Retrieving Information

Once information enters our long-term knowledge base, we must *retrieve* (or recover) it to use it again. We retrieve information in three ways: through recognition, recall, and reconstruction. As we discuss these approaches to remembering, we will consider how children's expanding knowledge base affects their memory performance. We will also delve into the accuracy of a special type of memory—children's eyewitness accounts in legal proceedings—that can seriously affect their own and others' welfare.

Recognition and Recall

TAKE A MOMENT... Show a young child a set of 10 pictures or toys. Then mix them up with some unfamiliar items, and ask the child to point to the ones in the original set. Noticing that a stimulus is identical or similar to one previously experienced is called **recognition.** It is the simplest form of retrieval, since the material to be remembered is fully present during testing to serve as its own retrieval cue.

As the habituation research discussed in Chapters 4 and 6 reveals, even young infants are good at recognition. The ability to recognize a larger number of stimuli over longer delays improves steadily with age, reaching a near-adult level during the preschool years. For example, after viewing a series of 80 pictures, 4-year-olds correctly discriminated 90 percent from pictures not in the original set (Brown & Campione, 1972). Because recognition appears early and develops rapidly, it is probably a fairly automatic process. Nevertheless, the ability of older children to apply strategies during storage, such as rehearsal and organization, increases the number of items recognized later (Mandler & Robinson, 1978).

TAKE A MOMENT... Now keep the items out of view, and ask the child to name the ones she saw. This more challenging task requires **recall**—generating a mental representation of an absent stimulus. The beginnings of recall appear in the second half of the first year for memories that are strongly cued. Think back to the rapid gains in deferred imitation under way after age 6 months, discussed in Chapter 6—good evidence for recall. Development of recall lags behind recognition from infancy on. In early childhood, young children's recall in tasks that require retention of pieces of information is far poorer than their recognition. At age 2, children can recall no more than one or two items, at age 4 only about three or four (Perlmutter, 1984).

Improvement in recall over the preschool years is strongly associated with language development, which greatly enhances long-lasting representations of both lists of items and past experiences (Melby-Lervag & Hulme, 2010; Ornstein, Haden, & Elischberger, 2006; Simcock & Hayne, 2003). Yet even when asked to recall an event that occurred weeks earlier, young children report only part of what could be remembered. In one longitudinal study, sixth graders were asked to tell what happened when they went to an archeological museum in kindergarten. They said less about the experience than when they had been asked the same question as kindergartners, six weeks after the museum trip. But in response to specific retrieval cues, including photos of the event, sixth graders remembered a great deal. And in some respects, their recall was more accurate (Hudson & Fivush, 1991). For example, they inferred that adults had hidden artifacts in a sandbox for them to find, whereas in kindergarten they simply recalled digging for objects.

Compared with recognition, recall shows far greater improvement because older children make use of a wider range of retrieval cues. With age, the long-term knowledge base grows larger and becomes organized into increasingly elaborate, hierarchically structured networks (Bjorklund, 2012; Schneider, 2002). When representations of items or experiences are interconnected in long-term memory, many internal retrieval cues can be used to recall them later.

Reconstruction

When we must remember complex, meaningful material, we do not merely copy material into the system at storage and faithfully reproduce it at retrieval. Instead, we select and interpret information we encounter in our everyday lives in terms of our existing knowledge. Once we have transformed the material, we often have difficulty distinguishing it from the original (Bartlett, 1932). Constructive processing can take place during any phase of information processing. It can occur during storage. In fact, the memory strategies of organization and elaboration are within the province of constructive memory because both involve generating relationships between stimuli. Constructive processing can also involve **reconstruction** of information, or recoding it while it is in the system or being retrieved.

Do children reconstruct stored information? Clearly, they do. When asked to recall and retell a story, children, like adults, condense, integrate, and add information. By age 5 or 6, children recall important features of a story while forgetting unimportant ones, combine information into more tightly knit units, reorder the sequence of events in more logical fashion, and even include new information that fits with a passage's meaning (Bischofshausen, 1985).

Furthermore, when children receive new information related to a story they previously recalled, they reconstruct the story further. In one study, before telling each of three stories, an adult gave kindergartners information about a main character that was positive ("a nice" child), negative ("not a nice" child), or neutral. Children reconstructed the main character's behaviors to fit with prior information (Greenhoot, 2000). Compared with those in the neutral condition, those in the positive condition offered a more positive account, those in the negative condition a more negative account. Seven to ten days later, a fourth story gave children additional information about the main character. In some conditions, the new information was consistent with the original information; in others, it conflicted—for example, the "nice" child was now described as a "mean" child. Children again revised their recollections of the main character's behavior accordingly.

In revising information in meaningful ways, children give themselves a wealth of helpful retrieval cues to use during recall. Over time, as originally provided information decays, children make more inferences about actors and actions, adding events and interpretations that help make sense of a story. This process

As he tells a story to his grandfather, this child growing up on a Colorado ranch engages in reconstruction, selecting, interpreting, and reordering events and details.

© NANCY RICHMOND/THE IMAGE WORKS

increases the coherence of reconstructed information and, therefore, its memorableness. Gains in working-memory capacity and language skills, which support the organization and complexity of children's recollections, predict the extent to which 9- to 11-year-olds reframe their story recall in response to new information—overriding previously acquired events and viewpoints, elaborating on and integrating old and new details into a coherent picture (Tsethlikai & Greenhoot, 2006). At the same time, as these findings reveal, much information children and adults recall can be inaccurate.

Another View of Reconstruction: Fuzzy-Trace Theory So far, we have emphasized deliberate reconstruction of meaningful material, using new information and the long-term knowledge base to interpret it. According to C. J. Brainerd and Valerie Reyna's (1993, 2001) **fuzzy-trace theory,** when we first encode information, we reconstruct it automatically, creating a vague, fuzzy version called a **gist,** which preserves essential meaning without details and is especially useful for reasoning. Although we can also retain a literal, verbatim version, we have a bias toward gist because it requires less space in working memory, freeing attention for the steps involved in thinking. For example, a person choosing among several recipes to prepare a dish for dinner relies on gist representations, noting which recipes are easier and have low-cost ingredients. But once he has selected a recipe, he needs verbatim information to prepare it. Because he is unlikely to have remembered those details, he consults the cookbook.

Fuzzy-trace theorists take issue with the assumption that all reconstructions are transformations of verbatim memory. Instead, they believe that both verbatim and gist memories are present but are stored separately to be used for different purposes. With age, children rely less on verbatim memory and more on fuzzy, reconstructed gists. To illustrate, researchers presented children with the following problem: "Farmer Brown owns many animals. He has three dogs, five sheep, seven chickens, nine horses, and eleven cows." Then they asked two types of questions: (1) questions requiring verbatim knowledge ("How many cows does Farmer Brown own, eleven or nine?") and (2) questions requiring only gist information ("Does Farmer Brown have more cows or more horses?"). As Figure 7.7 shows, preschoolers were better at answering verbatim- than gist-dependent questions, whereas the reverse was true for second graders (Brainerd & Gordon, 1994).

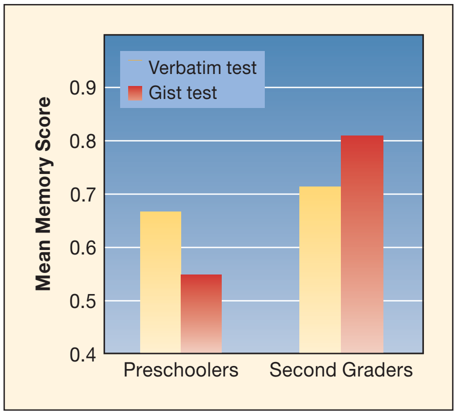

FIGURE 7.7 Preschoolers' and second graders' performance on verbatim and gist memory questions. Preschoolers did better on the verbatim than on the gist memory test; for second graders, the reverse was true. (Adapted from Brainerd & Gordon, 1994.)

Fuzzy-trace theory adds to our understanding of reconstruction by indicating that it can occur immediately, as soon as information is encoded. Fuzzy-trace research reveals that although memory is vital for reasoning, getting bogged down in details (as young children tend to do) can interfere with effective problem solving. And because fuzzy traces are less likely than verbatim memories to be forgotten, gists can serve as enduring retrieval cues, contributing to improved recall of details with age (Brainerd & Reyna, 1995).

In such recall, however, gists heighten the chances of reporting false items consistent with the fuzzy meaning of an experience. After studying a list containing the words *bed, rest, wake, tired, dream, blanket, nap,* and *snooze,* adolescents and adults—who are more skilled gist thinkers—not only recall more items correctly than children but also mention more gist-related words not in the list, such as *sleep.* Children's false reports, in contrast, are frequently unrelated to a just-studied list—for example, *candy* or *fire* following presentation of the *sleep* list (Brainerd, Holliday, & Reyna, 2004; Brainerd et al., 2006). Fuzzy-trace theory helps explain why some memory inaccuracies decrease with age, while others increase.

Knowledge and Semantic Memory

Our vast, taxonomically organized and hierarchically structured general knowledge system, consisting of concepts, language meanings, facts, and rules (such as memory strategies and arithmetic procedures) is often referred to as **semantic memory.** In previous sections, we suggested that children's expanding knowledge promotes improved memory by making new, related information more meaningful so that it is easier to store and retrieve.

These young Chinese chess players have become experts at the game. Their extensive knowledge of chess-related information gives them an advantage over less knowledgeable adults in accurately recalling complex chessboard arrangements.

A landmark study testing this idea looked at how well third- through eighth-grade chess experts could remember complex chessboard arrangements (Chi, 1978). The children recalled the configurations considerably better than adults who knew how to play chess but were not especially knowledgeable—findings that cannot be explained by the selection of very bright youngsters with exceptional memories. When participants were given a digit-span task, however, the adults did better.

In Chi's study of chess-playing children, better memory was credited to a larger chess-related knowledge base. Experts also have more elaborately structured knowledge. In another investigation, researchers classified elementary school children as either experts or novices in knowledge of soccer and then gave both groups lists of soccer and nonsoccer items to learn. As in Chi's study, the experts remembered far more items on the soccer list (but not on the nonsoccer list) than the nonexperts. And during recall, the experts' listing of items was better organized, as indicated by clustering of items into categories (Schneider & Bjorklund, 1992). This greater organization at retrieval suggests that highly knowledgeable children apply memory strategies in their area of expertise with little or no effort—by rapidly associating new items with the large number they already know. Such *automatic* recall lets experts devote more working-memory resources to using recalled information to reason and solve problems (Bjorklund & Douglas, 1997).

Knowledge, though powerfully influential, is not the only important factor in children's strategic memory processing. Children who are expert in an area are usually highly motivated as well. Faced with new information, they ask themselves, "What can I do to learn this more effectively?" As a result, they not only acquire knowledge more quickly but also *actively use what they know* to add more. In contrast, academically unsuccessful children fail to ask how previously stored information can clarify new information. This, in turn, interferes with the development of a broad knowledge base (Schneider & Bjorklund, 1998). In sum, extensive knowledge and use of memory strategies support one another.

Episodic Memory

The knowledge that makes up semantic memory does not require storage of when or where the information was acquired. In this way, it differs from **episodic memory,** recollections of personally experienced events that occurred at a specific time and place—for example, what you did after you got up this morning or how you celebrated your high school graduation. In Chapters 4 and 6, we saw that children begin acquiring semantic knowledge (such as categories and word meanings) in infancy, and by early childhood, their knowledge base is considerable (Murphy, 2002). Although they have less than older individuals, the structure of their semantic knowledge and the cognitive processes that support its acquisition are similar to those of adults.

Researchers agree that semantic memory develops earlier than episodic memory. Although infants and toddlers have some ability to encode unique events, their capacity to organize those events temporally and to retrieve event details is limited. Not until 3 or 4 years of age do children seem to have a well-functioning episodic memory system (Howe & Courage, 1997).

Semantic knowledge contributes vitally to the development of episodic memory (Murphy, McKone, & Slee, 2003). Children who have acquired substantial knowledge for interpreting personally experienced events are better able to recall those events than children with less knowledge (Robertson & Köhler, 2007). In addition to rapidly expanding semantic knowledge, 3- to 6-year-olds improve in memory for relations among stimuli. For example, in a set of photos, they remember not just the animals they saw but the contexts in which they saw them—a bear emerging from a tunnel, a zebra tied to a tree on a city street (Lloyd, Doydum, & Newcombe, 2009). The capacity to bind together information supports the development of episodic memory in early childhood.

Furthermore, young children's sense of self must be sufficiently developed to support episodic memory. To recall events, children must link time- and place-specific information to the self—to their own inner sense of "mental time travel" (Wheeler, Stuss, & Tulving, 1997, p. 332). They must realize that the remembered event is actually something that they themselves previously experienced—a milestone attained early in the preschool years.

In the following sections, we trace the development of two types of episodic memory: (1) memory for recurring events—ones that children experience repeatedly in the course of their everyday lives; and (2) memory for significant one-time events that children integrate into their personal life stories.

Scripts Like adults, preschoolers remember repeated events—what you do when you go to child care or get ready for bed—in terms of **scripts,** general descriptions of what occurs and when it occurs in a particular situation. Young children's scripts begin as a structure of main acts. For example, when asked to tell what happens at a restaurant, a 3-year-old might say, "You go in, get the food, eat, and then pay." Although children's first scripts contain only a few acts, as long as events in a situation take place in causal order, they are almost always recalled in correct sequence. Still, to obtain young children's scripted reports, adults must work hard, asking questions and prompting (Bauer, 2002, 2006). With age, scripts become more spontaneous and elaborate, as in this 5-year-old's account of going to a restaurant: "You go in. You can sit in the booths or at a table. Then you tell the waitress what you want. You eat. If you want dessert, you can have some. Then you pay and go home" (Hudson, Fivush, & Kuebli, 1992).

Scripts are a special form of reconstructive memory. When we experience repeated events, we fuse them into the same script representation. Then any specific instance of a scripted experience becomes hard to recall. **TAKE A MOMENT...** Try recalling what you had for dinner two or three days ago. Unless it was out of the ordinary, you probably cannot remember. The same is true for young children. In this way, scripts help prevent long-term memory from being cluttered with unimportant information.

Scripts help children (and adults) organize and interpret everyday experiences. Once formed, they can be used to predict what will happen on similar occasions in the future. Children rely on scripts to assist recall when listening to and telling stories. They also act out scripts in make-believe play as they pretend to go on a trip or play school. And scripts support children's earliest efforts at planning as they represent sequences of actions that lead to desired goals (Hudson & Mayhew, 2009).

© ANDY SACKS/GETTY IMAGES/RISER

Children remember repeated events in terms of scripts, general descriptions of what happens in a particular situation. With age, scripts become more elaborate: "You squeeze out the toothpaste and brush your teeth. You rinse your mouth, then your toothbrush."

Some researchers believe that the general event structures of scripts provide a foundation for organizing memory for unique events—a special birthday party or weekend trip. When given general event cues ("Tell me what happened one time *when you went to a birthday party*"), children as young as 3 could retrieve specific memories (Hudson & Nelson, 1986). But when given other cues, such as an emotion ("Tell me what happened one time *when you were scared*"), preschoolers had difficulty (Hudson et al., 1992). Let's turn to the development of this second type of episodic memory.

Autobiographical Memory Each of us has a unique **autobiographical memory,** made up of representations of one-time events that are long-lasting because they are imbued with personal meaning. How does memory for autobiographical events—the day a sibling was born or the first time you took an airplane—arise and persist for a lifetime? At least two developments make this possible. First, as noted earlier, children must have a sufficiently clear self-image to serve as an anchor for personally significant events. That is, they must be able to encode events as "something that happened to me"—a milestone reached around age 2 years (see Chapter 11) (Howe, Courage, & Rooksby, 2009). Second, children must integrate their experiences into a meaningful, time-organized life story. They learn to structure personally significant memories in narrative form by conversing about them with adults—

especially parents, who expand on their fragmented recollections (Nelson & Fivush, 2004).

Parents begin talking about past events with children as young as age 1½ to 2 years. As preschoolers' cognitive and language skills improve, parents' conversations about past events become more complex. Gradually, children adopt the narrative thinking of these dialogues: Their independent descriptions of special events become better organized, detailed, enriched with a personal perspective, and related to the larger context of their lives (Fivush, 2001). A young preschooler simply reports, "I went camping." Older preschoolers include specifics: when and where the event happened and who was present. With age, preschoolers add evaluative information—why, for example, an event was exciting, difficult, funny, sad, or made them feel proud or embarrassed ("I loved sleeping all night in the tent!")—that explains the event's personal significance.

Adults use two styles to elicit children's autobiographical narratives. In the *elaborative style,* they follow the child's lead, discussing topics of interest to the child, asking varied questions, adding information to the child's statements, and volunteering their own recollections and evaluations of events. For example, after visiting the zoo, one parent asked her 4-year-old, "What was the first thing we did? Why weren't the parrots in their cages? I thought the roaring lion was scary. What did you think?" In this way, the parent helped the child reestablish and reorganize his memory of the outing. In contrast, adults who use the *repetitive style* keep repeating the same questions regardless of the child's interest, providing little additional information: "Do you remember the zoo? What did we do at the zoo? What did we do there?"

© ROBERT BRENNER/PHOTOEDIT

As this toddler talks with his mother about past experiences, she responds in an elaborative style, asking varied questions and contributing her own recollections. Through such conversations, she enriches his autobiographical memory.

Preschoolers who experience the elaborative style recall more information about past events, and they also produce more organized and detailed personal stories when followed up 1 to 2 years later (Cleveland & Reese, 2005; Farrant & Reese, 2000). Parents can be trained to use an elaborative style, and doing so enhances the richness of preschoolers' autobiographical memories (Reese & Newcombe, 2007).

As children talk with adults about the past, they not only expand their autobiographical recollections but also create a shared history that strengthens close relationships and self-understanding. In line with these ideas, parents and preschoolers with secure attachment bonds engage in more elaborate reminiscing than those with insecure bonds, who generally limit themselves to the repetitive style (Bost et al., 2006; Fivush & Reese, 2002). And children of elaborative-style parents describe themselves in clearer, more consistent ways (Bird & Reese, 2006). When, in past-event conversations, a child discovers that she finds swimming, running, climbing, getting together with friends, and going to the zoo fun, she can begin to connect these specific experiences into a general understanding of "what I enjoy." The result is a clearer image of herself.

LOOK and LISTEN

Observe a parent or teacher conversing with one or more 4- to 7-year-olds about a special one-time past event, such as a vacation, birthday celebration, or school field trip. Did the adult use the elaborative style? How detailed and evaluative were the children's recollections?

Beginning in the preschool years, girls tend to have better organized and detailed autobiographical memories than boys (Bauer et al., 2007). And compared with Asian children, Western children produce narratives with more talk about their own thoughts, emotions, and preferences—knowledge that contributes to an appreciation of the personal meaning of events and, therefore, to better recall (Wang, 2008). These differences fit with variations in parent–child conversations. Parents reminisce in greater detail and talk more about the emotional significance of events with daughters (Bruce, Dolan, & Phillips-Grant, 2000; Fivush, 2009). And collectivist cultural valuing of interdependence leads many Asian parents to discourage children from talking about themselves. Chinese parents, for example, engage in less detailed and evaluative past-event dialogues with their preschoolers (Fivush & Wang, 2005; Wang, 2006a). Consistent with these early experiences, women report an earlier age of first memory and more vivid early memories than men. And Western adults' autobiographical memories include earlier, more detailed events that focus more on their own roles than do the memories of Asians, who tend to highlight the roles of others (Wang, 2003, 2006b).

Autobiographical memory becomes increasingly elaborate over middle childhood and adolescence. Teenagers expand greatly on the evaluative, personal meaning of autobiographical events—a change that may reflect a more intense desire to make sense of past experiences in their quest for an identity (see Chapter 11) (Pasupathi & Wainryb, 2010). Nevertheless, few of us can retrieve autobiographical events that happened to us before age 3. Why do we experience this *infantile amnesia?* Refer to the Biology and Environment box on the following page for research aimed at answering this question.

Eyewitness Memory

The accuracy and completeness of children's episodic memories are central to their ability to recount relevant experiences when testifying in court cases involving child abuse and neglect, child custody, and other legal matters. Until recently, children younger than age 5 were rarely asked to testify, and not until age 10 were they assumed fully competent to do so. As a result of societal reactions to rising rates of child abuse and the difficulty of prosecuting perpetrators, legal requirements for child testimony have been relaxed in the United States (Sandler, 2006). Children as young as age 3 frequently serve as witnesses.

Compared with preschoolers, school-age children are better at giving accurate, detailed descriptions of past experiences and correctly inferring others' motives and intentions. Older children are also more resistant to misleading questions that attorneys may ask when probing for more information or trying to influence the child's response (Roebers & Schneider, 2001). What makes younger children more prone to memory errors? The following factors are involved:

- Responding to interview questions is challenging for children whose language competence is not well-developed. Preschoolers are often unaware when they do not understand, and they answer the question anyway.
- Preschoolers are especially poor at *source-monitoring*—identifying where they got their knowledge, even minutes after they acquired it. They often confuse what they heard or saw on TV with what actually occurred.
- Accurately reporting certain temporal information is difficult for younger children. Before age 8 to 10, they are far better at providing the sequence of what happened than saying how often and on which dates an event occurred.
- Younger children are less skilled at *inhibition*—ignoring irrelevant information—which contributes to their greater willingness to accept adult suggestions that are inconsistent with experienced events.
- When an adult asks a yes-or-no question ("Was he holding a screwdriver?"), younger children are more likely to agree, perhaps out of a desire to please.
- Preschoolers' bias toward verbatim representations (encoding specifics) leads them to forget more easily than older children, whose gist memories persist over time and serve as retrieval cues for details. (But, as noted on page 296, older children are prone to memory inaccuracies consistent with their gists.)
- Because younger children are less competent at using narratives to report their autobiographical memories systematically and completely, they may omit information that they actually remember (Brainerd, Reyna, & Poole, 2000; Melinder, Endestad, & Magnusson, 2006; Pipe & Salmon, 2009; Poole & Lindsay, 2001; Roberts & Powell, 2005).

Nevertheless, when properly questioned, even 3-year-olds can recall recent events accurately (Peterson & Rideout, 1998). And in the face of biased interviewing, adolescents and adults often form elaborate false memories (Ceci et al., 2007).

Suggestibility Court testimony often involves repeated questioning—a procedure that, by itself, negatively affects children's response consistency and accuracy (Krähenbühl, Blades, & Eiser, 2009). When adults lead witnesses by suggesting incorrect "facts," interrupt their denials, reinforce them for giving desired answers, or use a confrontational questioning style, they further increase the likelihood of incorrect reporting—by children and adolescents alike (Bruck & Ceci, 2004; Owen-Kostelnik, Reppucci, & Meyer, 2006).

In one study, 4- to 7-year-olds were asked to recall details about a visitor who had come to their classroom a week earlier. Half the children received a low-pressure interview containing leading questions that implied abuse ("He took your clothes off, didn't he?"). The other half

BIOLOGY and ENVIRONMENT

Infantile Amnesia

If infants and toddlers remember many aspects of their everyday lives, how do we explain **infantile amnesia**—that most of us cannot retrieve events that happened to us before age 3? The reason we forget cannot be merely the passage of time because we can recall many events that happened long ago (Eacott, 1999). At present, several accounts of infantile amnesia exist.

One theory credits brain development, suggesting that vital changes in the hippocampus and the prefrontal cortex may pave the way for an *explicit memory* system—one in which children remember consciously rather than *implicitly,* without conscious awareness (Nelson, 1995). But mounting evidence indicates that even young infants engage in conscious recall: Their memory processing is not fundamentally different from that of children and adults. For example, as with adults, infant retention is greater with increased training and with training distributed over several sessions rather than massed into one session. And like adults, babies given memory prompts (retrieval cues) readily recover forgotten responses (see pages 141–142 in Chapter 4) (Bauer, 2006; Hayne & Simcock, 2009; Rovee-Collier & Cuevas, 2009).

Another conjecture is that older children and adults often use verbal means for storing information, whereas infants' and toddlers' memory processing is largely nonverbal—an incompatibility that may prevent long-term retention of early experiences. To test this idea, researchers sent two adults to the homes of 2- to 4-year-olds with a highly unusual toy that the children were likely to remember: the Magic Shrinking Machine, depicted in Figure 7.8. One adult showed the child how, after inserting an object in an opening on the top of the machine and turning a crank that activated flashing lights and musical sounds, the child could retrieve a smaller, identical object (discretely dropped down a chute by the second adult) from behind a door on the front of the machine.

A day later, the researchers tested the children to see how well they recalled the event. Their nonverbal memory—based on acting out the "shrinking" event and recognizing the "shrunken" objects in photos—was excellent. But even when they had the vocabulary, children younger than age 3 had trouble describing features of the "shrinking" experience. Verbal recall increased sharply between ages 3 and 4—the period during which children "scramble over the amnesia barrier" (Simcock & Hayne, 2003, p. 813). In a second study, preschoolers could not translate their nonverbal memory for the game into language six months to one year later, when their language had improved dramatically and they viewed a photo of the shrinking machine. Their verbal reports were "frozen in time," reflecting their limited language skill at the age they played the game (Simcock & Hayne, 2002).

These findings help us reconcile infants' and toddlers' remarkable memory skills with infantile amnesia. During the first few years, children rely heavily on nonverbal memory techniques, such as visual images and motor actions. But as language develops, their ability to use it to refer to preverbal memories requires strong contextual cues, such as direct exposure to the physical setting of the to-be-recalled experience (Morris & Baker-Ward, 2007). Only after age 3 do children often represent events verbally. As children encode one-time events in verbal form, they can use language-based cues to retrieve them, increasing the accessibility of these memories at later ages (Hayne, 2004).

Other findings indicate that the advent of a clear self-image contributes to the end of infantile amnesia. Without it, the child cannot construct an autobiography (Howe, Courage, & Rooksby, 2009). Toddlers who were advanced in development of a sense of self demonstrated better verbal memories a year later while conversing about past events with their mothers (Harley & Reese, 1999).

Very likely, both neurobiological change and social experience contribute to the decline of infantile amnesia. Brain development and adult–child interaction may jointly foster self-awareness, language, and improved memory, which enable children to talk with adults about personally significant past experiences (Bauer, 2007; Howe, Courage, & Rooksby, 2009). As a result, preschoolers begin to construct a long-lasting autobiographical narrative of their lives and enter into the history of their family and community.

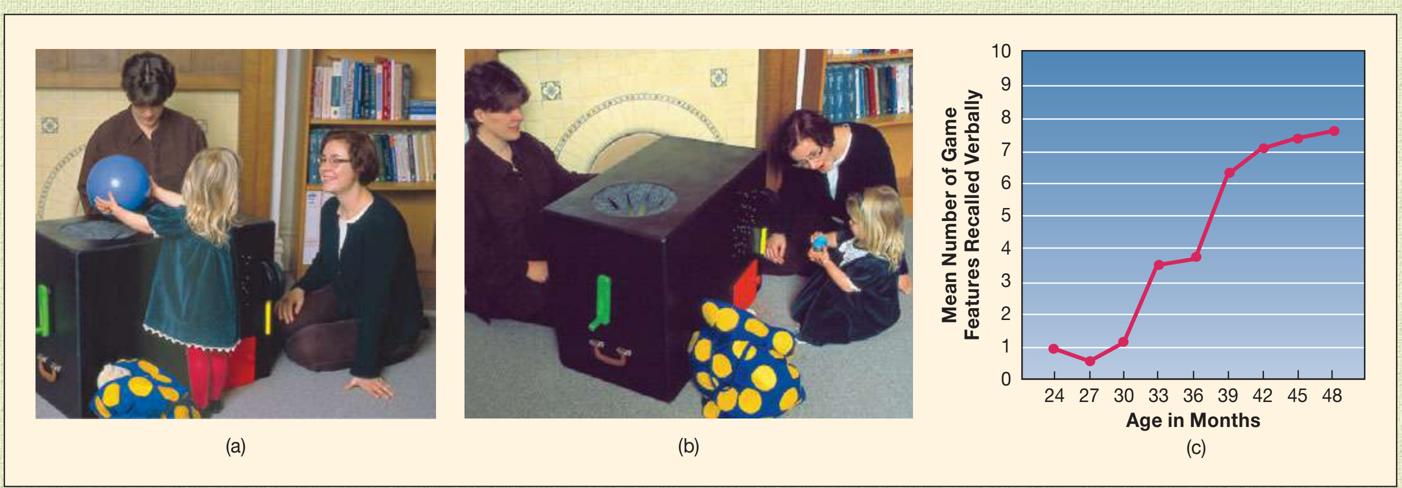

FIGURE 7.8 The Magic Shrinking Machine, used to test young children's verbal and nonverbal memory of an unusual event. After being shown how the machine worked, the child participated in selecting objects from a polka-dot bag, dropping them into the top of the machine (a) and turning a crank, which produced a "shrunken" object (b). When tested the next day, 2- to 4-year-olds' nonverbal memory for the event was excellent. But below 36 months, verbal recall was poor, based on the number of features recalled about the game during an open-ended interview (c). Recall improved between 36 and 48 months, the period during which infantile amnesia subsides. (From G. Simcock & H. Hayne, 2003, "Age-Related Changes in Verbal and Nonverbal Memory During Early Childhood," *Developmental Psychology, 39,* pp. 807, 809. Copyright © 2003 by the American Psychological Association. School-age eyewitnesses are better able than preschoolers to give accurate, detailed descriptions and correctly infer others' motives and intentions. This police officer can promote accurate recall by using a warm, supportive tone and avoiding leading questions.

received a high-pressure interview in which an adult told the child that her friends had said "yes" to the leading questions, praised the child for agreeing ("You're doing great"), and, if the child did not agree, repeated the question. Children were far more likely to give false information—even fabricating quite fantastic events—in the high-pressure condition (Finnilä et al., 2003). And children who have constructed a false memory often continue to give false reports when later questioned by an impartial interviewer (Garven, Wood, & Malpass, 2000).

By the time children appear in court, weeks, months, or even years have passed since the target events, and memory is likely to have decayed. When a long delay is combined with biased interviewing and with stereotyping of the accused ("He's in jail because he's been bad"), children can easily be misled into giving false information (Gilstrap & Ceci, 2005; Quas et al., 2007). The more distinctive and personally relevant an event is, the more likely children are to recall it accurately over time. For example, a year later, even when exposed to misleading information, children correctly reported details of an injury that required emergency room treatment (Peterson, Parsons, & Dean, 2004).

In many child sexual abuse cases, anatomically correct dolls are used to prompt children's recall. This method helps older children provide more detail about experienced events that otherwise might not be reported because of shame or embarrassment. However, it increases the suggestibility of preschoolers, prompting them to report physical and sexual contact that never happened (Goodman & Melinder, 2007).

Interventions Adults must prepare child witnesses so they understand the courtroom process and know what to expect. In some places, "court schools" take children through the setting and give them an opportunity to role-play court activities. Practice interviews—in which children learn to provide the most accurate, detailed information possible and to admit not knowing rather than agreeing or guessing—are helpful (Saywitz, Goodman, & Lyon, 2002). For example, when 3- and 4-year-olds are trained to monitor the source of their memories (recall whether an event occurred in real life or on TV) and to reject misleading source information, they responded more accurately to questions about new events (Thierry & Spence, 2002).

At the same time, legal professionals must use interviewing procedures that increase children's accurate reporting. Unbiased, open-ended questions or statements that prompt children to disclose details—"Tell me what happened" or "You said there was a man; tell me more about the man"—reduce the risk of suggestibility, even in young children (McAuliff, 2009). Also, a warm, supportive interview tone fosters accurate recall, perhaps by easing children's fears so they feel freer to counter an interviewer's false suggestions (Ceci, Bruck, & Battin, 2000).

If children are likely to experience emotional trauma or later punishment (as in a family dispute) for answering questions, courtroom procedures can be adapted to protect them. For example, children can testify over closed-circuit TV so they do not have to face an abuser. When it is not wise for a child to participate directly, expert witnesses can provide testimony that reports on the child's psychological condition and includes important elements of the child's story.

ASK YOURSELF

Review ■ According to fuzzy-trace theory, why do we encode information in gist form? Describe the development of gist and verbatim representations, and explain how gist contributes to improved reasoning and more detailed recall—but also to certain memory errors—with age.

Connect ■ Using what you know about development of autobiographical memory, explain why preschoolers' eyewitness testimony usually is less accurate than that of older children. What situational factors make children's reporting even more inaccurate?

Apply ■ When asked what happens at kindergarten, 5-year-old Ali replies, "First, you have center time and circle time. Sometimes you listen to a story. Next you eat your snack and go outdoors." But Ali can't remember what she did during center time two days ago. Explain Ali's memory performance. Why is this type of memory useful?

Reflect ■ Describe your earliest autobiographical memory. How old were you when the event occurred? Do your responses fit with research on infantile amnesia?

Metacognition

▶ Describe the development of metacognitive knowledge and cognitive self-regulation.

Throughout this chapter, we have mentioned many ways in which cognitive processing becomes more reflective and deliberate with age. These trends suggest that another form of knowledge may influence how well children remember and solve problems: **metacognition**—awareness and understanding of various aspects of thought.

During early and middle childhood, metacognition expands greatly as children construct a naïve **theory of mind,** a coherent understanding of people as mental beings, which they revise as they encounter new evidence. Most investigations into theory of mind address children's "mind reading"—their ability to detect their own and other people's perceptions, feelings, desires, and beliefs. We will take up this aspect when we consider emotional and social understanding in Chapters 10 and 11. A second facet of metacognitive research concerns children's knowledge of mental activity—*what it means to think.* To master increasingly complex tasks, children and adolescents must *think about their own thinking,* arriving at such realizations as "I'd better write that phone number down, or I'll forget it" and "This paragraph is complicated; I'll have to read it again to grasp the point."

For metacognitive knowledge to be helpful, children must closely monitor their cognitive activities. When they encounter difficulties, they must use what they know about thinking to redirect their efforts, systematically deploying attention, memory, reasoning, and problem-solving strategies to reach their goals. In the following sections, we consider these high-level aspects of executive function.

Metacognitive Knowledge

With age, children become increasingly conscious of their own cognitive capacities, of strategies for processing information, and of task variables that aid or impede performance.

Knowledge of Cognitive Capacities

TAKE A MOMENT... Listen closely to young children's conversations, and you will find early awareness of mental activities. As their vocabularies expand, 2-year-olds' verbs include such words as *want, think, remember,* and *pretend,* which they use appropriately to refer to internal states (Wellman, 2002). By age 3, children realize that thinking takes place inside their heads and that a person can think about something without seeing, talking about, or touching it (Flavell, Green, & Flavell, 1995).

But preschoolers' understanding of the workings of the mind is limited. Three- and 4-year-olds conclude that mental activity stops while people wait, look at pictures, or read books—when no obvious cues indicate that they are thinking (Flavell, Green, & Flavell, 1993, 1995, 2000). Furthermore, children younger than age 6 pay little attention to the *process* of thinking but, instead, focus on outcomes of thought. When asked about subtle distinctions between mental states, such as *know* and *forget,* they express confusion (Lyon & Flavell, 1994). And they often insist that they have always known information they just learned (Taylor, Esbensen, & Bennett, 1994).

School-age children have a more complete grasp of cognitive processes. Six- and 7-year-olds realize, for example, that doing well on a task depends on paying attention—concentrating and exerting effort (Miller & Bigi, 1979). Their understanding of *sources of knowledge* also expands: They realize that people can extend their knowledge not just by directly observing events and talking to others but also by making *mental inferences* (Miller, Hardin, & Montgomery, 2003).

By age 10, children distinguish mental activities on the basis of *certainty of knowledge.* They are aware that if you "remember," "know," or "understand," you are more certain than if you "guess," "estimate," or "compare." They also grasp the interrelatedness of cognitive processes—for example, that remembering is crucial for understanding and that understanding strengthens memory (Schwanenflugel, Fabricius, & Noyes, 1996; Schwanenflugel, Henderson, & Fabricius, 1998).

© LEILA CUTLER/ALAMY

This 7-year-old's expression reveals that she is thinking hard. As school-age children increasingly reflect on their mental activities, they realize that they can extend their knowledge not just by directly observing events but also by making mental inferences.

How, then, should we describe the difference between younger and older children's understanding of cognitive capacities? Preschoolers view the mind as a passive container of information and have difficulty inferring what people are thinking about. In view of their limited awareness of how knowledge is acquired, it is not surprising that preschoolers rarely plan or use memory strategies. In contrast, older children regard the mind as an active, constructive agent that selects and transforms information (Flavell, 2000).

Language development (especially mental-state vocabulary) and capacity for more complex thinking contribute greatly to school-age children's more reflective, process-oriented view of the mind (Lecce et al., 2010). So do relevant experiences. In a study of rural children of Cameroon, Africa, those who attended school had a more advanced awareness of mental activities than those who did not (Vinden, 2002). In school, teachers often call attention to the workings of the mind by reminding children to pay attention, remember mental steps, share points of view with peers, and evaluate their own and others' reasoning.

Knowledge of Strategies Consistent with their more active view of the mind, school-age children are far more conscious of mental strategies than preschoolers. When shown video clips depicting two children using different recall strategies and asked which one is likely to produce better memory, kindergarten and young elementary school children knew that rehearsing or organizing is better than looking or naming. Older children recognize more subtle differences—that organizing is better than rehearsing (Justice, 1986; Schneider, 1986).

Between third and fifth grade, children develop a much better appreciation of how and why strategies work (Alexander et al., 2003). Consequently, fifth graders are considerably better than younger school-age children at discriminating good from bad reasoning, regardless of its outcome (correctness of answer, happiness with a choice) (Amsterlaw, 2006). When given examples varying in quality, fifth graders consistently rated "good" reasoning as based on weighing of possibilities (rather than jumping to conclusions) and gathering of evidence (rather than ignoring important facts), even if such reasoning led to an unfavorable result.

Once children become conscious of the many factors that influence mental activity, they combine them into a more effective understanding. By the end of middle childhood, children start to consider how *interactions* among multiple variables—age and motivation of the learner, effective use of strategies, and nature and difficulty of the task—affect performance (Schneider, 2010; Wellman, 1990). In this way, metacognitive knowledge becomes more complex and integrated.

Cognitive Self-Regulation

Although metacognitive knowledge expands, school-age children and adolescents often have difficulty putting what they know about thinking into action. They are not yet proficient at **cognitive self-regulation,** the process of continually monitoring and controlling progress toward a goal—planning, checking outcomes, and redirecting unsuccessful efforts. For example, most third to sixth graders know that they should group items when memorizing, reread a complicated paragraph to make sure they understand it, and relate new information to what they already know. But they do not always do so. And as we saw in Chapter 6, many teenagers, though aware of the ingredients of good reasoning, fail to engage in effective decision making.

To study cognitive self-regulation, researchers sometimes look at the impact of children's awareness of memory strategies on how well they remember. By second grade, the more children know about memory strategies, the more they recall—a relationship that strengthens over middle childhood (Pierce & Lange, 2000). And when children apply a strategy consistently, their knowledge of strategies strengthens, resulting in a bidirectional

APPLYING WHAT WE KNOW

Promoting Children's Cognitive Self-Regulation

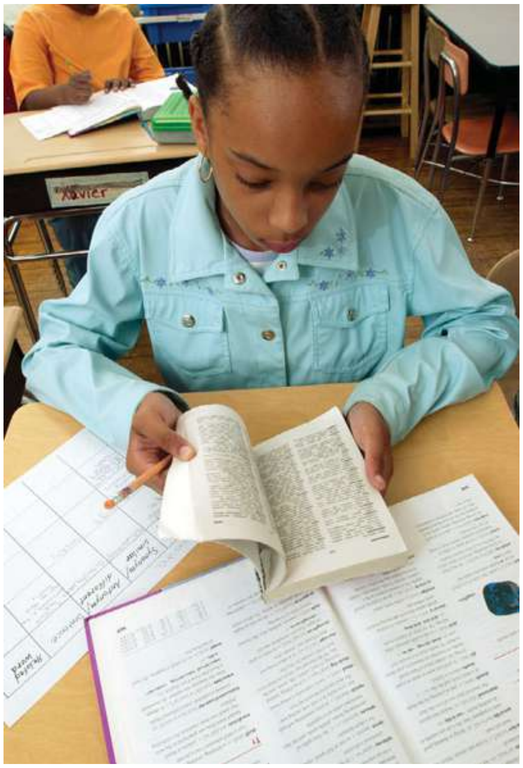
STRATEGY	DESCRIPTION
Stress the importance of planful learning.	Encourage children to organize the learning task and to plan—by considering a variety of ways to approach the task and by setting appropriate learning goals, including how much time and practice they will need to complete it.
Suggest effective learning strategies.	Show children how to use effective learning strategies, and explain why those strategies work well, so children know when and why to use certain strategies in the future.
Emphasize monitoring of progress.	Encourage children to check progress toward their learning goals through self-monitoring, asking such questions as, "Am I staying focused?" "Am I using the strategy, as planned?" "Is the strategy working, or do I need to adjust it?"
Provide for evaluation of strategy effectiveness.	Have children evaluate their performance to improve learning, by answering such questions as, "How well did I do?" "Were my learning strategies effective?" "What strategies might work better?" "What other tasks might benefit from these strategies?"

Source: Schunk & Zimmerman, 2003.

relationship between metacognition and strategic processing that enhances self-regulation (Schlagmüller & Schneider, 2002).

Why does cognitive self-regulation develop gradually? Monitoring and controlling task outcomes is highly demanding, requiring constant evaluation of effort and progress. Throughout elementary and secondary school, better self-regulatory skills predict academic success (Valiente et al., 2008; Zimmerman & Cleary, 2009). Students who do well in school know whether or not their learning is going well. If they encounter obstacles, they take steps to address them—for example, organize the learning environment, review confusing material, or seek support from more expert adults or peers. This active, purposeful approach contrasts sharply with the passive orientation of students who achieve poorly.

Parents and teachers play vital roles in promoting children's self-regulation (Larkin, 2010). In one study, researchers observed parents helping their children with problem solving during the summer before third grade. Parents who patiently pointed out important features of the task and suggested strategies had children who, in the classroom, more often discussed ways to approach problems and monitored their own performance (Stright et al., 2001). In another investigation, first-grade teachers who provided clear organizational information about classroom rules, procedures, and assignments had students who engaged in more independent work and who were advanced in reading progress (Cameron et al., 2008). Finally, explaining the effectiveness of strategies—telling children not just what to do but why to do it—is particularly helpful because it provides a rationale for future action.



© ELLEN B. SENISI PHOTOGRAPHY

This fifth-grader's capacity for cognitive self-regulation is evident in the way she organizes materials, keeping her textbook glossary and dictionary handy. When she encounters an unfamiliar word while working on an assignment, she swiftly looks up its definition.

Applying What We Know above lists ways to foster children's cognitive self-regulation. Children who acquire effective self-regulatory skills develop a sense of *academic self-efficacy*—confidence in their own ability, which supports future self-regulation (Zimmerman & Moylan, 2009). As we turn now to development within academic skill areas, we will encounter the importance of self-regulation again. But first, consult the Milestones table on page 306, which summarizes the diverse changes in information processing we have considered.

Milestones

Development of Information Processing

AGE	BASIC ABILITIES	STRATEGIES	KNOWLEDGE	METACOGNITION
2–5 years 	• Working-memory capacity and processing speed increase. • Many processing skills are evident, including attention, recognition, recall, and reconstruction.	• Attention becomes more focused and sustained, and adaptable and planful attention emerge. • Inhibition improves. • Experimentation with and adaptive selection among strategies are evident.	• Semantic memory expands and becomes better organized. • Episodic memory emerges and becomes more elaborate. • Familiar events are remembered in scripts. • Autobiographical memory emerges and takes on narrative organization.	• Awareness of mental activities is present, but preschoolers view the mind as a passive container of information.
6–10 years 	• Working-memory capacity and processing speed continue to increase.	• Attention becomes increasingly selective, adaptable, and planful. • Inhibition continues to improve. • Memory strategies of rehearsal, organization, and elaboration emerge and become more effective. • Ability to use multiple strategies at once increases. • Reliance on gist memory for reasoning increases.	• Semantic memory continues to expand and become better organized. • Autobiographical memory becomes more elaborate. 	• View of the mind as an active constructive agent develops. • Knowledge of cognitive processes and their relationships increases. • Knowledge of the impact of strategies on performance increases. • Knowledge of interactions among cognitive processes, strategies, and type of task increases. • Cognitive self-regulation improves gradually.
11 years–adulthood	• Working-memory capacity and processing speed continue to increase, but at a slower pace.	• Inhibition and attention and memory strategies continue to improve. 	• Semantic memory expands further and becomes more intricately organized. • Autobiographical memory becomes more focused on personal meaning.	• Metacognitive knowledge and cognitive self-regulation continue to improve.

Note: These milestones represent overall age trends. Individual differences exist in the precise age at which each milestone is attained.

ASK YOURSELF

Review ■ What evidence indicates that preschoolers view the mind as a passive container of information, whereas school-age children view it as an active, constructive agent?

Connect ■ How does research on adolescent brain development contribute to our understanding of the gradual development of cognitive self-regulation and the special self-regulatory challenges of the teenage years (see pages 190–191 in Chapter 5)?

Apply ■ Although 9-year-old Melody knows she should look over her homework, she nevertheless often turns in assignments with careless mistakes. What might account for the gap between what Melody knows and what she does?

Reflect ■ Suppose you had the opportunity to help a second grader with the following assignment: Write a five-sentence paragraph comparing and contrasting fruits and vegetables. What would you do to promote cognitive self-regulation?

Applications of Information Processing to Academic Learning

▶ Discuss the development of reading, mathematics, and scientific reasoning, noting implications of research findings for teaching.

Over the past two decades, fundamental discoveries about the development of information processing have been applied to children's mastery of academic skills. In various academic subjects, researchers are identifying the cognitive ingredients of skilled performance, tracing their development, and pinpointing differences in cognitive skills between good and poor learners. They hope, as a result, to design teaching methods that will improve children's learning. In the following sections, we discuss several of these efforts in reading, mathematics, and scientific reasoning.

Reading

Reading makes use of many skills at once, taxing all aspects of our information-processing system. We must perceive single letters and letter combinations, translate them into speech sounds, recognize the visual appearance of many common words, hold chunks of text in working memory while interpreting their meaning, and combine the meanings of various parts of a text passage into an understandable whole. Because reading is so demanding, most or all of these skills must be done automatically. If one or more are poorly developed, they will compete for space in our limited working memories, and reading performance will decline. Becoming a proficient reader is a complex process that begins in the preschool years.

Early Childhood

Preschoolers understand a great deal about written language long before they learn to read and write in conventional ways. This is not surprising: Children in industrialized nations live in a world filled with written symbols. Each day, they observe and participate in activities involving storybooks, calendars, lists, and signs and, while doing so, try to figure out how written symbols convey meaning. Children's active efforts to construct literacy knowledge through informal experiences are called **emergent literacy.**

Young preschoolers search for units of written language as they "read" memorized versions of stories and recognize familiar signs ("PIZZA"). But they do not yet understand the symbolic function of the elements of print (Bialystok & Martin, 2003). Many preschoolers think that a single letter stands for a whole word or that each letter in a person's signature represents a separate name. In fact, initially preschoolers do not distinguish between drawing and writing. Around age 4, their writing shows some distinctive features of print, such as separate forms arranged in a line. But they often include picturelike devices, such as writing "sun" by using a yellow marker or a circular shape (Levin & Bus, 2003). They use their understanding of the symbolic function of drawings to make a "drawing of print."

Preschoolers acquire literacy knowledge informally by participating in everyday activities involving written symbols. This young chef "jots down" a phone order for a take-out meal.

© LAURA DWIGHT PHOTOGRAPHY

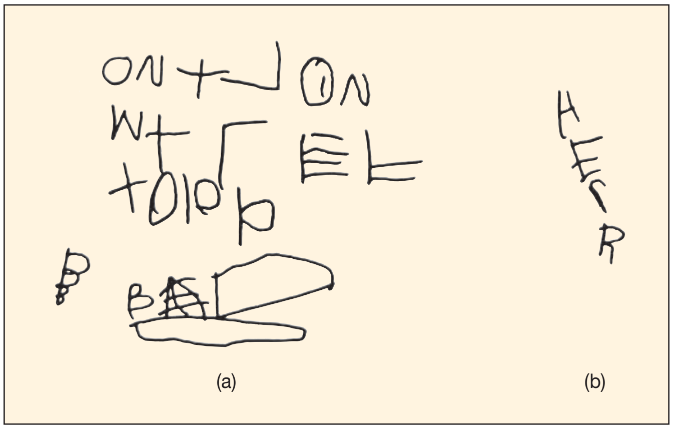

FIGURE 7.9 A story (a) and a grocery list (b) written by a 4-year-old child. This child's writing has many features of real print. It also reveals an awareness of different kinds of written expression. (From McGee, Lea M.; Richgels, Donald J., *Literacy's Beginnings: Supporting Young Readers and Writers,* 4th Edition, © 2004. Reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ.)

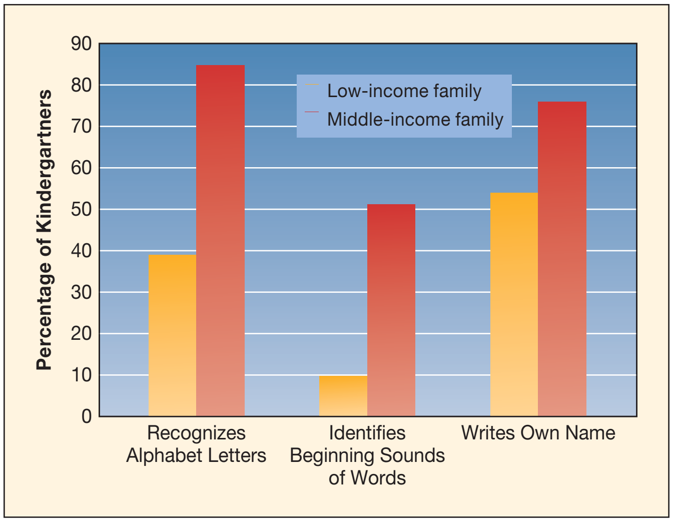
Preschoolers revise these ideas as their perceptual and cognitive capacities improve, as they encounter writing in many contexts, and as adults help them with written communication. Gradually, they notice more features of written language and depict writing that varies in function, as in the "story" and "grocery list" in Figure 7.9.

Eventually children figure out that letters are parts of words and are linked to sounds in systematic ways, as seen in the invented spellings typical between ages 5 and 7. At first, children rely on sounds in the names of letters: "ADE LAFWTS KRMD NTU A LAVATR" ("eighty elephants crammed into a[n] elevator"). Over time, they grasp sound–letter correspondences and learn that some letters have more than one common sound and that context affects their use (*a* is pronounced differently in "cat" than in "table") (McGee & Richgels, 2012).

Literacy development builds on a broad foundation of spoken language and knowledge about the world (Dickinson, Golinkoff, & Hirsh-Pasek, 2010). Over time, children's language and literacy progress facilitate each other. **Phonological awareness**—the ability to reflect on and manipulate the sound structure of spoken language, as indicated by sensitivity to changes in sounds within words, to rhyming, and to incorrect pronunciation—is a strong predictor of emergent literacy knowledge (Dickinson et al., 2003; Paris & Paris, 2006). When combined with sound–letter knowledge, it enables children to isolate speech segments and link them with their written symbols. Vocabulary and grammatical knowledge are also influential. And adult–child narrative conversations enhance diverse language skills essential for literacy progress.

The more informal literacy experiences preschoolers have, the better their language and emergent literacy development and their later reading skills (Dickinson & McCabe, 2001; Speece et al., 2004). Pointing out letter–sound correspondences and playing language–sound games enhance children's awareness of the sound structure of language and how it is represented in print (Ehri & Roberts, 2006; Foy & Mann, 2003). *Interactive reading,* in which adults discuss storybook content with preschoolers, promotes many aspects of language and literacy development. Adult-supported writing activities that focus on narrative, such as preparing a letter or a story, also have wide-ranging benefits (Purcell-Gates, 1996; Wasik & Bond, 2001). In longitudinal research, each of these literacy experiences is linked to improved reading achievement in middle childhood (Hood, Conlon, & Andrews, 2008; Senechal & LeFevre, 2002; Storch & Whitehurst, 2001).

FIGURE 7.10 Some kindergarten reading readiness skills by family income. The gap in emergent literacy development between entering-kindergarten students from low-income and middle-income families is large. (Adapted from Lee & Burkham, 2002.)



Compared to their economically advantaged agemates, preschoolers from low-income families have fewer home and preschool language and literacy learning opportunities—a major reason that they are behind in emergent literacy skills and in reading achievement throughout the school years (Foster et al., 2005; Foster & Miller, 2007; Turnbull et al., 2009). Age-appropriate books, for example, are scarce in their environments. In one survey of four middle- and low-income communities, the middle-income neighborhoods averaged 13 books per child, the low-income neighborhoods just 1 book for every 300 children (Neuman & Celano, 2001).

On average, a preschooler from a low-income family is read to for a total of 25 hours during early childhood, a middle-income child for 1,000 hours. The gap in early literacy experiences translates into large differences in knowledge and skills vital for reading readiness at kindergarten entry (see Figure 7.10). Kindergartners who are behind in emergent literacy development tend to remain behind, performing poorly in reading in the early grades (National Early Literacy Panel, 2008). Over time, skilled readers acquire wide-ranging knowledge more efficiently, progressing more rapidly than poor readers in all achievement areas (Neuman, 2006). In this way, literacy deficiencies at the start of school contribute to

APPLYING WHAT WE KNOW

Supporting Emergent Literacy in Early Childhood

STRATEGY	EXPLANATION
Provide literacy-rich home and preschool environments.	Homes and preschools with abundant reading and writing materials—including a wide variety of children's storybooks, some relevant to children's ethnic backgrounds—open the door to a wealth of language and literacy experiences.
Engage in interactive book reading.	When adults discuss story content, ask open-ended questions about story events, explain the meaning of words, and point out features of print, they promote language development, comprehension of story content, knowledge of story structure, and awareness of units of written language.
Provide outings to libraries, museums, parks, zoos, and other community settings.	Visits to child-oriented community settings enhance children's general knowledge and offer many opportunities to see how written language is used in everyday life. They also provide personally meaningful topics for narrative conversation, which promotes many language skills essential for literacy development.
Point out letter–sound correspondences, play rhyming and other language-sound games, and read rhyming poems and stories.	Experiences that help children isolate the sounds in words foster phonological awareness—a powerful predictor of early childhood literacy knowledge and later reading and spelling achievement.
Support children's efforts at writing, especially narrative products.	Assisting children in their efforts to write—especially letters, stories, and other narratives—fosters many language and literacy skills.
Model literacy activities.	When children see adults engaged in reading and writing activities, they better understand the diverse everyday functions of literacy skills and the knowledge and pleasure that literacy brings. As a result, children's motivation to become literate is strengthened.

Sources: McGee & Richgels, 2012; Neuman, 2006.

widening achievement disparities between economically advantaged and disadvantaged children that often persist into high school.

Providing low-income parents with children's books, along with guidance in how to stimulate emergent literacy, greatly enhances literacy activities in the home (High et al., 2000; Huebner & Payne, 2010). And when preschool teachers were given a tuition-free college course on effective early childhood literacy instruction, they readily applied what they learned, offering many more literacy activities in their classrooms (Dickinson & Sprague, 2001). For ways to support early childhood literacy development, see Applying What We Know above.

Middle Childhood As children make the transition from emergent literacy to conventional reading, phonological awareness continues to predict reading (and spelling) progress. Other information-processing skills also contribute. Gains in processing speed foster school-age children's rapid conversion of visual symbols into sounds—an ability that also distinguishes good from poor readers (McBride-Chang & Kail, 2002). Visual scanning and discrimination play important roles and improve with reading experience (Rayner, Pollatsek, & Starr, 2003). Performing all these skills efficiently releases working memory for higher-level activities involved in comprehending the text's meaning.

Until recently, researchers were involved in an intense debate over how to teach children to read. Those who took a **whole-language approach** argued that from the beginning, children should be exposed to text in its complete form—stories, poems, letters, posters, and lists—so that they can appreciate the communicative function of written language. According to this view, as long as reading is kept meaningful, children will be motivated to discover the specific skills they need (Watson, 1989). Other experts advocated a **phonics approach,** believing that children should first be coached on *phonics*—the basic rules for translating written symbols into sounds. Only after mastering these skills should they get complex reading material (Rayner & Pollatsek, 1989).

© ELLEN B. SENISI PHOTOGRAPHY

With their teacher's guidance, first graders identify words and sort them by initial consonant. Effective reading instruction balances teaching of phonics with exposure to interesting, meaningful texts.

Many studies show that children learn best with a mixture of both approaches. In kindergarten, first, and second grades, teaching that includes phonics boosts reading scores, especially for children who lag behind in reading progress (Stahl & Miller, 2006; Xue & Meisels, 2004). And when teachers combine real reading and writing with teaching of phonics and engage in other excellent teaching practices—encouraging children to tackle reading challenges and integrating reading into all school subjects—first graders show far greater literacy progress (Pressley et al., 2002).

Why might combining phonics with whole language work best? Learning relations between letters and sounds enables children to *decode,* or decipher, words they have never seen before. Children who enter school low in phonological awareness make far better reading progress when given training in phonics (Casalis & Cole, 2009). Soon they detect new letter–sound relations while reading on their own, and as their fluency in decoding words increases, they are freer to attend to text meaning. Without early phonics training, such children (many of whom come from poverty-stricken families) are substantially behind their agemates in text comprehension skills by third grade (Foster & Miller, 2007).

Yet too much emphasis on basic skills may cause children to lose sight of the goal of reading: understanding. Children who read aloud fluently without registering meaning know little about effective reading strategies—for example, that they must read more carefully if they will be tested than if they are reading for pleasure, that they must draw connections between parts of a passage to comprehend effectively, and that explaining a passage in their own words is a good way to assess comprehension. Providing instruction aimed at increasing knowledge and use of such strategies readily enhances reading performance from third grade on (McKeown & Beck, 2009; Paris & Paris, 2006).

Around age 7 to 8, children make a major shift—from "learning to read" to "reading to learn" (Melzi & Ely, 2009). As decoding and comprehension skills become efficient, adolescent readers actively engage with the text, adjusting the way they read to fit their current purpose—at times seeking new facts and ideas, at other times questioning, agreeing with, or disagreeing with the writer's viewpoint.

Mathematics

Mathematical reasoning, like reading, builds on informally acquired knowledge. Recall from Chapter 6 that violation-of-expectation evidence suggests that babies have some basic number concepts (see page 263), although the connection between these early discriminations and later quantitative development is not yet clear. Between 14 and 16 months, toddlers display a beginning grasp of **ordinality,** or order relationships between quantities—for example, that 3 is more than 2 and 2 is more than 1 (Starkey, 1992; Strauss & Curtis, 1984). And 2-year-olds often indicate without counting that certain sets of items have "lots," "many," or "little" in relation to others (Ginsburg, Lee, & Boyd, 2008). These attainments serve as the basis for more complex understandings.

Early Childhood Sometime in the third year, children begin to count. By the time children turn 3, most can count rows of about five objects, saying the correct number words, although they do not know exactly what the words mean. For example, when asked for *one,* they give one item, but when asked for *two, three, four,* or *five,* they usually give a larger, but incorrect, amount. Nevertheless, 2½- to 3½-year-olds understand that a number word refers to a unique quantity—that when a number label changes (for example, from *five* to *six*), the number of items should also change (Sarnecka & Gelman, 2004).

© ELLEN B. SENISI PHOTOGRAPHY

Preschoolers "hop" a toy frog along a number line, measuring the length of each jump. Through informal exploration of number concepts, they construct basic arithmetic understandings essential for learning math skills later on.

By age 3½ to 4, most children have mastered the meaning of numbers up to *ten,* count correctly, and grasp the vital principle of **cardinality**—that the last word in a counting sequence indicates the quantity of items in a set (Geary, 2006a). Mastery of cardinality increases the efficiency of children's counting. By age 4, children use counting to solve simple arithmetic problems. At first, their strategies are tied to the order of numbers as presented; when given 2 + 4, they count on from 2 (Bryant & Nunes, 2002). But soon they experiment with other strategies and master the *min* strategy, a more efficient approach (refer back to Siegler's model of strategy choice, pages 284–286). Around this time, children realize that subtraction cancels out addition. Knowing, for example, that 4 + 3 = 7, they infer without counting that 7 – 3 = 4 (Rasmussen, Ho, & Bisanz, 2003). Grasping basic arithmetic rules greatly facilitates rapid computation.

Understanding basic arithmetic computation makes possible beginning *estimation*—the ability to generate approximate answers, which can be used to evaluate the accuracy of exact answers. After watching several doughnuts being added to or removed from a plate of four to ten doughnuts, 3- and 4-year-olds make sensible predictions of how many doughnuts are on the plate (Zur & Gelman, 2004). Still, children can estimate only just beyond the limit of their calculation competence (Dowker, 2003). For example, those who can solve addition problems with sums up to 10 can estimate answers with sums up to about 20. And as with arithmetic operations, children try out diverse estimation strategies, gradually moving to more accurate, efficient techniques.

The arithmetic knowledge just described emerges in many cultures around the world. But children construct these understandings sooner when adults provide many occasions for counting, comparing quantities, and talking about number concepts (Ginsburg, Lee, & Boyd, 2008; Klibanoff et al., 2006). Math proficiency at kindergarten entry predicts math achievement years later, in elementary and secondary school (Duncan et al., 2007; Geary, 2006a).

As with emergent literacy, children from low-income families begin kindergarten with considerably less math knowledge than their economically advantaged agemates—a gap due to differences in environmental supports. For example, just a few sessions devoted to playing a number board game with an adult led to a dramatic improvement in number concepts and counting proficiency of 4-year-olds from low-income families (Siegler, 2009). And in an early childhood math curriculum called Building Blocks, materials that promote math concepts and skills enable teachers to weave math into many preschool daily activities, from block-building to art to stories (Clements & Sarama, 2008). Compared with agemates randomly assigned to other preschool programs, economically disadvantaged preschoolers experiencing Building Blocks showed substantially greater year-end gains in math concepts and skills, including counting, sequencing, and arithmetic computation.

LOOK and LISTEN

Ask several parents of preschoolers what they routinely do to help their children learn about math. Then ask what they do to support literacy. Do the parents promote math as much as literacy learning?

Middle Childhood Mathematics teaching in elementary school builds on and greatly enriches children's informal knowledge of number concepts and counting. Written notation systems and formal computational techniques enhance children's ability to represent numbers, compute, and estimate. Over the early elementary school years, children acquire basic math facts through a combination of frequent practice, reasoning about number concepts, and teaching that conveys effective strategies. (Return to pages 284–285 for research supporting the importance of both extended practice and a grasp of concepts.) Eventually, children retrieve answers automatically and apply this knowledge to more complex problems.

Arguments about how to teach math resemble those in reading, pitting drill in computing against "number sense," or understanding. Again, a blend of both approaches is most beneficial (Fuson, 2009). In learning basic math, poorly performing students use cumbersome techniques or try to retrieve answers from memory too soon. They have not sufficiently experimented with strategies to see which are most effective and to reorganize their observations in logical, efficient ways—for example, noticing that multiplication problems involving 2 (2 × 8) are equivalent to addition doubles (8 + 8). On tasks that reveal their grasp of math concepts, their performance is weak (Canobi, 2004; Canobi, Reeve, & Pattison, 2003). This suggests that encouraging students to apply strategies and making sure they understand why certain strategies work well are essential for solid mastery of basic math.

A similar picture emerges for more complex skills, such as carrying in addition, borrowing in subtraction, and operating with decimals and fractions. Children taught by rote cannot apply the procedure to new problems. Instead, they persistently make mistakes, following a "math rule" that they recall incorrectly because they do not understand it (Carpenter et al., 1999). Look at the following subtraction errors:

$$\begin{array}{r} 427 \\ -138 \\ \hline 311 \end{array} \qquad\qquad \begin{array}{r} 7002 \\ -5445 \\ \hline 1447 \end{array}$$

In the first problem, the child consistently subtracts the smaller from the larger digit, regardless of which is on top. In the second, the child skips columns with zeros in a borrowing operation and, whenever there is a zero on top, writes the bottom digit as the answer.

Children who have rich opportunities to experiment with problem solving, to appreciate the reasons behind strategies, and to evaluate solution techniques seldom make such errors. In one study, second graders who were taught in these ways not only mastered correct procedures but even invented their own successful strategies—some of them superior to standard, school-taught methods! Consider this solution:

$$\begin{array}{rrrr} 3 & 15 & 14 & 12 \\ \cancel{4} & \cancel{6} & \cancel{5} & \cancel{2} \\ -1 & 9 & 6 & 8 \\ \hline 2 & 6 & 8 & 4 \end{array}$$

In subtracting, the child performed all trades first, flexibly moving either from right to left or from left to right, and then subtracted all four columns—a highly efficient, accurate approach (Fuson & Burghard, 2003).

In a German study, the more teachers emphasized conceptual knowledge—by having children actively construct meanings in word problems before practicing computation and memorizing math facts—the more children gained in math achievement from second to third grade (Staub & Stern, 2002). Children with these learning experiences draw on their solid knowledge of relationships between operations (for example, that the inverse of division is multiplication) to generate efficient, flexible procedures (De Brauwer & Fias, 2009). And because they have been encouraged to estimate answers, if they go down the wrong track in computation, they are usually self-correcting. Furthermore, they appreciate connections between math operations and problem contexts. They can solve a word problem ("If Jesse spent $3.45 for bananas, $2.62 for bread, and $3.55 for peanut butter, can he pay for it all with a $10 bill?") quickly through estimation instead of exact calculation (De Corte & Verschaffel, 2006).

Fifth graders use manipulative materials to help them understand mathematical concepts such as "squared" and "cubed." Learning experiences that promote conceptual knowledge help children become more flexible, effective math problem solvers.

© ELLEN B. SENISI PHOTOGRAPHY

In Asian countries, students receive a variety of supports for acquiring mathematical knowledge and often excel at both math reasoning and computation. Use of the metric system, which presents ones, tens, hundreds, and thousands values in all areas of measurement, helps Asian children grasp place value. The consistent structure of number words in Asian languages (*ten-two* for 12, *ten-three* for 13) also makes this idea clear (Miura & Okamoto, 2003). And because Asian number words are shorter and more quickly pronounced, more digits can be held in working memory at once, increasing the speed of thinking. Furthermore, Chinese parents provide their children with extensive everyday practice in counting and computation—experiences that contribute to the superiority of Chinese over U.S. children's math knowledge, even before school entry (Siegler & Mu, 2008; Zhou et al., 2006).

Finally, compared with the United States, math lessons in Asian classrooms devote more time to exploring math concepts and strategies and less to drill and repetition (Woodward & Ono, 2004; Zhou & Peverly, 2005). As Chapter 15 will reveal, Asian countries consistently score at or near the top in international comparisons of high school achievement in math—and in other subjects as well.

Scientific Reasoning

During a free moment in physical education class, 13-year-old Heidi wondered why more of her tennis serves and returns passed the net and dropped in her opponent's court when she used a particular brand of balls. "Is it something about their color or size?" she asked herself. "Hmm . . . or maybe it's their surface texture—that might affect their bounce."

According to Deanna Kuhn, the heart of scientific reasoning is coordinating theories with evidence. A scientist can clearly describe the theory he or she favors, knows what evidence is needed to support it and what would refute it, and can explain how pitting evidence against theories has led to the acceptance of one theory as opposed to others. What evidence would Heidi need to confirm her theory about the tennis balls?

Kuhn (2002) has conducted extensive research into the development of scientific reasoning, using problems that resemble Piaget's tasks in that several variables might affect an outcome. In one series of studies, third, sixth, and ninth graders and adults were first given evidence, sometimes consistent and sometimes conflicting with theories, then questioned about the accuracy of each theory.

For example, participants were given a problem much like Heidi's: to theorize about which of several features of sports balls—size (large or small), color (light or dark), surface texture (rough or smooth), or presence or absence of ridges on the surface—influences the quality of a player's serve. Next, they were told about the theory of Mr. (or Ms.) S, who believes that the ball's size is important, and the theory of Mr. (or Ms.) C, who thinks color matters. Finally, the interviewer presented evidence, placing balls with certain characteristics into two baskets, one labeled "good serve" and the other "bad serve" (see Figure 7.11).

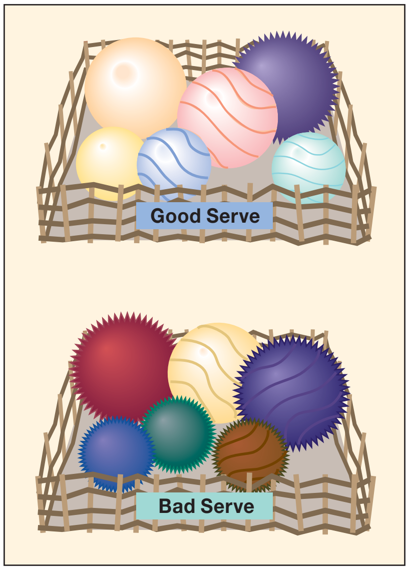


FIGURE 7.11 **Which features of these sports balls—size, color, surface texture, or presence or absence of ridges—influence the quality of a player's serve?** This set of evidence suggests that color might be important, since light-colored balls are largely in the good-serve basket and dark-colored balls in the bad-serve basket. But the same is true for texture! The good-serve basket has mostly smooth balls, the bad-serve basket rough balls. Since all light-colored balls are smooth and all dark-colored balls are rough, we cannot tell whether color or texture makes a difference. But we can conclude that size and presence or absence of ridges are not important because these features are equally represented in the good-serve and bad-serve baskets. (Adapted from Kuhn, Amsel, & O'Loughlin, 1988.)

Age-Related Change

Kuhn found that the capacity to reason like a scientist improves with age. The youngest participants often discounted obviously causal variables, ignored evidence conflicting with their own initial judgments, and distorted evidence in ways consistent with their theory. When one third grader, who judged that size was causal (with large balls producing good serves and small balls producing bad serves), was shown incomplete evidence (a single, large, light-colored ball in the good-serve basket and no balls in the bad-serve basket), he insisted on the accuracy of Mr. S's theory (which was also his own). Asked to explain, he stated flatly, "Because this ball is big . . . the color doesn't really matter" (Kuhn, 1989, p. 677).

These findings, and others like them, suggest that on complex, multivariable tasks, children—instead of viewing evidence as separate from and bearing on a theory—often blend the two into a single representation of "the way things are." Children are especially likely to overlook evidence that does not match their prior beliefs when a causal variable is implausible (like color affecting performance of a sports ball) and when task demands (number of variables to be evaluated) are high (Zimmerman, 2005, 2007). The ability to distinguish theory from evidence and use logical rules to examine their relationship improves from childhood through adolescence, continuing into adulthood (Kuhn & Dean, 2004; Kuhn & Pearsall, 2000).

How Scientific Reasoning Develops

What factors support skill at coordinating theory with evidence? Greater working-memory resources, permitting simultaneous comparison of a theory and the effects of several variables, is vital. In addition, participants benefit from exposure to increasingly complex problems and instruction that highlights critical features of scientific reasoning—for example, why a scientist's expectations in a particular

© BOB DAEMMRICH/THE IMAGE WORKS

At an engineering summer camp, high school students design a catapult for shooting water balloons. As they coordinate theory with evidence, reflecting on and revising their problem-solving strategies, they gain in scientific reasoning.

situation are inconsistent with everyday beliefs and experiences (Chinn & Malhotra, 2002). These findings explain why scientific reasoning is strongly influenced by years of schooling, whether individuals grapple with traditional scientific tasks (like the sports ball problem) or engage in informal reasoning—for example, justifying a theory about what causes children to fail in school (Amsel & Brock, 1996; Kuhn, 1993).

Researchers believe that sophisticated *metacognitive understanding* is vital for scientific reasoning (Kuhn, 2009; Kuhn & Pease, 2006). Microgenetic research (see pages 64–65 in Chapter 2) shows that when older children and adolescents regularly pit theory against evidence over many weeks, they experiment with various strategies, reflect on and revise them, and become aware of the nature of logic. Then they apply their abstract appreciation of logic to a wide variety of situations. The ability to *think about* theories, *deliberately isolate* variables, *consider all influential* variables, and *actively seek* disconfirming evidence is rarely present before adolescence (Kuhn, 2000; Kuhn et al., 2008; Moshman, 1998).

Though far more competent than children, adolescents and adults vary widely in scientific reasoning skills. Many continue to show a self-serving bias, applying logic more effectively to ideas they doubt than to those they favor (Klaczynski, 1997; Klaczynski & Narasimham, 1998). Reasoning scientifically requires the metacognitive capacity to evaluate one's objectivity—to be fair-minded rather than self-serving (Moshman, 2005). As we will see in Chapter 11, this flexible, open-minded approach is not just a cognitive attainment but a personality trait—one that assists teenagers greatly in forming an identity and developing morally.

Children and adolescents develop scientific reasoning skills in a similar step-by-step fashion on different kinds of tasks. In a series of studies, 10- to 20-year-olds were given sets of problems graded in difficulty. One set contained causal-experimental tasks like the sports ball problem in Figure 7.11, another contained quantitative-relational tasks like Piaget's pendulum problem, and still another consisted of verbal propositional tasks (see pages 257–258 in Chapter 6). In each type of task, adolescents mastered component skills in sequential order by expanding their metacognitive awareness (Demetriou et al., 1993, 1996, 2002). For example, on causal-experimental tasks, they first became aware of the many variables—separately and in combination—that could influence an outcome. This enabled them to formulate and test hypotheses. Over time, adolescents combined separate skills into a smoothly functioning system, constructing a general model that they could apply to many instances of a given type of problem.

Do the metacognitive advances just described remind you of the concept of *central conceptual structures* in Robbie Case's neo-Piagetian theory, discussed on page 283? Piaget also underscored the role of metacognition in formal operational thought when he spoke of "operating on operations" (see Chapter 6, page 253). But information-processing findings confirm that scientific reasoning does not result from an abrupt, stagewise change, as Piaget believed. Instead, it develops gradually out of many specific experiences with different types of problems, each of which requires children and adolescents to match theory against evidence and reflect on and evaluate their thinking.

▶ Summarize the strengths and limitations of the information-processing approach.

Evaluation of the Information-Processing Approach

A major strength of the information-processing approach is its explicitness and precision in breaking down complex cognitive activities into their components. Information processing has provided a wealth of detailed evidence on how younger versus older and more-skilled versus less-skilled individuals attend, remember, reason, and solve problems. It also offers precise mechanisms of cognitive development; Table 7.1 summarizes the most important of these. **TAKE A MOMENT...** As you review them, think back to theories and findings that illustrate the role of each. Finally, because of its precision, information-processing

TABLE 7.1 **Mechanisms of Cognitive Development from the Information-Processing Perspective**

MECHANISM	DESCRIPTION
Basic processing capacity	Capacity of the mental system increases, enabling more information to be held in working memory at once.
Processing efficiency	Speed of basic operations increases, freeing up available space in working memory for additional mental activities.
Encoding of information	Encoding, in the form of attention, becomes more thorough and better adapted to task demands.
Inhibition	Ability to prevent internal and external distracting stimuli from capturing attention improves, freeing up working memory for remembering, reasoning, and solving problems.
Strategy execution	Strategies become more effective, improving storage, retrieval, and use of information for reasoning and problem solving.
Knowledge	Amount and structure of the knowledge base increase, making new, related information more meaningful so it is easier to store and retrieve.
Metacognitive knowledge	Awareness and understanding of cognitive processes expand.
Self-regulation	Self-regulation improves, leading strategies to be applied more effectively in a wider range of situations.

research has contributed greatly to the design of teaching techniques that advance many aspects of children's thinking.

The principal limitation of the information-processing perspective stems, ironically, from its central strength: By analyzing cognition into its components, information processing has had difficulty reassembling them into a broad, comprehensive theory of development. As we have seen, the neo-Piagetian perspective is one effort to build a general theory by retaining Piaget's stages while drawing on information-processing mechanisms to explain cognitive change.

Furthermore, the computer metaphor, while bringing precision to research on the human mind, has drawbacks. Computer models of cognitive processing, though complex in their own right, do not reflect the richness of real-life learning experiences. They overlook aspects of cognition that are not linear and logical, such as imagination and creativity. Moreover, computers do not have desires, interests, and intentions, nor can they engage in interaction with others, as children do when they learn from parents, teachers, and peers. Perhaps because of the narrowness of the computer metaphor, information processing has not told us much about the links between cognition and other areas of development. In later chapters, we will look at findings of investigators who have applied information-processing assumptions to children's thinking about certain aspects of their social world. But in research on children's social and moral understanding, extensions of Piaget's theory still prevail.

Despite its shortcomings, the information-processing approach holds great promise. The near future is likely to bring new breakthroughs in understanding mechanisms of cognitive development and neurological changes that underlie various mental activities, and in identifying teaching techniques that support children's learning.

ASK YOURSELF

Review ■ Why are gains in metacognition important for the development of scientific reasoning? How can teachers promote the development of scientific reasoning?

Connect ■ Using mechanisms of cognitive development discussed in this chapter, explain why teaching both basic skills and understanding of concepts and strategies is vital for children's progress in reading and mathematics.

Apply ■ Review Heidi's reasoning about the impact of several variables on the bounce of tennis balls on page 313. What features of her thinking suggest that she is beginning to reason scientifically?

Reflect ■ Describe early, informal experiences important for literacy and math development that you experienced while growing up. How do you think those experiences contributed to your academic progress after you started school?

SUMMARY

The Information-Processing Approach (p. 278)

- Information-processing theorists view the mind as a complex, symbol-manipulating system through which information flows, much like a computer. Researchers use computer-like diagrams and flowcharts to analyze thinking into its components, mapping the precise steps involved in thinking about a task or problem.

A General Model of Information Processing (p. 278)

Describe the store model of the human information processing system, noting implications for cognitive development and related findings.

- We hold, or store, information in three parts of the mental system for processing. The **sensory register** takes in a wide panorama of information, but only momentarily. The **short-term memory store** retains attended-to information briefly so we can actively manipulate it in **working memory** to accomplish our goals. The **central executive** is the conscious, reflective part of the system, directing the flow of information and implementing basic procedures and complex strategies. The more effectively we process information, the greater the likelihood that mental activities will become **automatic processes** and that information will transfer to **long-term memory,** our limitless, permanent knowledge base.

© LAURA DWIGHT PHOTOGRAPHY

- The store model suggests, and research confirms, that several aspects of the cognitive system improve with age. Working-memory capacity increases, with individual differences predicting intelligence test scores and academic achievement. Gains in processing speed also occur, contributing to working-memory resources. Furthermore, children make strides in **executive function,** with preschoolers gaining in attention, suppressing impulses, and flexible thinking and school-age children and adolescents in integration of cognitive operations and strategies that enable increasingly difficult tasks.

Developmental Theories of Information Processing (p. 282)

How do Case's neo-Piagetian theory and Siegler's model of strategy choice explain changes in children's thinking?

- Case's **neo-Piagetian theory** accepts Piaget's stages but attributes change within and between stages to greater efficiency in use of working-memory capacity. Brain development, practice with schemes and automization, and formation of **central conceptual structures** contribute to development. Case's theory provides an information-processing explanation of the continuum of acquisition—that many understandings appear in specific situations at different times—and thus is better able than Piaget's theory to account for unevenness in cognitive development.
- Siegler's **model of strategy choice** highlights children's experimentation with and selection of mental strategies to account for the diversity and ever-changing nature of children's thinking. Strategy development follows an overlapping-waves pattern. When given challenging problems, children generate a variety of strategies, gradually selecting from them on the basis of accuracy and speed.

Attention (p. 286)

Describe the development of attention, including sustained, selective, and adaptable strategies.

- Gains in sustained attention depend on rapid growth of the prefrontal cortex, the capacity to generate increasingly complex play goals, and adult scaffolding of attention. As sustained attention increases, children become better at focusing on relevant aspects of a task and at flexibly adapting attention to task requirements. Sustained, selective, and adaptable attention depend on **inhibition,** the ability to control distracting stimuli.
- Development of attentional (and memory) strategies tends to occur in four phases: (1) **production deficiency** (failure to produce the strategy); (2) **control deficiency** (failure to execute the strategy effectively); (3) **utilization deficiency** (consistent use of the strategy, but with little or no performance improvement); and (4) **effective strategy use.**
- From age 5 on, children undergo marked advances in **planning.** They learn much from cultural tools that support planning, adult guidance and encouragement, and opportunities to practice.

Memory (p. 292)

Describe the development of strategies for storing and retrieving information from memory.

- Although the beginnings of memory strategies can be seen in early childhood, young children seldom engage in **rehearsal** or **organization.** As use of these strategies improves, school-age children combine them; the more strategies they use simultaneously, the better they remember. **Elaboration** emerges at the end of middle childhood. Task demands and cultural circumstances influence the development of memory strategies.

© PAUL SMITH/PANOS PICTURES

- **Recognition,** the simplest form of retrieval, is a fairly automatic process that is highly accurate by the preschool years. **Recall**—generating a mental representation of an absent stimulus—is more challenging, shows much greater improvement with age, and is strongly associated with language development.
- Even young children engage in **reconstruction** when remembering complex, meaningful material. As originally provided information decays and new information is presented, children make more inferences, and the coherence of reconstructed information and its memorableness increase. However, much recalled information can be inaccurate.
- According to **fuzzy-trace theory,** when information is encoded, it is reconstructed automatically into a **gist**—a vague, fuzzy version that is especially useful for reasoning. With age, children rely less on verbatim memory and more on reconstructed gists, contributing to improved recall of details with age.

Explain the development of episodic memory and its relationship to semantic memory.

- **Semantic memory**—our vast general knowledge system—contributes vitally to and develops earlier than **episodic memory.** Not until 3 or 4 years of age do children have a well-functioning memory system of personally experienced events that occurred at a specific time and place.

- Like adults, young children remember familiar experiences in terms of **scripts**—a special form of episodic memory that permits them to predict what might happen on future similar occasions. And as preschoolers talk with adults about personally significant past events, they adopt the narrative thinking generated in these dialogues, forming an **autobiographical memory.** Children whose parents use an elaborative rather than a repetitive conversational style produce more coherent and detailed personal stories.

How does eyewitness memory change with age, and what factors influence the accuracy of children's reports?

- Compared with preschoolers, school-age children are better at giving accurate and detailed eyewitness accounts and resisting adults' misleading questions. When a biased adult repeatedly asks leading questions, children are far more likely to give false information. Negative stereotyping of the accused and a long delay between the events and the child's eyewitness report further contribute to inaccurate reporting.

Metacognition (p. 303)

Describe the development of metacognitive knowledge and cognitive self-regulation.

- **Metacognition** expands greatly as children construct a naïve **theory of mind,** a coherent understanding of people as mental beings. From early to middle childhood, children become increasingly conscious of cognitive capacities and strategies. They come to view the mind as an active, constructive agent rather than a passive container of information. As older children consider interactions among variables, metacognitive knowledge becomes more complex and integrated.
- **Cognitive self-regulation**—continually monitoring and controlling progress toward a goal—develops gradually. It improves with adult instruction in effective strategy use and predicts academic success.

Applications of Information Processing to Academic Learning (p. 307)

Discuss the development of reading, mathematics, and scientific reasoning, noting the implications of research findings for teaching.

- **Emergent literacy** reveals that young children understand a great deal about written language before they read and write in conventional ways. Preschoolers gradually revise incorrect ideas about the meaning of written symbols as their cognitive capacities improve, as they encounter writing in many contexts, and as adults help them with written communication.
- **Phonological awareness** strongly predicts emergent literacy knowledge and later reading achievement. Vocabulary and grammatical knowledge, adult–child narrative conversations, and informal literacy-related experiences also foster literacy development.
- As children make the transition to conventional literacy, phonological awareness, processing speed, and visual scanning and discrimination contribute to reading progress. A combination of **whole-language** and **phonics approaches** is most effective for teaching beginning reading.
- Mathematical reasoning also builds on informally acquired knowledge. Toddlers beginning grasp of **ordinality** serves as the basis for more complex understandings. As preschoolers gain experience with counting, they understand **cardinality** and begin to solve simple addition and subtraction problems. When adults provide many occasions for counting and comparing quantities, children construct basic numerical concepts sooner.
- During the early school years, children acquire basic math facts through a combination of frequent practice, reasoning about number concepts, and teaching that conveys effective strategies. The best mathematics instruction combines practice in experimenting with strategies and conceptual understanding.
- The ability to coordinate theory with evidence—the heart of scientific reasoning—improves from childhood to adolescence. Greater working-memory resources and exposure to increasingly complex problems in school contribute to the metacognitive understanding that is vital for reasoning scientifically.

Evaluation of the Information-Processing Approach (p. 314)

Summarize the strengths and limitations of the information-processing approach.

- A major strength of the information-processing approach is its precision in breaking down cognition into its components. Information processing research has contributed greatly to the design of teaching techniques that advance children's thinking.
- Nevertheless, computer models of cognitive processing do not reflect the richness of real-life learning experiences and have not told us much about the links between cognition and other areas of development.

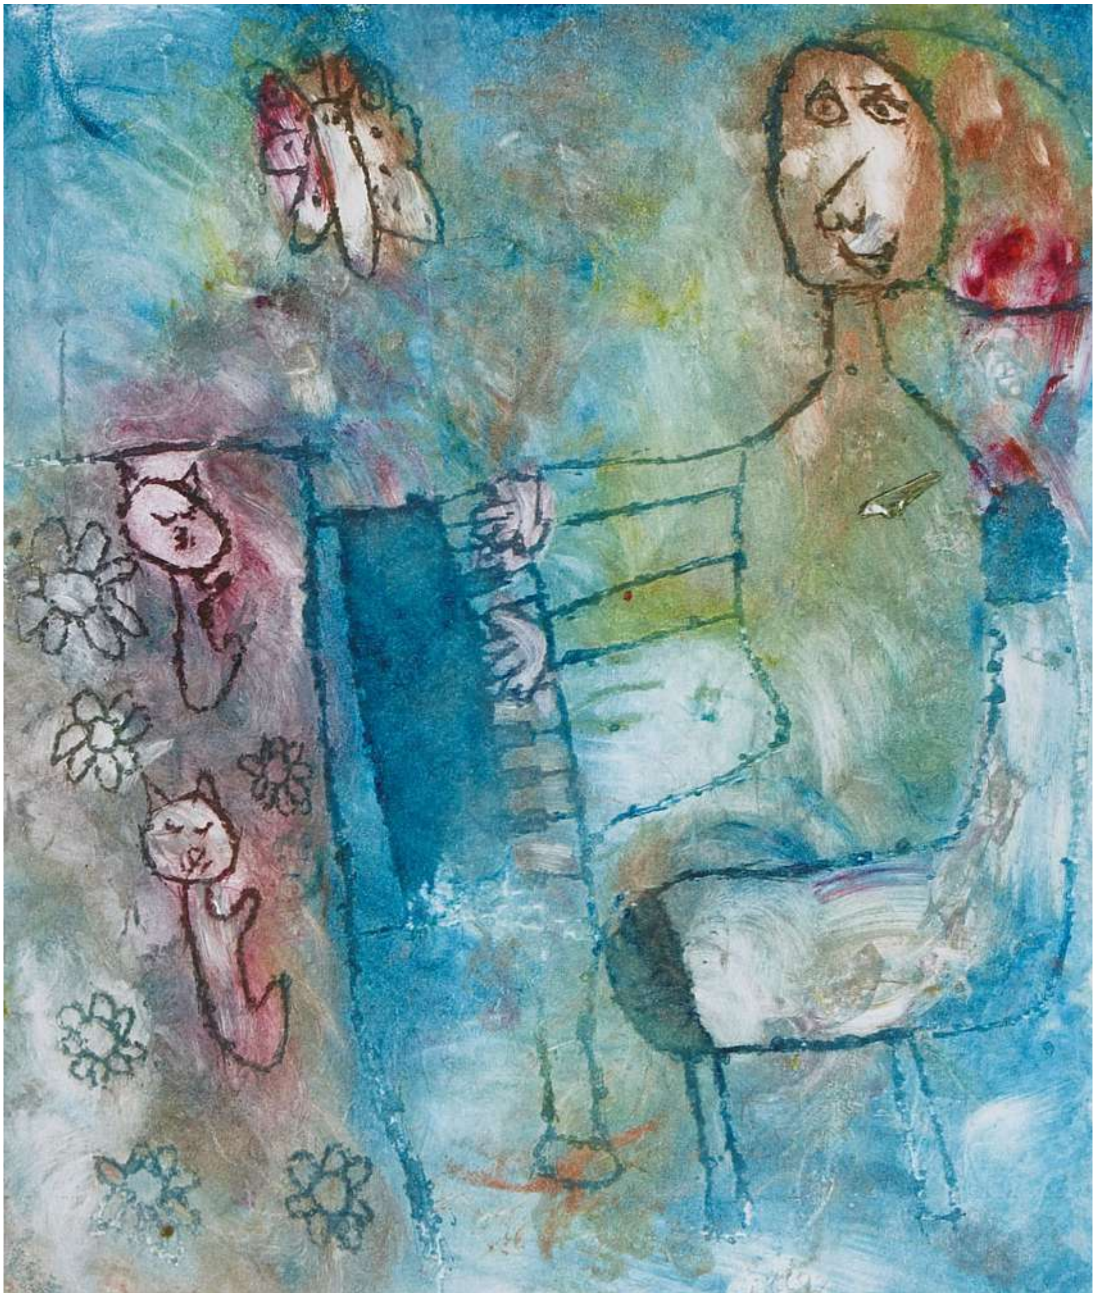
CHAPTER 8



"Playing the Piano"

Eliska Feitiova
7 years, Czech Republic

Although intelligence tests predict children's academic achievement, they are far less effective at evaluating the creativity and talent evident in this pianist's fluid playing—or in the artist's expressive image.

Intelligence

James Cleveland is past president of Jumpstart, a U.S. nonprofit organization that provides 3- to 5-year-olds from low-income families with several hundred hours per year of intensive, supplementary educational enrichment, aimed at increasing their readiness for kindergarten. Several times a week, Jumpstart corps members (college students and older adults) go to a preschool or child-care center, where they read to and converse with two to three designated children, engage in additional individualized learning activities, and play collaborative games in small groups. Currently, Jumpstart serves more than 9,000 preschoolers across the country.

After stepping into Jumpstart's top leadership position, James wrote to his nationwide staff, expressing his passion and resolve to help ever-increasing numbers of at-risk children start school with the literacy, self-regulation, and social skills they need to succeed. He had an inspiring personal story to tell.

James started public school as a weak, self-doubting reader—the very situation Jumpstart strives to prevent. He struggled with language arts assignments and frequently spent recess at his desk, barred from participating because he could not do—and soon refused to do—his reading work. "Pressure from my teacher and the embarrassment of being singled out added to my frustration," James recalled.

After weeks without progress, James's teacher called his parents. His father, an African American who had not had the chance to go to college, responded immediately. "He became my inspiration," said James. "He regarded his involvement as vital to my academic success—and to a life path of greater opportunity than his own."

James's father began taking him to the public library regularly. On each visit, he guided James in selecting a book, insisting that he choose a challenging one. Then father and son read together, jointly deciphering difficult passages. If James did not understand a word, they looked it up in the dictionary. "That unlocked the world of reading for me," said James, who went on to become a voracious reader, an excellent student, valedictorian of his high school class, and a graduate of Stanford University.

James summed up: "My dad's involvement taught me firsthand about the power of caring adult intervention. I began believing in myself because I knew my dad believed in me." His father's inspiration led James to devote his energies to early educational intervention—a topic we consider in depth later in this chapter.

The **psychometric approach** to cognitive development is the basis for the wide variety of intelligence tests available for assessing children's mental abilities. Unlike Piagetian, Vygotskian, and information-processing views, which focus on the *process* of thinking, the psychometric perspective is *product*-oriented, largely concerned with outcomes and results—how many and what kinds of questions children of different ages answer correctly. Psychometric researchers ask questions like these:

- What factors, or dimensions, make up intelligence, and how do they change with age?
- How can intelligence be measured so that scores predict future academic achievement, career attainment, and other aspects of intellectual success?
- Are mental test scores largely stable over childhood and adolescence, or can performance change dramatically?
- To what extent do children of the same age differ in intelligence, and what explains those differences?

To what extent do children of the same age differ in intelligence, and what explains those differences? Heredity plays a role, but so do children's home environments and the kind of schooling they experience.

As we examine these questions, we will quickly become immersed in the long-standing debate over the contribution of nature (heredity) and nurture (environment) to intelligence and the related controversy over whether intelligence tests are biased, or inaccurate, measures of the mental abilities of members of certain ethnic minority groups. We will see how the cognitive perspectives considered in previous chapters, as well as research on environmental contexts—home, school, societal attitudes, and public policies—have contributed to our understanding of children's test performance. We conclude with a discussion of giftedness, in the form of talent and creativity. ■

Definitions of Intelligence

- Describe changing definitions of intelligence on which mental tests are based.

TAKE A MOMENT... Jot down a list of behaviors that you regard as typical of highly intelligent people. Does your list contain just one or two items or a great many? In a study in which laypeople and experts completed a similar exercise, both groups viewed intelligence as made up of at least three broad attributes: verbal ability, practical problem solving, and social competence (Sternberg & Detterman, 1986). But respondents differed in their descriptions of these attributes. And contemporary experts showed much less agreement about the makeup of intelligence than did experts in a similar study conducted a half-century earlier!

Clearly, most people think of intelligence as a complex combination of attributes, though little consensus exists among experts on its ingredients. And whereas some people view the various abilities that make up intelligence as closely interconnected, others expect them to be relatively distinct—to correlate weakly (Siegler & Richards, 1980). This tension between intelligence as a single capacity versus a collection of loosely related skills is ever-present in historical and current theories on which mental tests are based.

LOOK and LISTEN

Ask several of your classmates to list three traits that characterize an intelligent toddler, an intelligent preschooler, an intelligent school-age child, and an intelligent adolescent. Did your respondents view the makeup of intelligence as changing with age? Explain.

Alfred Binet: A Holistic View

The social and educational climate of the late nineteenth and early twentieth centuries led to the development of the first intelligence tests. With the beginning of universal public education in Europe and North America—allowing all children, not just society's privileged, to enroll in school—educators sought methods to identify students who were unable to benefit from regular classroom instruction. The first successful intelligence test, constructed by French psychologist Alfred Binet and his colleague Theodore Simon in 1905, responded to this need.

The French Ministry of Instruction asked Binet to devise an objective method for assigning pupils to special classes—one based on mental ability, not classroom disruptiveness. Other researchers had tried to assess intelligence using simple measures of sensory responsiveness and reaction time (Cattell, 1890; Galton, 1883). In contrast, Binet believed that test items should tap complex mental activities involved in intelligent behavior, such as memory and reasoning. Consequently, Binet and Simon (1908) devised a test of general ability that included a variety of verbal and nonverbal items, each requiring thought and judgment. Their test was also the first to associate items of increasing difficulty with chronological age (Wasserman & Tulsky, 2005). This enabled Binet and Simon to estimate how much a child was behind or ahead of her agemates in intellectual development.

The Binet test was so successful in predicting school performance that it became the basis for new intelligence tests. In 1916, Lewis Terman at Stanford University adapted it for use with English-speaking schoolchildren. Since then, the English version has been known as the *Stanford-Binet Intelligence Scale.* As we will see later, the Stanford-Binet has changed greatly; it no longer provides just a single, holistic measure of intelligence.

The Factor Analysts: A Multifaceted View

To find out whether intelligence is a single trait or an assortment of abilities, researchers used a complicated correlational procedure called **factor analysis,** which identifies sets of test items that cluster together, meaning that test-takers who do well on one item in a cluster tend to do well on the others. Distinct clusters are called *factors.* For example, if vocabulary, verbal comprehension, and verbal analogy items all correlate highly, they form a factor that the investigator might label "verbal ability." Using factor analysis, many researchers tried to identify the mental abilities that contribute to successful intelligence test performance.

Early Factor Analysts

British psychologist Charles Spearman (1927) was the first influential factor analyst. He found that all test items he examined correlated with one another. As a result, he proposed that a common underlying **general intelligence,** called ***g,*** influenced each of them. At the same time, noticing that the test items were not perfectly correlated, Spearman concluded that they varied in the extent to which *g* contributed to them and suggested that each item, or a set of similar items, also measured a **specific intelligence** unique to the task.

Spearman downplayed the significance of specific intelligences, regarding *g* as central and supreme. Because test items that involved forming relationships and applying general principles clustered together especially strongly—and also were the best predictors of cognitive performance outside the testing situation—he inferred that *g* represents abstract reasoning capacity.

American psychologist Louis Thurstone (1938) questioned the importance of *g.* His factor analysis of college students' scores on more than 50 intelligence tests indicated that separate, unrelated factors exist. Declaring the supremacy of these factors, Thurstone called them *primary mental abilities.*

Contemporary Extensions

Spearman and Thurstone eventually resolved their differences, each acknowledging findings that supported the other's perspective (Wasserman & Tulsky, 2005). Current theorists and test designers, combining both approaches, propose *hierarchical models* of mental abilities. At the highest level is *g,* assumed to be present to some degree in all separate factors. These factors, in turn, are measured by *subtests,* groups of related items. Subtest scores provide information about a child's strengths and weaknesses. They also can be combined into a total score representing general intelligence.

Contemporary theorists have extended factor-analytic research. The two most influential are R. B. Cattell and John Carroll, each of whom offers a unique, multifaceted perspective on intelligence.

Crystallized versus Fluid Intelligence. According to Raymond B. Cattell (1971, 1987), in addition to *g,* intelligence consists of two broad factors: **Crystallized intelligence** refers to skills that depend on accumulated knowledge and experience, good judgment, and mastery of social customs—abilities acquired because they are valued by the individual's culture. On intelligence tests, vocabulary, general information, and arithmetic problems are examples of items that emphasize crystallized intelligence. In contrast, **fluid intelligence** depends more heavily on basic information-processing skills—the ability to detect relationships among stimuli, the speed with which the individual can analyze information, and the capacity of working memory. Fluid intelligence, which is assumed to be influenced more by conditions in the brain and less by culture, often works with crystallized intelligence to support effective reasoning, abstraction, and problem solving (Horn & Noll, 1997).

© BOB DAEMMRICH/PHOTOEDIT

To solve a complex three-dimensional puzzle based on the design of St. Peter's Basilica in Rome, this 10-year-old, who has never seen the building, relies on fluid intelligence—the ability to analyze information efficiently and to detect relationships among stimuli.

Among children with similar cultural and educational backgrounds, crystallized and fluid intelligence are highly correlated and difficult to distinguish in factor analyses, probably because children high in fluid intelligence acquire information more easily. But in children differing greatly in cultural and educational experiences, the two abilities show little relationship; children with the same fluid capacity may perform quite differently on crystallized tasks (Horn, 1994). As these findings suggest, Cattell's theory has important implications for the issue of *cultural bias* in intelligence testing. Tests aimed at reducing culturally specific content usually emphasize fluid over crystallized items.

The Three-Stratum Theory of Intelligence. Using improved factor-analytic methods, John Carroll (1993, 2005) reanalyzed relationships among items in hundreds of studies. His findings yielded a **three-stratum theory of intelligence** that elaborates the models proposed by Spearman, Thurstone, and Cattell. Carroll represented the structure of intelligence as having three tiers. As Figure 8.1 shows, *g* presides at the top. In the second tier are an array of *broad abilities,* which Carroll considered the basic biological components of intelligence; they are arranged from left to right in terms of decreasing relationship with *g*. In the third tier are *narrow abilities*—specific behaviors through which people display the second-tier factors.

Carroll's model is the most comprehensive factor-analytic classification of mental abilities to date. As we will see in the next section, it provides a useful framework for researchers seeking to understand mental-test performance in cognitive-processing terms. It also reminds us of the great diversity of intellectual factors. Currently, no test measures all of Carroll's factors.

Reaction time

FIGURE 8.1 **Carroll's hierarchical model of intelligence.** At the top is general intelligence, or *g*. The second tier shows eight broad abilities, or factors, arranged from left to right in terms of decreasing strength of relationship with *g*. In the third tier are examples of narrow factors, specific behaviors through which people display the broad abilities. The child on the left is completing a spatial-relations task in which she solves a puzzle—a type of broad visual perception. The child on the right is applying his broad retrieval ability as he uses art materials creatively. Carroll's model reflects the wide array of abilities tapped by mental tests, but no single test includes all of his factors. (Adapted from Carroll, 1993, 2005.) *Photos:* (left) © J. Burleson/Alamy; (right) © Jeff Greenberg/PhotoEdit

Recent Advances in Defining Intelligence

How do contemporary researchers use and expand componential analyses of intelligence test scores to define intelligence?

Many researchers believe that factors on intelligence tests have limited usefulness unless we can identify the cognitive processes responsible for those factors. Once we discover exactly what separates individuals who can solve certain mental test items from those who cannot, we will know more about why a particular child does well or poorly and what skills must be strengthened to improve performance.

Combining Psychometric and Information-Processing Approaches

To overcome the limitations of factor analysis, investigators combine psychometric and information-processing approaches. They conduct **componential analyses** of children's test scores, looking for relationships between aspects (or components) of information processing and children's intelligence test performance.

Processing speed, measured in terms of reaction time on diverse cognitive tasks, is moderately related to general intelligence and to gains in mental test performance over time (Deary, 2001; Li et al., 2004). Individuals whose central nervous systems function more efficiently, permitting them to take in and manipulate information quickly, appear to have an edge in intellectual skills. In support of this interpretation, fast, strong ERPs (EEG brain waves in response to stimulation) predict both speedy cognitive processing and higher mental test scores (Rijsdijk & Boomsma, 1997; Schmid, Tirsch, & Scherb, 2002). Also, fMRI research reveals that the metabolic rate of the cerebral cortex is lower for high-scoring individuals, suggesting that they require less mental energy for thinking (Neubauer & Fink, 2009; van den Heuvel et al., 2009).

But other factors, including flexible attention, memory, and reasoning strategies, are as important as basic processing efficiency in predicting IQ, and they explain some of the relationship between response speed and good test performance (Lohman, 2000; Miller & Vernon, 1992). Indeed, measures of working-memory capacity (see page 280 in Chapter 7) correlate well with mental test scores—especially fluid measures—in both school-age children and adults (Conway, Kane, & Engle, 2003; de Ribaupierre & Lecerf, 2006; Kane, Hambrick, & Conway, 2005). Children who apply strategies effectively acquire more knowledge and can retrieve it rapidly—advantages that carry over to test performance. Similarly, recall from Chapter 7 that working-memory resources depend in part on effective inhibition—keeping irrelevant information from intruding on the task at hand. Inhibition and sustained and selective attention are among a wide array of attentional skills that are good predictors of IQ (Schweizer, Moosbrugger, & Goldhammer, 2006).

© RICHARD HUTCHINGS/PHOTOEDIT

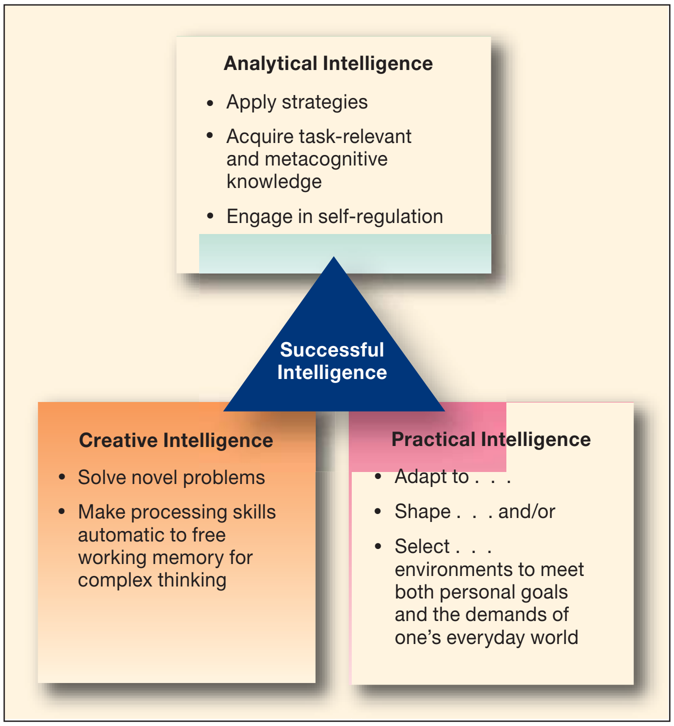
First graders solve problems using specially designed math manipulatives. Children who apply strategies effectively acquire more knowledge and can retrieve it rapidly. As a result, they score higher on intelligence tests.

As these findings illustrate, identifying relationships between cognitive processing and mental test scores brings us closer to isolating the cognitive skills that contribute to high intelligence. But the componential approach has one major shortcoming: It regards intelligence as entirely due to causes within the child. In previous chapters, we have seen how cultural and situational factors also affect children's thinking. Robert Sternberg has expanded the componential approach into a comprehensive theory that views intelligence as a product of inner and outer forces.

Sternberg's Triarchic Theory

As Figure 8.2 on page 324 shows, Sternberg's (2001, 2005, 2008) **triarchic theory of successful intelligence** is made up of three broad, interacting intelligences: (1) *analytical intelligence,* or information-processing skills; (2) *creative intelligence,* the capacity to solve novel problems;

and (3) *practical intelligence,* application of intellectual skills in everyday situations. Intelligent behavior involves balancing all three intelligences to achieve success in life, according to one's personal goals and the requirements of one's cultural community.



Analytical Intelligence
• Apply strategies
• Acquire task-relevant and metacognitive knowledge
• Engage in self-regulation
Successful Intelligence
Creative Intelligence
• Solve novel problems
• Make processing skills automatic to free working memory for complex thinking
Practical Intelligence
• Adapt to . . .
• Shape . . . and/or
• Select . . .
environments to meet both personal goals and the demands of one's everyday world

FIGURE 8.2 Sternberg's triarchic theory of successful intelligence. People who behave intelligently balance three interrelated intelligences—analytical, creative, and practical—to achieve success in life, defined by their personal goals and the requirements of their cultural communities.

Analytical Intelligence *Analytical* intelligence consists of the information-processing components that underlie all intelligent acts: applying strategies, acquiring task-relevant and metacognitive knowledge, and engaging in self-regulation. But on mental tests, processing skills are used in only a few of their potential ways, resulting in far too narrow a view of intelligent behavior. As we have seen, children in tribal and village societies do not necessarily perform well on measures of "school" knowledge but thrive when processing information in out-of-school situations that most Westerners would find highly challenging.

Creative Intelligence In any context, success depends not only on processing familiar information but also on generating useful solutions to new problems. People who are *creative* think more skillfully than others when faced with novelty. Given a new task, they apply their information-processing skills in exceptionally effective ways, rapidly making those skills automatic so that working memory is freed for more complex aspects of the situation. Consequently, they quickly move to high-level performance. Although all of us are capable of some creativity, only a few individuals excel at generating novel solutions. We will address the ingredients of creativity in greater detail at the end of this chapter.

Practical Intelligence Finally, intelligence is a *practical,* goal-oriented activity aimed at *adapting to, shaping,* or *selecting environments.* Intelligent people skillfully *adapt* their thinking to fit with both their desires and the demands of their everyday worlds. When they cannot adapt to a situation, they try to *shape,* or change, it to meet their needs. If they cannot shape it, they *select* new contexts that better match their skills, values, or goals. Practical intelligence reminds us that intelligent behavior is never culture-free. Children with certain life histories do well at the behaviors required for success on intelligence tests and adapt easily to the testing conditions and tasks. Others, with different backgrounds, may misinterpret or reject the testing context. Yet such children often display sophisticated abilities in daily life—for example, telling stories, engaging in complex artistic activities, or interacting skillfully with other people.

To examine the validity of the triarchic theory, Sternberg and his collaborators gave thousands of children and adolescents in Finland, Spain, Russia, and the United States test items that tap analytical, creative, and practical skills. Factor analyses repeatedly indicated that the three intelligences are relatively distinct (Grigorenko & Sternberg, 2001; Sternberg, 2003a; Sternberg et al., 1999, 2001).

The triarchic theory emphasizes the complexity of intelligent behavior and the limitations of current intelligence tests in assessing that complexity. For example, out-of-school, practical forms of intelligence are vital for life success and help explain why cultures vary widely in the behaviors they regard as intelligent (Sternberg et al., 2000). When researchers asked ethnically diverse parents to describe an intelligent first grader, Caucasian Americans mentioned cognitive traits. In contrast, ethnic minorities (Cambodian, Filipino, Vietnamese, and Mexican immigrants) saw noncognitive capacities—motivation, self-management, and social skills—as particularly important (Okagaki & Sternberg, 1993). According to Sternberg, mental tests can easily underestimate, and even overlook, the intellectual strengths of some children, especially ethnic minorities.

Gardner's Theory of Multiple Intelligences

© IAN SHAW/NTPL/THE IMAGE WORKS

According to Gardner, children are capable of at least eight distinct intelligences. As these children distinguish among bird species, they enrich their naturalist intelligence.

In yet another view of how information-processing skills underlie intelligent behavior, Howard Gardner's (1983, 1993, 2000) **theory of multiple intelligences** defines intelligence in terms of distinct sets of processing operations that permit individuals to solve problems, create products, and discover new knowledge in a wide range of culturally valued activities. Dismissing the idea of general intelligence, Gardner proposes at least eight independent intelligences (see Table 8.1).

Gardner believes that each intelligence has a unique biological basis, a distinct course of development, and different expert, or "end-state," performances. At the same time, he emphasizes that a lengthy process of education is required to transform any raw potential into a mature social role (Connell, Sheridan, & Gardner, 2003). Cultural values and learning opportunities affect the extent to which a child's strengths are realized and the way they are expressed.

Gardner acknowledges that if tests were available to assess all these abilities, they should show little relationship to one another. But he finds neurological support for their separateness particularly compelling. Research indicating that damage to a certain part of the adult brain influences only one ability (such as linguistic or spatial), while sparing others, suggests that the affected ability is independent. The existence of people with unusual profiles of intelligence also fits with Gardner's belief in distinct abilities. Individuals with *savant syndrome,* who display one area of outstanding strength alongside deficits in many others, provide an illustration. Children with *autism* occasionally show this pattern. Though severely impaired in language and communication, a few individuals with autism have remarkable abilities, always featuring dazzling memory. These usually involve numerical and spatial skills—such as effortless calculation, detailed drawing, or performance of long piano pieces after hearing them only once—that are primarily housed in the right hemisphere of the cerebral cortex. Savant syndrome often is associated with damage to the left cerebral hemisphere, which may have caused the right hemisphere to compensate, yielding an "island of strength" (Treffert, 2010).

TABLE 8.1 Gardner's Multiple Intelligences

INTELLIGENCE	PROCESSING OPERATIONS	END-STATE PERFORMANCE POSSIBILITIES
Linguistic	Sensitivity to the sounds, rhythms, and meaning of words and the functions of language	Poet, journalist
Logico-mathematical	Sensitivity to, and capacity to detect, logical or numerical patterns; ability to handle long chains of logical reasoning	Mathematician
Musical	Ability to produce and appreciate pitch, rhythm (or melody), and aesthetic quality of the forms of musical expressiveness	Instrumentalist, composer
Spatial	Ability to perceive the visual-spatial world accurately, to perform transformations on those perceptions, and to re-create aspects of visual experience in the absence of relevant stimuli	Sculptor, navigator
Bodily-kinesthetic	Ability to use the body skillfully for expressive as well as goal-directed purposes; ability to handle objects skillfully	Dancer, athlete
Naturalist	Ability to recognize and classify all varieties of animals, minerals, and plants	Biologist
Interpersonal	Ability to detect and respond appropriately to the moods, temperaments, motivations, and intentions of others	Therapist, salesperson
Intrapersonal	Ability to discriminate complex inner feelings and to use them to guide one's own behavior; knowledge of one's own strengths, weaknesses, desires, and intelligences	Person with detailed, accurate self-knowledge

Sources: Gardner, 1993, 1998a, 2000.

Does Gardner's theory remind you of the *core knowledge perspective,* discussed in Chapter 6? Indeed, he accepts the existence of innately specified, core domains of thought, present at birth or emerging early in life. Then, as children respond to the demands of their culture, they transform those intelligences to fit the activities they are called on to perform. Gardner's theory has stimulated innovations in education extending from kindergarten through college in many countries (Chen, Moran, & Gardner, 2009). Applications typically provide students with many opportunities to construct knowledge through hands-on projects that foster diverse intelligences, in classroom communities that highly value individual differences in abilities. Gardner's work has been especially helpful in efforts to understand and nurture children's special talents, a topic we address at the end of this chapter.

Critics of Gardner's theory, however, question the independence of his intelligences. They point out that the unusual skills of people with savant syndrome are mechanical and inflexible because those skills are not aided by other abilities. In contrast, excellence in most fields requires a combination of intelligences. A talented musician, for example, uses logico-mathematical intelligence to interpret the score, linguistic intelligence to respond to teaching, spatial intelligence to orient to the keyboard, interpersonal intelligence to react to the audience, and intrapersonal intelligence to play expressively. Furthermore, some exceptionally gifted individuals have abilities that are broad rather than limited to a particular domain (Piirto, 2007). Finally, current mental tests do tap several of Gardner's intelligences (linguistic, logico-mathematical, and spatial), and evidence for *g* suggests that they have at least some features in common (Visser, Ashton, & Vernon, 2006).

Nevertheless, Gardner calls attention to several intelligences not tapped by intelligence tests. For example, his interpersonal and intrapersonal intelligences include a set of capacities for dealing with people and understanding oneself. As the Social Issues: Education box on the following page indicates, researchers are attempting to define and measure these vital abilities.

ASK YOURSELF

Review ■ Using Sternberg's triarchic theory, explain the limitations of current mental tests in assessing the complexity of human intelligence.

Connect ■ Describe similarities between Gardner's theory of multiple intelligences and the core knowledge perspective on cognitive development (see Chapter 6, pages 261–262). What questions raised about this view also apply to Gardner's theory?

Apply ■ Eight-year-old Charya, an immigrant from Cambodia, had difficulty responding to test items asking for word definitions and general information. But she solved puzzles easily, and she quickly figured out which number comes next in a complex series. How does Charya score in crystallized and fluid intelligence? What might explain the difference?

Reflect ■ Select one of your intellectual strengths from Gardner's multiple intelligences, listed in Table 8.1 on page 325. How do you display that intelligence? What other intelligences contribute to your strong performance?

- Describe commonly used intelligence tests for children, distinguish between aptitude and achievement tests, and discuss the usefulness of infant tests.
- How are IQ scores computed and distributed in large, representative samples?

Measuring Intelligence

Although intelligence tests sample only a narrow range of human cognitive capacities, psychologists and educators give them to school-age children because the scores, as we will see shortly, are modest to good predictors of future success—in school, on the job, and in other aspects of life. The *group-administered tests* given from time to time in classrooms permit large numbers of students to be tested at once and are useful for instructional planning and for identifying students who require more extensive evaluation with *individually administered tests.* Unlike group tests, which teachers can give with minimal training, individually administered tests demand considerable training and experience to give well. The examiner not only considers the child's answers but also carefully observes the child's behavior, noting such reactions as attention to and interest in the tasks and wariness of the adult. These observations provide insights into whether the test results accurately reflect the child's abilities.

SOCIAL ISSUES: EDUCATION

Emotional Intelligence

During recess, Emily handed a birthday party invitation to every fifth-grade girl except Claire, who looked on sadly as her classmates chattered about the party. But one of Emily's friends, Jessica, looked troubled. Pulling Emily aside, she exclaimed, "Why'd you do that? You hurt Claire's feelings—you embarrassed her! If you bring invitations to school, you've got to give everybody one!" And after school, Jessica comforted Claire, saying, "If you aren't invited, I'm not going, either!"

Jessica's IQ is only slightly above average, but she excels at *emotional intelligence*—a term that has captured public attention because of popular books suggesting that it is an overlooked set of skills that can greatly improve life success (Goleman, 1995, 1998). According to one influential definition, **emotional intelligence** is a set of emotional abilities that enable individuals to process and adapt to emotional information (Salovey & Pizarro, 2003). To measure it, researchers have devised items tapping emotional skills that enable people to manage their own emotions and interact competently with others. One test requires individuals to identify and rate the strength of emotions expressed in photographs of faces (emotional perception), to reason about emotions in social situations (emotional understanding), to identify which emotions promote certain thoughts and activities (emotional facilitation), and to evaluate the effectiveness of strategies for controlling negative emotions (emotion regulation). Factor analyses of the scores of hundreds of adolescents and young adults identified several emotional capacities as well as a higher-order general factor (Mayer, Salovey, & Caruso, 2003).

Emotional intelligence is no more than modestly related—and sometimes unrelated—to IQ and academic achievement. Among school-age children, adolescents, and adults, it is positively associated with self-esteem, empathy, prosocial behavior, cooperation, leadership skills, and life satisfaction and negatively related to drug and alcohol use, dependency, depression, and aggressive behavior (Brackett, Mayer, & Warner, 2004; Mavroveli et al., 2007, 2009; Petrides et al., 2006). In adulthood, emotional intelligence predicts many aspects of workplace success, including managerial effectiveness, productive co-worker relationships, and job performance (Mayer, Roberts, & Barsade, 2008; Mayer, Salovey, & Caruso, 2008).

© LAURA DWIGHT PHOTOGRAPHY

These first graders display high emotional intelligence as they accurately interpret a younger child's frustration and take time to help him put on heavy winter outerwear.

Only a few assessments of emotional intelligence are available for children. These require careful training of teachers in observing and recording children's emotional skills during everyday activities, gathering information from parents, and taking ethnic backgrounds into account (Denham, 2005; Denham & Burton, 2003). As more and better measures are devised, they may help identify children with weak social and emotional competencies who would profit from intervention (Denham, 2006; Stewart-Brown & Edmunds, 2007).

The concept of emotional intelligence has increased teachers' awareness that providing experiences that meet students' social and emotional needs can improve their adjustment. Lessons that teach emotional understanding, respect and caring for others, strategies for regulating emotion, and resistance to unfavorable peer pressure—using active learning techniques that provide skill practice both in and out of the classroom—are becoming more common (Bowkett & Percival, 2011).

Some Commonly Used Intelligence Tests

Two individual tests—the Stanford-Binet and the Wechsler—are most often used to identify highly intelligent children and diagnose those with learning problems. Figure 8.3 on page 328 provides examples of items that typically appear on intelligence tests for children.

The Stanford-Binet Intelligence Scales

The modern descendant of Alfred Binet's first successful intelligence test is the **Stanford-Binet Intelligence Scales, Fifth Edition,** for individuals from age 2 to adulthood. This latest edition measures general intelligence and five intellectual factors: fluid reasoning, quantitative reasoning, knowledge, visual-spatial processing, and working memory (Roid, 2003). Each factor includes both a verbal mode and a nonverbal mode of testing, yielding 10 subtests in all. The nonverbal subtests, which do not require spoken language, are especially useful when assessing individuals with limited English, hearing impairments, or communication disorders. The knowledge and quantitative reasoning factors emphasize crystallized intelligence (culturally loaded, fact-oriented information), such as vocabulary and arithmetic problems. In contrast, the fluid reasoning, visual-spatial processing, and working-memory factors, which tap fluid intelligence, are assumed to be less culturally biased.

A special edition of the test, the *Stanford-Binet Intelligence Scales for Early Childhood,* includes fewer items and is tailored for assessing children between ages 2 years and 7 years 3 months. This makes the current Stanford-Binet more useful than its previous edition for diagnosing intellectual difficulties in early childhood.

The Wechsler Intelligence Scale for Children

The **Wechsler Intelligence Scale for Children–IV (WISC–IV)** is the fourth edition of a widely used test for 6- through 16-year-olds. A downward extension of it, the *Wechsler Preschool and Primary Scale of Intelligence–III (WPPSI–III),* is appropriate for children 2 years 6 months through 7 years 3 months (Wechsler, 2002, 2003). The Wechsler tests offered both a measure of general intelligence and a variety of factor scores long before the Stanford-Binet. As a result, many psychologists and educators came to prefer them.

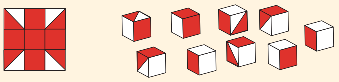
The WISC–IV includes four broad intellectual factors: verbal reasoning, perceptual reasoning, working memory, and processing speed. Each factor is made up of two or three subtests, yielding 10 separate scores in all. The WISC–IV was designed to downplay crystallized, culture-dependent intelligence, which is emphasized on only one factor (verbal reasoning). The remaining three factors focus on fluid, information-processing skills. According to the test designers, the result is the most theoretically current and "culture-fair" intelligence test available (Williams, Weiss, & Rolfhus, 2003). The Wechsler tests were the first to use samples representing the total population of the United States, including ethnic minorities, to devise standards for interpreting test scores.

TYPICAL VERBAL ITEMS

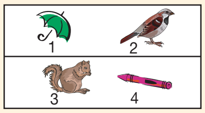
Vocabulary	Tell me what *carpet* means.
General Information	What day of the week comes right after Thursday?
Verbal Comprehension	Why do we need police officers?
Similarities	How are a ship and a train alike?
Arithmetic	If a $60 jacket is 25% off, how much does it cost?

TYPICAL PERCEPTUAL- AND SPATIAL-REASONING ITEMS

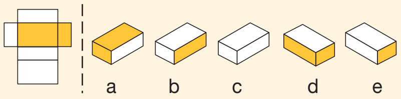
Block Design	Make these blocks look just like the picture.



Picture Concepts	Choose one object from each row to make a group of objects that goes together.



Spatial Visualization	Which of the boxes on the right can be made from the pattern on the left?



TYPICAL WORKING-MEMORY ITEMS

Digit Span	Repeat these digits in the same order. Now repeat these digits (a similar series) backward. **2, 6, 4, 7, 1, 8**
Letter–Number Sequencing	Repeat these numbers and letters, first giving the numbers, then the letters, each in correct sequence. **8 G 4 B 5 N 2**

TYPICAL PROCESSING-SPEED ITEM

Symbol Search	If the shape on the left is the same as any of those on the right, mark YES. If the shape is not the same, mark NO. Work as quickly as you can without making mistakes.

FIGURE 8.3 **Test items like those on commonly used intelligence tests for children.** The verbal items emphasize culturally loaded, fact-oriented information (crystallized intelligence). The perceptual- and spatial-reasoning, working-memory, and processing-speed items emphasize aspects of information processing and are assumed to assess more biologically based skills (fluid intelligence).

Aptitude and Achievement Tests

Two other types of tests are closely related to intelligence tests. **Aptitude tests** assess an individual's potential to learn a specialized activity. For example, mechanical aptitude is the capacity to acquire mechanical skills, musical aptitude is the capacity to acquire musical skills, and scholastic aptitude is the capacity to master school tasks. The well-known Scholastic Assessment Test (SAT) and American College Testing Assessment (ACT), which you may have submitted as part of your college application, yield measures of scholastic aptitude. In contrast, **achievement tests** aim to assess actual knowledge and skill attainment. When a school district assesses fourth-grade reading comprehension or a college professor gives a final exam, an achievement test has been used.

Note, however, that differences among intelligence, aptitude, and achievement tests are not clear-cut. Certain items on each, especially those assessing verbal and math skills, are similar. As this overlap suggests, most tests tap both aptitude and achievement, though in different balances. The three test types do differ in breadth of content. Intelligence tests assess the widest array of skills. Aptitude tests are narrower, focusing on particular skill areas. And achievement tests cover the narrowest range because they are aimed at measuring recent learning, usually in particular school subjects.

Tests for Infants

Accurately measuring infants' intelligence is a challenge because they cannot answer questions or follow directions. All we can do is present them with stimuli, coax them to respond, and observe their behavior. In addition, these young test-takers are not necessarily cooperative. To compensate for their unpredictable behaviors, some tests depend heavily on information supplied by parents.

Most infant measures emphasize perceptual and motor responses. But increasingly, new tests are being developed that tap early language, cognition, and social behavior, especially with older infants and toddlers. One commonly used test, the *Bayley Scales of Infant and Toddler Development,* is suitable for children between 1 month and 3½ years. The most recent edition, the *Bayley–III,* has three main subtests: (1) the Cognitive Scale, which includes such items as attention to familiar and unfamiliar objects, looking for a fallen object, and pretend play; (2) the Language Scale, which taps understanding and expression of language—for example, recognition of objects and people, following simple directions, and naming objects and pictures; and (3) the Motor Scale, which assesses gross- and fine-motor skills, such as grasping, sitting, stacking blocks, and climbing stairs (Bayley, 2005).

Two additional Bayley–III scales depend on parental report: (4) the Social-Emotional Scale, which asks caregivers about such behaviors as ease of calming, social responsiveness, and imitation in play; and (5) the Adaptive Behavior Scale, which asks about adaptation to the demands of daily life, including communication, self-control, following rules, and getting along with others.

Despite careful construction, most infant tests—including previous editions of the Bayley—predict later intelligence poorly. Infants and toddlers easily become distracted, fatigued, or bored during testing, so their scores often do not reflect their true abilities. And infant perceptual and motor items differ from the tasks given to older children, which increasingly emphasize verbal, conceptual, and problem-solving skills. In contrast, the Bayley–III Cognitive and Language Scales, which better dovetail with childhood tests, are good predictors of preschool mental test performance (Albers & Grieve, 2007). But because most infant scores do not tap the same dimensions of intelligence assessed in older children, they are conservatively labeled **developmental quotients (DQs)** rather than IQs.

PHOTO BY STEPHEN AUSMUS/USDA

A trained examiner administers a test based on the Bayley Scales of Infant Development to a 1-year-old sitting in her mother's lap. Compared with earlier editions, the Bayley-III Cognitive and Language Scales better predict preschool mental test performance.

Infant tests are somewhat better at making long-term predictions for very low-scoring babies. Today, they are largely used for *screening*—helping to identify for further observation and intervention infants whose very low scores mean that they are at risk for future developmental problems.

Recall from Chapter 4 that speed of habituation and recovery to visual stimuli is among the best infant correlates of later intelligence (see page 145). One test, the *Fagan Test of Infant Intelligence,* consists entirely of habituation/recovery items. To take it, the infant sits on the mother's lap and views a series of pictures. After exposure to each, the examiner records looking time toward a novel picture paired with the familiar one. Outside of highly controlled laboratory conditions, however, measures of babies' looking behavior are unreliable, or inconsistent from one occasion to the next. Because of its low test–retest reliability (see Chapter 2, page 54), the Fagan test is less successful than researchers' assessments of infant habituation/recovery in predicting childhood mental test scores. And contradictory findings exist concerning whether Fagan test scores are useful for identifying infants at risk for delays in mental development (Andersson, 1996; Fagan & Detterman, 1992; Tasbihsazan, Nettelbeck, & Kirby, 2003).

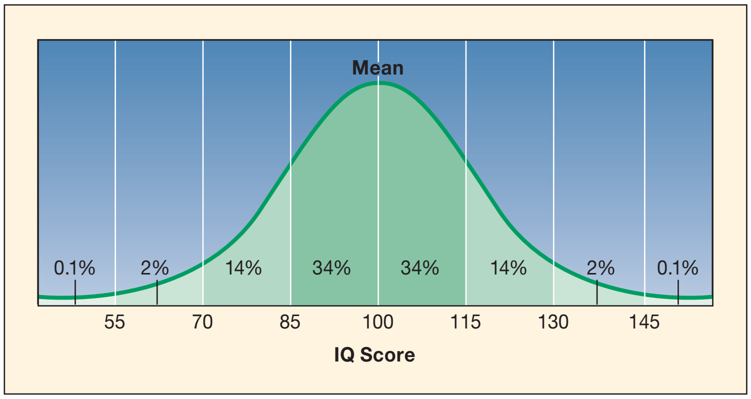


FIGURE 8.4 **Normal distribution of intelligence test scores.** To determine the percentage of same-age individuals in the population a person with a certain IQ outperformed, add the figures to the left of that IQ score. For example, an 8-year-old child with an IQ of 115 scored better than 84 percent of the population of 8-year-olds.

Computation and Distribution of IQ Scores

Intelligence tests for infants, children, and adults are scored in the same way—by computing an **intelligence quotient (IQ),** which indicates the extent to which the raw score (number of items passed) deviates from the typical performance of same-age individuals. To make this comparison possible, test designers engage in **standardization**—giving the test to a large, representative sample and using the results as the *standard* for interpreting scores.

Within the standardization sample, scores at each age level form a **normal distribution,** in which most scores cluster around the mean, or average, with progressively fewer falling toward each extreme (see Figure 8.4). This *bell-shaped distribution* results whenever researchers measure individual differences in large samples. When intelligence tests are standardized, the mean IQ is set at 100. An individual's IQ is higher or lower than 100 by an amount that reflects how much his or her test performance deviates from the standardization-sample mean.

Because we know the percentage of people who fall within each unit of the normal curve, we can figure out exactly what any IQ score means. For example, a child with an IQ of 100 performed better than 50 percent of same-age children. A child with an IQ of 85 did better than only 16 percent, whereas a child with an IQ of 130 outperformed 98 percent. The IQs of the great majority of people (96 percent) fall between 70 and 130; only a few achieve higher or lower scores.

ASK YOURSELF

Review ■ Why are aptitude and achievement tests closely related to intelligence tests and to each other?

Connect ■ Both the Stanford-Binet and the Wechsler tests provide a measure of general intelligence and an array of subtest scores. What evidence presented earlier in this chapter supports the use of these hierarchical models of intelligence?

Apply ■ Assia's score on the Stanford-Binet Intelligence Scales is 115; Leila's score is 145. Using Figure 8.4, explain how well each child performed in relation to other children her age.

▶ Discuss the stability of IQ and its prediction of academic achievement, occupational attainment, and psychological adjustment.

What Do Intelligence Tests Predict, and How Well?

Psychologists and educators who use test scores to make decisions about children's educational placement assume that the scores are good indicators of future intelligence and scholastic performance. How well does IQ actually fare as a predictive measure?

Stability of IQ Scores

Stability refers to how effectively IQ at one age predicts itself at the next. Do children who obtain a particular IQ score at age 3 or 4 perform about the same during elementary school and again in high school? To answer this question, researchers rely on longitudinal studies in which the same children are tested repeatedly.

Correlational Stability One way of examining the stability of IQ is to correlate scores obtained at different ages. This tells us whether children who score low or high in comparison to their agemates at one age continue to do so later. Examining these correlations, researchers have identified two generalizations about the stability of IQ:

- *The older the child at time of first testing, the better the prediction of later IQ.* Preschool IQs do not predict school-age scores well; correlations are typically no better than in the .30s. But after age 6, stability improves, with many correlations in the .70s and .80s. Relationships between two testings in adolescence are as high as the .80s and .90s (Deary et al., 2004; Kaufman & Lichtenberger, 2002).
- *The closer in time two testings are, the stronger the relationship between the scores.* In one long-term study, 4-year-old IQ correlated with 5-year-old IQ at .52, but prediction dropped to .46 by age 9 and to .42 by age 12 (Schneider et al., 1999).

Why do preschool scores predict less well than later scores? One reason is that with age, test items focus less on concrete knowledge and more on complex reasoning and problem solving, which require different skills. Another explanation is that during periods of rapid development, children frequently change places in a distribution. One child may spurt ahead and reach a plateau; a second child, progressing slowly and steadily, may eventually overtake the first. Finally, IQ may become more stable after schooling is under way because daily classroom activities and test items become increasingly similar. Then, variations among children in quality of school experiences and in mastery of those experiences may help sustain individual differences in IQ.

Stability of Absolute Scores So far, we have considered IQ stability in terms of how well children maintain their relative standing among agemates. Stability can also be viewed in *absolute* terms—by examining each child's profile of IQ scores over repeated testings. Longitudinal research reveals that the majority of children show substantial IQ fluctuations during childhood and adolescence—typically 10 to 20 points, and sometimes much more (McCall, 1993; Weinert & Hany, 2003).

Children who change the most tend to have orderly profiles, with scores either increasing or decreasing with age. Examining personality traits and life experiences associated with these profiles reveals that gainers tended to be more independent and competitive about doing well in school. Also, their parents were more likely to use warm, rational discipline and encourage them to succeed. In contrast, decliners often had parents who used either very severe or very lax discipline and who offered little intellectual stimulation (Honzik, Macfarlane, & Allen, 1948; McCall, Appelbaum, & Hogarty, 1973; Sontag, Baker, & Nelson, 1958).

When children who live in poverty are selected for special study, many show mental-test score declines. According to the **environmental cumulative deficit hypothesis,** the negative effects of underprivileged rearing conditions increase the longer children remain in those conditions. As a result, early cognitive deficits lead to more deficits, which become harder to overcome (Klineberg, 1963). In support of this idea, many studies show that children from economically disadvantaged families fall further and further behind their agemates in both IQ and achievement as they get older, and children who suffer from more stressors (such as parental divorce, job loss, illness, or deaths in the family) experience greater declines (Gutman, Sameroff, & Cole, 2003; Gutman, Sameroff, & Eccles, 2002).

In sum, many children show substantial changes in the absolute value of IQ that are the combined result of personal characteristics, child-rearing practices, and living conditions. Nevertheless, once IQ becomes reasonably stable in a correlational sense, it predicts a variety of important outcomes.

IQ as a Predictor of Academic Achievement

In thousands of studies, correlations between IQ and achievement test scores range from the .40s to the .80s, typically falling between .50 and .60 (Deary et al., 2007; Rhode & Thompson, 2007; Zhu & Weiss, 2005). Students with higher IQs also get better grades and stay in school

© LAURA DWIGHT PHOTOGRAPHY

Research indicates that IQ predicts academic achievement. But other factors, including motivation and personality characteristics, are at least as important in accounting for children's learning in school.

longer. Beginning at age 7, IQ is moderately correlated with adult educational attainment (McCall, 1977).

Why does IQ predict scholastic performance? Some researchers believe that both IQ and achievement depend on the same abstract reasoning processes that underlie *g*. Consistent with this interpretation, IQ correlates best with achievement in the more abstract school subjects, such as English, mathematics, and science (Jensen, 1998). Other researchers disagree, arguing that both IQ and achievement tests draw on the same pool of culturally specific information. From this perspective, an intelligence test is, in fact, partly an achievement test, and a child's past experiences affect performance on both measures. Support for this view comes from evidence that crystallized intelligence (which reflects acquired knowledge) is a better predictor of academic achievement than is its fluid counterpart (Kaufman, Kamphaus, & Kaufman, 1985; Kunina et al., 2007).

As you can imagine, researchers who believe that heredity contributes strongly to individual differences in IQ prefer the first of these explanations. Those who favor the power of environment prefer the second. We will delve into this nature–nurture debate shortly, but for now let's note that although IQ predicts achievement better than any other tested measure, the correlation is far from perfect. Other factors, such as motivation and personality characteristics that lead some children to try hard in school, are at least as important as IQ in accounting for individual differences in school performance.

IQ as a Predictor of Occupational Attainment

If IQ scores were unrelated to long-term life success, psychologists and educators would probably be less concerned with them. But research indicates that childhood IQ predicts adult occupational attainment just about as well as it correlates with academic achievement. By second grade, children with the highest IQs are more likely, as adults, to enter prestigious professions, such as engineering, law, medicine, and science (McCall, 1977).

Again, the relationship between IQ and occupational attainment is far from perfect. Factors related to family background, such as parental encouragement, modeling of career success, and connections in the world of work, also predict occupational choice and attainment (Kalil, Levine, & Ziol-Guest, 2005). Furthermore, one reason that IQ is associated with occupational status is that IQ-like tests (the SAT and ACT) affect access to higher education. Educational attainment is a stronger predictor than IQ of occupational success and income (Ceci & Williams, 1997).

Another prominent factor in occupational achievement is personality. Examining seven longitudinal studies spanning one to four decades, researchers found that, after childhood IQ and parents' educational and occupational attainment were controlled, such traits as childhood emotional stability, conscientiousness, and sociability positively predicted career success, whereas belligerence and negative emotionality forecast unfavorable career outcomes, including job instability, reduced occupational prestige, and lower income (Roberts et al., 2007).

Finally, once a person enters an occupation, **practical intelligence**—mental abilities apparent in the real world but not in testing situations—predicts on-the-job performance as well as, and sometimes better than, IQ. Yet mental test performance and practical intelligence require distinctly different capacities. Whereas test items are formulated by others, provide complete information, are often detached from real life, and have only one solution, practical problems are not clearly defined, are embedded in everyday experiences, and generally have several appropriate solutions, each with strengths and limitations (Sternberg et al., 2000). Practical intelligence is evident in the assembly-line worker who discovers the fewest moves needed to complete a product or the business manager who increases productivity by making her subordinates feel valued. Unlike IQ, practical intelligence does not vary with ethnicity. And the two types of intelligence are unrelated and make independent contributions to job success (Cianciolo et al., 2006; Sternberg, 2003a).

In sum, occupational outcomes are a complex function of traditionally measured intelligence, education, family influences, motivation, and practical know-how. Current evidence indicates that IQ, though influential, is not more important than these other factors.

© LAURA DWIGHT PHOTOGRAPHY

This teenager's practical intelligence—evident in his ability to diagnose the cause of a malfunctioning computer and ably repair it—taps distinctly different capacities than those represented by IQ.

IQ as a Predictor of Psychological Adjustment

IQ is moderately correlated with emotional and social adjustment. For example, higher-IQ children and adolescents tend to be better-liked by their agemates. But the reasons for this association are not clear. Besides IQ, good peer relations are linked to patient but firm child-rearing practices and an even-tempered, sociable personality, both of which are positively correlated with IQ (Hogan, Harkness, & Lubinski, 2000; Scarr, 1997).

Another way of exploring the relationship of IQ to psychological adjustment is to look at the mental test performance of aggressive youths who frequently engage in lawbreaking acts. On average, juvenile delinquents score about 8 points lower in IQ than nondelinquents; persistently aggressive children and adolescents are especially deficient in verbal ability (Dodge, Coie, & Lynam, 2006). Perhaps similar genetic and environmental factors (such as proneness to impulsivity, parenting quality, and family functioning) influence both IQ and conduct problems. Alternatively, low IQ (especially verbal scores) may predispose children to conduct difficulties by affecting their ability to make mature moral judgments, evaluate future consequences of their actions, and control their emotions and behavior. Consistent with both interpretations, longitudinal research indicates that low IQ in early and middle childhood is associated with later antisocial behavior only when children also score high in emotional and behavior problems and when their poor intellectual functioning persists (Fergusson, Horwood, & Ridder, 2005; Leech et al., 2003).

Lower childhood mental test scores are also associated with other psychological disorders, including high anxiety and depression in adolescence and adulthood (Martin et al., 2007; Zammit et al., 2004). But these relationships are modest, and they are further reduced after childhood family instability and economic disadvantage are controlled (Fergusson, Horwood, & Ridder, 2005; Gale et al., 2009). In Chapter 1, we saw that children high in intelligence are more resilient in the face of stressful life experiences (see page 10).

In sum, IQ predicts diverse life success indicators, but does so imperfectly. These findings provide strong justification for not relying on IQ alone when forecasting a child's future or making important educational placement decisions.

ASK YOURSELF

Review ■ Provide two competing explanations for the correlation between IQ and academic achievement.

Connect ■ Describe evidence from previous chapters that non-Western children with little or no formal schooling display considerable practical intelligence, despite poor performance on tasks commonly used to assess Western children's cognitive skills. (*Hint:* See Chapter 6, page 252, and Chapter 7, page 294.)

Apply ■ When 5-year-old Paul had difficulty adjusting to kindergarten, his teacher arranged for special testing. Paul's IQ turned out to be below average, at 95. When discussing Paul's score with his parents and teacher, what should the psychologist say about the stability of IQ?

Reflect ■ How do James's experiences, described in the opening to this chapter, fit with findings on children who show mental test score gains with age?

- Describe ethnic and socioeconomic variations in IQ.

Ethnic and Socioeconomic Variations in IQ

People in industrialized nations are stratified on the basis of what they do at work and how much they earn for doing it—factors that determine their social position and economic well-being. Researchers assess a family's standing on this continuum through an index called **socioeconomic status (SES),** which combines three interrelated—but not completely overlapping—variables: (1) years of education and (2) the prestige of one's job and the skill it requires, both of which measure social status; and (3) income, which measures economic status.

© WILL HART/PHOTOEDIT

These students' IQ scores may vary with ethnicity and SES. Research designed to uncover the reasons for these associations has generated heated controversy.

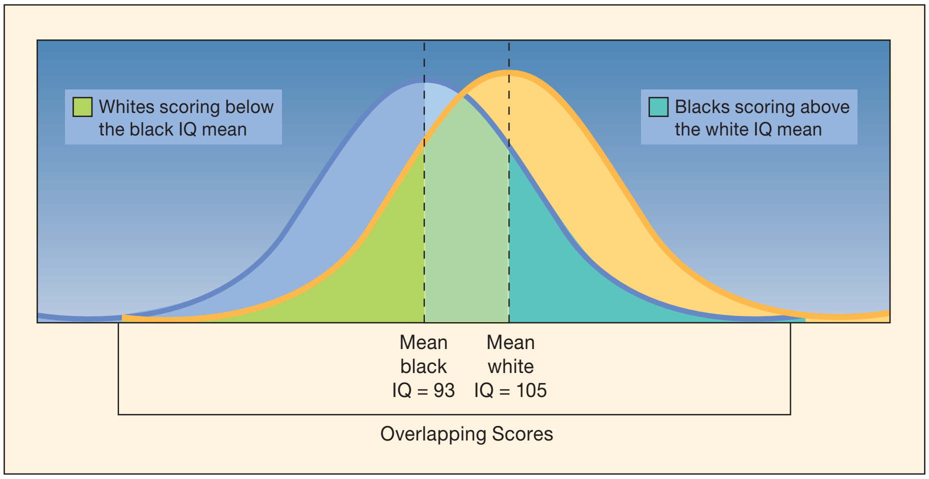
In searching for the roots of socioeconomic disparities, researchers have compared the IQ scores of SES and ethnic groups because certain ethnicities (for example, African American and Hispanic) are heavily represented at lower SES levels and others (for example, Caucasian and Asian American) at middle and upper SES levels. These findings are responsible for the IQ nature–nurture debate. If group differences in IQ exist, then either heredity varies with SES and ethnicity, or certain groups have fewer opportunities to acquire the skills needed for successful test performance.

American black children and adolescents score, on average, 10 to 12 IQ points below American white children. Although the difference has been shrinking over the past several decades, a substantial gap—present by age 3—remains (Edwards & Oakland, 2006; Flynn, 2007; Nisbett, 2009; Peoples, Fagan, & Drotar, 1995). Hispanic children fall midway between black and white children, and Asian Americans score slightly higher than their white counterparts—about 3 points (Ceci, Rosenblum, & Kumpf, 1998).

The gap between middle- and low-SES children—about 9 points—accounts for some of the ethnic differences in IQ, but not all. When black children and white children are matched on parental education and income, the black–white IQ gap is reduced by a third to a half (Brooks-Gunn et al., 2003). Of course, IQ varies greatly *within* each ethnic and SES group. For example, as Figure 8.5 shows, the IQ distributions of blacks and whites overlap substantially. About 20 percent of blacks score above the white mean, and the same percentage of whites score below the black mean. In fact, ethnicity and SES account for only about one-fourth of the total variation in IQ. Nevertheless, these group differences are large enough and of serious enough consequence that they cannot be ignored.

In the 1970s, the IQ nature–nurture controversy escalated after psychologist Arthur Jensen (1969) published a controversial monograph entitled, "How Much Can We Boost IQ

FIGURE 8.5 **IQ score distributions for black and for white children.** The means represent approximate values obtained in studies of children reared by their biological parents.



and Scholastic Achievement?" Jensen's answer was "not much." He claimed—and still maintains—that heredity is largely responsible for individual, ethnic, and SES differences in IQ (Jensen, 1998, 2001; Rushton & Jensen, 2006, 2010). Jensen's work sparked an outpouring of research studies and responses, including ethical challenges reflecting deep concern that his conclusions would fuel social prejudices. Richard Herrnstein and Charles Murray rekindled the controversy with *The Bell Curve* (1994). Like Jensen, they argued that heredity contributes substantially to individual and SES differences in IQ, and they implied that heredity plays a sizable role in the black–white IQ gap.

As with Jensen's monograph, Herrnstein and Murray's book was praised by some researchers and deplored by others, who underscored its damaging social consequences. Let's look closely at some important evidence.

Explaining Individual and Group Differences in IQ

- Discuss the contributions of heredity and environment to individual and group differences in IQ.
- Evaluate evidence on whether ethnic differences in IQ result from test bias, and discuss efforts to reduce cultural bias in testing.
- Summarize the impact of shared and nonshared environmental influences on IQ.

Researchers have carried out hundreds of studies aimed at explaining individual, ethnic, and SES differences in mental abilities. The evidence is of three broad types: (1) investigations addressing the importance of heredity, (2) those that look at whether IQ scores are biased measures of the abilities of low-SES and minority children, and (3) those that examine the influence of children's home environments on their mental test performance.

Genetic Influences

Recall from Chapter 3 that behavioral geneticists examine the relative contributions of heredity and environment to complex traits by conducting *kinship studies,* which compare the characteristics of family members. Let's look closely at what they have discovered about IQ.

Heritability of Intelligence In Chapter 3, we introduced the *heritability estimate.* To review briefly, researchers correlate the IQs of family members who vary in the extent to which they share genes. Then, using a complicated statistical procedure to compare the correlations, they arrive at an index of heritability, ranging from 0 to 1, which indicates the proportion of variation in a specific population due to genetic factors.

Figure 8.6 summarizes findings on IQ correlations from more than 100 studies on approximately 50,000 pairs of twins and other relatives (Bouchard & McGue, 1981; Scarr,

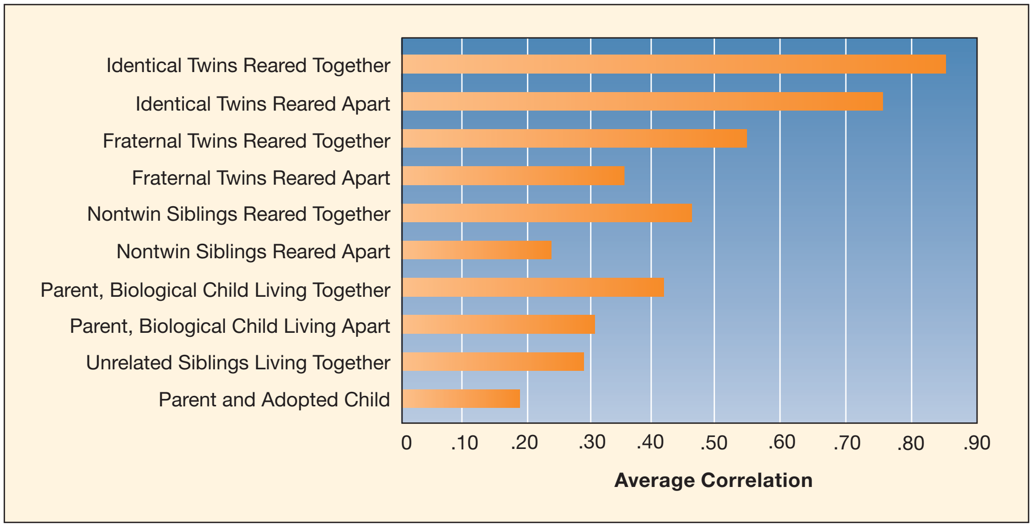


FIGURE 8.6 Worldwide summary of IQ correlations between twins and other relatives. The correlations show that the greater the genetic similarity between family members, the more similar their IQ scores. But the same correlations also show that greater environmental similarity yields more similar IQ scores. (Adapted from Bouchard & McGue, 1981; Scarr, 1997.)

1997). The greater the genetic similarity between family members, the more they resemble one another in IQ. In fact, two correlations reveal that heredity is, without question, partially responsible for individual differences in mental test performance. The correlation for identical twins reared apart (.76) is much higher than for fraternal twins reared together (.55).

Age-related changes in these twin correlations provide additional support for the contribution of heredity. As Figure 8.7 shows, correlations for identical twins increase modestly into adulthood, whereas those for fraternal twins drop sharply at adolescence. Do these trends remind you of the *niche-picking* idea, discussed in Chapter 3? Common rearing experiences support the similarity of fraternal twins during childhood. But as they get older and experience more influences outside their families, each fraternal twin follows a path of development, or finds a niche, that fits with his or her unique genetic makeup. As a result, their IQ scores diverge. In contrast, the genetic likeness of identical twins causes them to seek out similar niches in adolescence and adulthood. Consequently, their IQ resemblance strengthens (Loehlin, Horn, & Willerman, 1997; McGue et al., 1993).

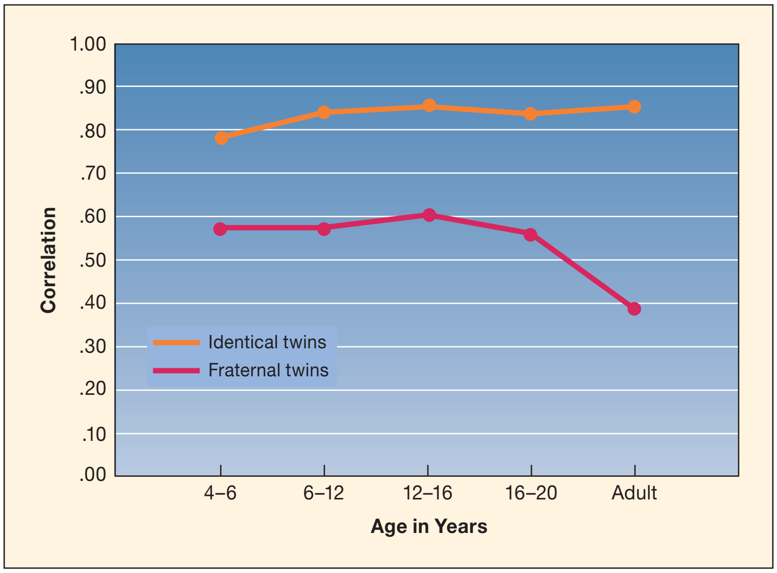

FIGURE 8.7 **Cross-sectional age-related changes in IQ correlations for identical and fraternal twins.** Correlations for identical twins increase modestly into adulthood, whereas those for fraternal twins drop sharply at adolescence. Similar trends appear when twins are followed longitudinally. The findings are derived from studies including thousands of twin pairs. (From M. McGue, T. J. Bouchard, Jr., W. G. Iacono, & D. T. Lykken, 1993, "Behavioral Genetics of Cognitive Ability: A Life-Span Perspective," in R. Plomin & G. E. McCleam [Eds.], *Nature, Nurture, and Psychology,* 1993, p. 63. Copyright © 1993 by the American Psychological Association. Adapted by permission of the American Psychological Association and M. McGue.)

Although kinship research underscores the importance of heredity, the correlations in Figure 8.6 reveal that environment is clearly involved. Correlations for twin, nontwin sibling, and parent–child pairs living together are stronger than for those living apart. And parents and adopted children, as well as unrelated siblings living together, show low positive correlations, again supporting the influence of environment.

As indicated in Chapter 3, heritability estimates usually are derived from comparisons of identical and fraternal twins. In Western industrialized nations, the typical value is about .50, meaning that half the variation in IQ is due to individual differences in heredity. But the values vary greatly between studies, ranging from the .40s to the .80s (Jacobs et al., 2007; Plomin, 2003).

Furthermore, recall from Chapter 3 that this moderate heritability estimate may be too high because twins reared together often experience very similar overall environments. Even twins reared apart generally are placed in homes that are advantaged and similar in many ways. When the range of environments to which twins are exposed is restricted, heritabilities underestimate the role of environment and overestimate the role of heredity.

In sum, although heritability research offers convincing evidence that genes contribute to IQ, disagreement persists over the extent of heredity's role. And heritability estimates do not reveal the complex processes through which genetic and environmental factors influence intelligence as children develop.

Do Heritability Estimates Explain Ethnic and SES Variations in IQ? Despite the limitations of the heritability estimate, Jensen relied on it to support the argument that ethnic and SES differences in IQ have a strong genetic basis. This line of reasoning is widely regarded as inappropriate. Heritability estimates computed *within* black and white populations, though similar, provide no direct evidence on what accounts for between-group differences (Plomin et al., 2001; Sternberg, Grigorenko, & Kidd, 2005). Also, in Chapter 3 we saw that the heritability of IQ is *higher* under advantaged (higher-SES) than disadvantaged (lower-SES) rearing conditions (Bronfenbrenner & Morris, 2006; Turkheimer et al., 2003). Factors associated with low income and poverty, including weak or absent prenatal care, family stress, low-quality schools, and lack of community supports for effective child rearing, prevent children from attaining their genetic potential.

According to geneticist Richard Lewontin (1976, 1995), using within-group heritabilities to account for between-group differences is like comparing different seeds in different soil. Imagine planting a handful of flower seeds in a pot of soil generously enriched with fertilizer and another handful in a pot with very little fertilizer. The plants in each pot vary in height, but those in the first pot grow much taller than those in the second. *Within each group,* individual differences in plant height are largely due to heredity because the growth environments of all plants were about the same. But the average difference in height *between the two groups* is probably environmental because the second group got far less fertilizer.

To verify this conclusion, we could design a study in which we expose the second group of seeds to a full supply of fertilizer and see if they reach an average height that equals that of the first group. Then we would have powerful evidence that environment is responsible for the group difference. As we turn now to adoption research, we will see that researchers have conducted natural experiments of this kind.

Adoption Studies: Joint Influence of Heredity and Environment

In adoption studies, researchers gather two types of information: (1) correlations of the IQs of adopted children with those of their biological and adoptive parents, for insight into genetic and environmental influences; and (2) changes in the absolute value of IQ as a result of growing up in an advantaged adoptive family, for evidence on the power of the environment.

Findings consistently reveal that when young children are adopted into caring, stimulating homes, their IQs rise substantially compared with the IQs of nonadopted children who remain in economically deprived families (van IJzendoorn, Juffer, & Poelhuis, 2005). But adopted children benefit to varying degrees. In one investigation, called the Texas Adoption Project, children of two extreme groups of biological mothers—those with IQs below 95 and those with IQs above 120—were adopted at birth by parents who were well above average in income and education. During the school years, the children of the low-IQ biological mothers scored above average in IQ but did less well than the children of high-IQ biological mothers placed in similar adoptive families (see Figure 8.8). Furthermore, parent–child correlations revealed that as the children grew older, they became more similar in IQ to their biological mothers and less similar to their adoptive parents (Loehlin, Horn, & Willerman, 1997).

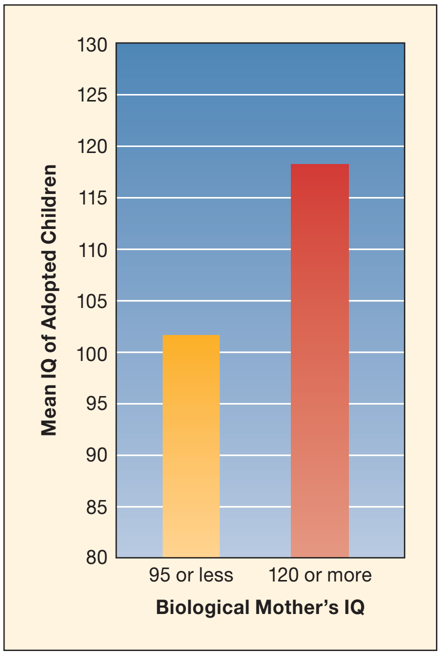

FIGURE 8.8 **IQs of adopted children as a function of biological mothers' IQ in the Texas Adoption Project.** Children of both low-IQ and high-IQ biological mothers scored above average in IQ, but those of the high-IQ mothers did better. (Adapted from Loehlin, Horn, & Willerman, 1997.)

The Texas Adoption Project and other similar investigations confirm that *both* environment and heredity contribute to IQ. In fact, children adopted in the early years attain IQs that, on average, match the scores of their adoptive parents' biological children and the scores of nonadopted peers in their schools and communities (van IJzendoorn, Juffer, & Poelhuis, 2005). These outcomes suggest a sizable role for environment in explaining SES variations in mental test scores. At the same time, adoption studies repeatedly reveal stronger correlations between the IQ scores of biological relatives than between those of adoptive relatives—clear evidence for a genetic contribution (Bouchard, 1997; Plomin et al., 2001; Scarr, 1997).

Adoption research also sheds light on the black–white IQ gap. In two studies, African-American children adopted into economically well-off white homes during the first year of life scored high on intelligence tests, attaining mean IQs of 110 and 117 by middle childhood—20 to 30 points higher than the typical scores of children growing up in low-income black communities (Moore, 1986; Scarr & Weinberg, 1983). In one investigation, the IQs of black adoptees declined in adolescence, perhaps because of the challenges faced by minority teenagers in forming an ethnic identity that blends birth and adoptive backgrounds (DeBerry, Scarr, &

CULTURAL INFLUENCES

The Flynn Effect: Massive Generational Gains in IQ

After gathering IQ scores from 20 industrialized nations that had either military mental testing or frequent testing of other large, representative samples, James Flynn (1994, 1999, 2007) reported a finding so consistent and intriguing that it became known as the **Flynn effect:** IQs have increased steadily from one generation to the next. The largest increases have occurred on fluid-ability tests of spatial reasoning—tasks often assumed to be "culture-fair" and, therefore, largely genetically based. Figure 8.9 shows these gains for one such test, administered to military samples consisting of almost all young men in Belgium, Israel, the Netherlands, and Norway. IQ rose, on average, 18 points per generation (30 years).

Consistent with this *secular trend* (see page 184 in Chapter 5 to review this concept), when intelligence tests are revised, the new standardization sample almost always performs better than the previous one. After locating every study in which the same individuals had taken two or more versions of Stanford-Binet or Wechsler tests (a total of 81 samples, with nearly 10,000 participants), Flynn used the data to estimate the rate of IQ change between 1932 and 2002. On average, IQ increased about ⅓ point per year, steadily over time and similarly across all ages, for a total of 22 points over the 46-year period (Flynn, 2007; Flynn & Weiss, 2007). When subtest scores were examined, gains were (again) largest for fluid-ability tasks.

The Flynn effect has been reconfirmed in research spanning the years 1986 to 2004 that included over 27,000 nationally representative U.S. 5- to 13-year-olds (Ang, Rodgers, & Wänström, 2010; Rodgers & Wänström, 2007). The effect held for both genders; across African Americans, Hispanics, and Caucasians; and across families varying in maternal education and household income. And it was accelerated among children who had college-educated mothers and who were growing up in financially well-off homes.

Clearly, the Flynn effect is environmental. Improved education, health, technological innovations (including TV and computers), more time devoted to cognitively demanding leisure activities (from chess to video games), a generally more stimulating world, and greater test-taking motivation may have contributed to the better reasoning ability of each successive generation (Flynn, 2003; Rodgers & Wänström, 2007; Steen, 2009).

Recently, the Flynn effect has slowed or stopped in certain developed nations with especially favorable health, social, and economic conditions (Scandinavia, for example) (Schneider, 2006; Sundet, Barlaug, & Torjussen, 2004). At the same time, it has spread to the developing world. The IQs of rural schoolchildren in Kenya underwent a large increase from 1984 to 1998 (Daley et al., 2003). During this period, TV sets appeared in some households, parental education and literacy increased, and family size declined, permitting parents to devote more time and resources to each child.

Notice that the generational gain in intelligence (18 points) is larger than the black–white IQ gap (about 12 to 13 points), indicating that environmental explanations for ethnic differences in IQ are highly plausible. Flynn argues that large, environmentally induced IQ increases over time present a major challenge to the assumption that black–white and other ethnic variations in IQ are genetic (Dickens & Flynn, 2001; Flynn, 2007; Nisbett, 2009).

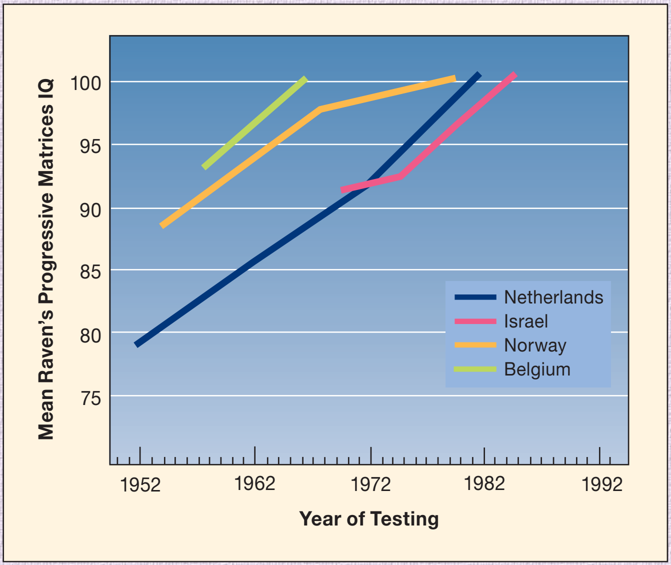

FIGURE 8.9 The Flynn effect: Generational gains in performance on a test of spatial reasoning in four nations. Findings are based on military testing that includes nearly all young adults in each country. (From J. R. Flynn, 1999, "Searching for Justice: The Discovery of IQ Gains over Time," *American Psychologist, 54,* p. 7. Copyright © 1999 by the American Psychological Association. Adapted with permission from the American Psychological Association and James Flynn.)

Weinberg, 1996). When this process is filled with emotional turmoil, it can dampen motivation on tests and in school.

Still, the black adoptees remained above the IQ average for low-SES African Americans. The IQ gains of black children "reared in the culture of the tests and schools" are consistent with a wealth of evidence that poverty severely depresses the scores of many ethnic minority children (Nisbett, 2009). Dramatic gains in IQ from one generation to the next further support the conclusion that, given new experiences and opportunities, members of oppressed groups can move far beyond their current test performance. See the Cultural Influences box above to learn about the *Flynn effect.*

Race and Ethnicity: Genetic or Cultural Groupings?

© KEN CHERNUS/GETTY IMAGES/TAXI

These children, brothers by adoption, are growing up in the same stimulating, advantaged home. Adoption research supports the view that experiences and opportunities explain racial and ethnic differences in IQ.

DNA analyses reveal wide genetic variation *within* races (identified by physical features, such as skin color) and minimal genetic variation *between* them (Lewontin, 2003; Sternberg, Grigorenko, & Kidd, 2005; Templeton, 2002). Members of ethnic groups that have been the focus of the IQ nature–nurture controversy are far more similar in cultural values, experiences, and opportunities than in genetic makeup.

Nevertheless, many people incorrectly assume that genetic, racial differences underlie ethnic group differences in psychological traits. Yet racial labels themselves are often arbitrary. In the United States, "black" designates people with dark skin. In Brazil and Peru, where "black" refers to hair texture, eye color, and stature, many African Americans would be called "white." Asians and the !Kung of Botswana, Africa, could be regarded as one race because they have similarly shaped eyes. Alternatively, Asians, Native Americans, and Swedes might be grouped together because of their similarly shaped teeth (Fish, 2002; Renzetti & Curran, 1998).

Differences in racial designations over time and across nations underscore their unclear boundaries. On the U.S. Census form, ten racial categories appeared in 1930, only five in 1990, and six in 2000, with respondents permitted to check more than one race—all six, if they chose! On the 2010 form, racial categories expanded to 15, and once again respondents were allowed to mark as many as appropriate, and they also could write in specific races not listed.

Many racial designations encompass enormous cultural, linguistic, and biological diversity: "Black" includes, for example, people from Africa, Haiti, and Jamaica; "Hispanic" includes people from Argentina, Costa Rica, Cuba, Guatemala, and Spain. In research as in census surveys, people self-identify, expressing their cultural heritage and sense of group belonging. Finally, in countries as culturally diverse as the United States, ethnic mixing is extensive. Consider this Hawaiian native's description of his ethnicity: "I'm Asian on my birth certificate and the census form, but I'm really multiracial. My mother's parents were Japanese, my father's mother was Filipino, and my father's father was Irish."

As one scholar of race relations summed up, "Classification of human beings into races is in the end a futile exercise" (Payne, 1998, p. 32). And perpetuating the belief that some ethnic groups are genetically inferior in IQ promotes an ever-present danger: unfair allocation of resources, making an unfounded assumption seem true.

Cultural Bias in Testing

A controversial question raised about ethnic differences in IQ has to do with whether they result from *test bias.* If a test samples knowledge and skills that not all groups of children have had equal opportunity to learn, or if the testing situation impairs the performance of some groups but not others, then the resulting score is a biased, or unfair, measure.

Some experts reject the idea that intelligence tests are biased, claiming that they are intended to represent success in the common culture. According to this view, because IQ predicts academic achievement equally well for majority and minority children, IQ tests are fair to both groups (Edwards & Oakland, 2006; Jensen, 2002). Others believe that lack of exposure to certain communication styles and knowledge, along with negative stereotypes about the test-taker's ethnic group, can undermine children's performance (Ceci & Williams, 1997; Sternberg, 2005). Let's look at the evidence.

Communication Styles Ethnic minority families often foster unique language skills that do not match the expectations of most classrooms and testing situations. Shirley Brice Heath (1990), an anthropologist who spent many hours observing in low-SES black homes in a southeastern U.S. city, found that African-American adults rarely asked their children the types of knowledge-training questions typical of middle-SES white families ("What color is it?" "What's this story about?"), which resemble the questioning style of tests and classrooms. Instead, the black parents asked only "real" questions, ones that they themselves could not answer. Often these were analogy questions ("What's that like?") or story-starter questions ("Did you hear Sally this morning?") that called for elaborate responses about personal experiences and had no "right answer."

These experiences led the black children to develop complex verbal skills at home, such as storytelling and exchanging quick-witted remarks. But their language emphasized emotional and social concerns rather than facts about the world. Not surprisingly, when the black children started school, many were unfamiliar with and confused by the "objective" questions they encountered on tests and in classrooms.

Also, African-American children often take a unique approach to storytelling that reflects a culturally specific form of narrative. Instead of the *topic-focused* style of most school-age children, who describe an experience from beginning to end, they use a *topic-associating* style, in which they blend several similar experiences. One 9-year-old, for example, related having a tooth pulled, then described seeing her sister's tooth being pulled, next told how she had removed one of her baby teeth, and concluded, "I'm a pullin' teeth expert . . . call me, and I'll be over'" (McCabe, 1997, p. 164). Despite its complexity, many teachers criticize this culturally distinctive narrative form as "disorganized," and it is not included in verbal test items (Beck, 2008). Rather, mental tests typically ask children to rearrange events in consecutive order.

© EASTCOTT-MOMATIUK/THE IMAGE WORKS

This Canadian Inuit grandmother and granddaughter communicate collaboratively, smoothly coordinating actions in cleaning freshly caught fish. Many children from ethnic minority families are unfamiliar with the hierarchical communication style typical of classrooms—a reason they may do poorly on tests and assignments.

Furthermore, many ethnic minority parents without extensive schooling prefer a *collaborative style of communication* when completing tasks with children. They work together in a coordinated, fluid way, each focused on the same aspect of the problem. This pattern of adult–child engagement has been observed in Native American, Canadian Inuit, Hispanic, and Guatemalan Mayan cultures (Chavajay & Rogoff, 2002; Crago, Annahatak, & Ningiuruvik, 1993; Delgado-Gaitan, 1994; Paradise & Rogoff, 2009). With increasing education, parents establish a *hierarchical style of communication,* like that of classrooms and tests. The parent directs each child to carry out an aspect of the task, and children work independently (Greenfield, Suzuki, & Rothstein-Fish, 2006). This sharp discontinuity between home and school communication practices may contribute to low-SES minority children's lower IQ and school performance.

Indeed, intelligence testing is an extreme of this directive approach. Tasks are presented in only one way, and test-takers get no feedback. When an adult refuses to reveal whether the child is on the right track, minority children may react with "disruptive apprehension"—giving any answer that comes to mind and rejecting the testing situation as personally irrelevant (Ferguson, 1998). In one study, Australian Aboriginal 7- to 14-year-olds—who scored far below their Australian European agemates on a typical, paper-and-pencil math skills test—showed dramatic performance gains when given a computerized, interactive version. The computerized test provided immediate feedback about the accuracy of answers and, after an incorrect response, allowed the child to invoke a brief, narrated lesson on how to solve the item (Hippisley, Douglas, & Houghton, 2005). Providing feedback and prompting children to look at missed problems in new ways resulted in a more "culture-fair" assessment of their math competencies.

LOOK and LISTEN

Review the perceptual- and spatial-reasoning, working-memory, and processing-speed items in Figure 8.3 on page 328, which emphasize fluid intelligence. For each, describe one home and one school experience likely to facilitate children's performance.

Knowledge Many researchers argue that IQ scores are affected by specific information acquired as part of majority-culture upbringing. Consistent with this view, low-SES African-American preschoolers often miss vocabulary words on mental tests that have alternative meanings in their cultural community—for example, interpreting the word *frame* to mean "physique" or *wrapping* as "rapping," referring to the style of music (Champion, 2003a).

Knowledge affects ability to reason effectively. When researchers assessed black and white community college students' familiarity with vocabulary taken from items on an intelligence test, the whites had considerably more knowledge (Fagan & Holland, 2007). But the black students were just as capable as the white students at learning new words, either from dictionary definitions or from their use in sentences. When verbal comprehension, similarities, and analogies test items depended on words and concepts that the white students knew better, the whites scored higher than the blacks. But when the same types of items involved words and concepts that the two groups knew equally well, the two groups did not differ. Prior knowledge, not reasoning ability, fully explained ethnic differences in performance.

Even nonverbal test items, such as spatial reasoning, depend on learning opportunities. For example, using small blocks to duplicate designs and playing video games requiring fast responding and mental rotation of visual images increase success on spatial test items (Dirks, 1982; Maynard, Subrahmanyam, & Greenfield, 2005). Low-income minority children, who often grow up in more "people-oriented" than "object-oriented" homes, may lack opportunities to use games and objects that promote certain intellectual skills.

Furthermore, the sheer amount of time a child spends in school predicts IQ. When children of the same age who are in different grades are compared, those who have been in school longer score higher on intelligence tests. Similarly, the earlier young people leave school, the greater their loss of IQ points (Ceci, 1991, 1999). Taken together, these findings indicate that children's exposure to the knowledge and ways of thinking valued in classrooms has a sizable impact on their intelligence test performance.

© LAURA DWIGHT PHOTOGRAPHY

When same-age children are compared, those who have spent more time in school have higher IQs—evidence that exposure to the knowledge and ways of thinking valued in classrooms improves mental test performance.

Stereotypes **TAKE A MOMENT...** Imagine trying to succeed at an activity when the prevailing attitude is that members of your group are incompetent. What might you be feeling and saying to yourself? **Stereotype threat**—the fear of being judged on the basis of a negative stereotype—can trigger anxiety that interferes with performance. Mounting evidence confirms that stereotype threat undermines test taking in children and adults (McKown & Strambler, 2009; Steele, 1997). For example, researchers gave African-American, Hispanic-American, and Caucasian-American 6- to 10-year-olds verbal tasks. Some children were told that the tasks were "not a test." Others were told that they were "a test of how good children are at school problems"—a statement designed to induce stereotype threat in the ethnic minority children. Among children who were aware of ethnic stereotypes (such as "black people aren't smart"), African Americans and Hispanics performed far worse in the "test" condition than in the "not a test" condition. Caucasian children, in contrast, performed similarly in both conditions (see Figure 8.10) (McKown & Weinstein, 2003). The researchers concluded that only under the "not a test" instructions did the minority children do as well as would have been expected on the basis of a prior measure of their verbal ability.

Over middle childhood, children become increasingly conscious of ethnic stereotypes, and those from stigmatized groups are especially mindful of them. By early adolescence, many low-SES, minority students start to devalue doing well in school, saying it is not important to them (Cooper & Huh, 2008; Major et al., 1998). Self-protective disengagement, sparked by stereotype threat, may be responsible. This weakening of motivation can have serious long-term consequences. Research shows that self-discipline—effort and delay of gratification—predicts school performance at least as well as IQ does—and sometimes better (Duckworth & Seligman, 2005).

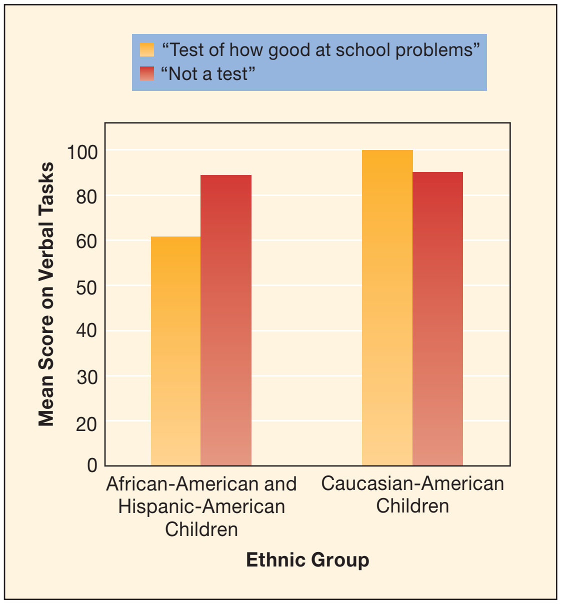

FIGURE 8.10 Effect of stereotype threat on performance. Among African-American and Hispanic-American children who were aware of ethnic stereotypes, being told that verbal tasks were a "test of how good children are at school problems" led to far worse performance than being told the tasks "were not a test." These statements had little impact on the performance of Caucasian-American children. (Adapted from McKown & Weinstein, 2003.)

© LAURA DWIGHT PHOTOGRAPHY

By tailoring teaching to students' individual needs, dynamic assessment reveals what a child can learn with social support.

Reducing Cultural Bias in Testing

Although not all experts agree, many acknowledge that IQ scores can underestimate the intelligence of children from ethnic minority groups. A special concern exists about incorrectly labeling minority children as slow learners and assigning them to remedial classes, which are far less stimulating than regular school experiences. Because of this danger, test scores need to be combined with assessments of children's adaptive behavior—their ability to cope with the demands of their everyday environments. The child who does poorly on an IQ test yet plays a complex game on the playground or figures out how to rewire a broken TV is unlikely to be mentally deficient.

In addition, culturally relevant testing procedures enhance minority children's performance. In an approach called **dynamic assessment,** an innovation consistent with Vygotsky's *zone of proximal development,* the adult introduces purposeful teaching into the testing situation to find out what the child can attain with social support (Lidz, 2001; Sternberg & Grigorenko, 2002). Dynamic assessment often follows a pretest–intervene–retest procedure. While intervening, the adult seeks the teaching style best suited to the child and communicates strategies that the child can apply in new situations.

Research shows that "static" assessments, such as IQ scores, frequently underestimate how well children do on test items after receiving adult assistance. Children's receptivity to teaching and their capacity to transfer what they have learned to novel problems add considerably to the prediction of future performance (Haywood & Lidz, 2007; Sternberg & Grigorenko, 2002; Tzuriel, 2001). In one study, Ethiopian 6- and 7-year-olds who had recently immigrated to Israel scored well below their Israeli-born agemates on spatial reasoning tasks. The Ethiopian children had little experience with this type of thinking. After several dynamic assessment sessions in which the adult suggested effective strategies, the Ethiopian children's scores rose sharply, nearly equaling those of Israeli-born children (see Figure 8.11). They also transferred their learning to new test items (Tzuriel & Kaufman, 1999).

Dynamic assessment is time-consuming and requires extensive knowledge of minority children's cultural values and practices. As yet the approach has not been more effective than traditional tests in predicting academic achievement (Grigorenko & Sternberg, 1998). Better correspondence may emerge in classrooms where teaching interactions resemble the dynamic testing approach—namely, individualized assistance on tasks carefully selected to help the child move beyond her current level of development.

But rather than adapting testing to support high-quality classroom learning experiences, U.S. education is placing greater emphasis on traditional test scores. To upgrade the academic achievement of poorly performing students, a *high-stakes testing* movement has arisen, making progress through the school system contingent on test performance. As the Social Issues: Education box on the following page indicates, this stepped-up emphasis on passing standardized tests has narrowed the focus of instruction in many classrooms to test preparation, and it may widen SES and ethnic group differences in educational attainment.

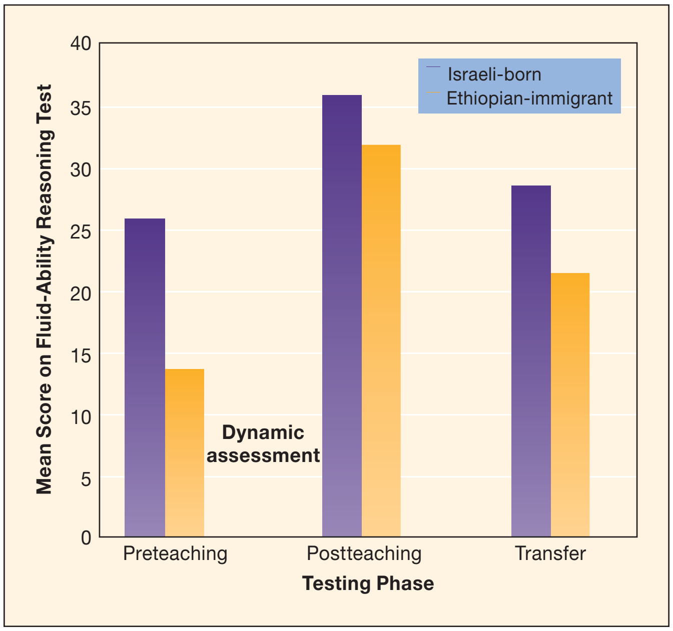

FIGURE 8.11 **Influence of dynamic assessment on mental test scores of Ethiopian-immigrant and Israeli-born 6- and 7-year-olds.** Each child completed test items in a preteaching phase, a postteaching phase, and a transfer phase, in which they had to generalize their learning to new problems. After dynamic assessment, Ethiopian and Israeli children's scores were nearly equal. Ethiopian children also transferred their learning to new test items, performing much better in the transfer phase than in the preteaching phase. (Adapted from Tzuriel & Kaufman, 1999.)

SOCIAL ISSUES: EDUCATION

High-Stakes Testing

To better hold schools accountable for educating students, during the past two decades many U.S. states have mandated that students pass exams for high school graduation. Currently, about two-thirds of public high school students take exit exams (Center on Education Policy, 2009). As these high-stakes achievement tests spread, schools stepped up their testing programs, extending them downward to elementary school. Some states and school districts also made grade promotion (in New York City, as early as the third grade) and secondary-school academic course credits contingent on test scores.

The U.S. No Child Left Behind Act broadens high-stakes testing to the identification of "passing" and "failing" schools. The law mandates that each state evaluate every public school's performance through annual achievement testing and publicize the results. Schools that consistently perform poorly (have a high percentage of failing students) must give parents options for upgrading their children's education, such as transfers to nearby higher-performing schools or enrollment in remedial classes. When they lose students, such schools also lose state and federal funds. Some states offer schoolwide rewards for high scores, including official praise and financial bonuses to school staff. Penalties imposed for low scores include staff firing, withdrawal of accreditation, state takeover, closure, or other restructuring.

Proponents of high-stakes testing believe that it introduces greater rigor into classroom teaching, improves student motivation and achievement, and either turns around poor-performing schools or protects students from being trapped in them. But accumulating evidence indicates that high-stakes testing often undermines, rather than upgrades, the quality of education.

Research shows that high-stakes tests cause teachers to spend large amounts of time on activities that closely resemble test items—typically, drill-based exercises. Classroom experiences and assignments that require high-level reasoning, including extended writing and research projects, are de-emphasized, as are subjects not covered on the tests (Jones & Egley, 2004; Ravitch, 2010). In a national survey of U.S. teachers, those in states with high-stakes tests reported that to "cover" the material likely to be tested, they felt pressured to move through the curriculum too quickly, yielding surface knowledge rather than in-depth understanding (Center on Education Policy, 2007).

© DAVID GROSSMAN/PHOTO RESEARCHERS, INC.

Classroom teaching narrowly focused on preparation for high-stakes tests leads to superficial learning and loss of interest. When low-income minority youths test poorly and are punished with course failure and grade retention, they are likely to drop out.

Because the main goal of high-stakes testing is to upgrade the performance of poorly achieving students, low-income and ethnic minority children are especially likely to be exposed to narrowly focused, regimented teaching (Darling-Hammond, 2010). Simultaneously, the educational needs of gifted and talented students are neglected (Scot, Callahan, & Urquhart, 2009).

An additional concern is that high-stakes testing promotes fear—a poor motivator for upgrading teaching and learning. Principals and teachers worry about losing funding and their jobs if students do poorly—punishments that have sparked unprecedented levels of adult cheating and other educationally detrimental behaviors. These range from giving students answers, changing students' scores, and offering students rewards (including money and expensive toys) for earning high scores to suspending or expelling students likely to perform poorly just before test administration (Nichols & Berliner, 2007).

Furthermore, many students who get passing school grades, even high grades, fail high-stakes exams because a time-limited test can tap only a small sampling of the skills covered in the classroom (Hursh, 2007). Students most likely to score poorly are minority youths living in poverty. When they are punished with course failure and grade retention, their self-esteem and motivation drop sharply. Research confirms that high-stakes testing requirements have contributed to the high dropout rates among U.S. inner-city minority youths (Balfanz et al., 2007).

The trend toward teaching to tests induced by high-stakes testing contrasts sharply with the emphasis on teaching for deeper understanding in countries that rank at the top in cross-cultural comparisons of academic achievement (see Chapter 15). Even after hundreds of hours of class time devoted to test preparation, thousands of U.S. students fail school-exit exams and do not graduate. Although most retake these exams, some fail repeatedly, with potentially dire consequences for the course of their lives.

Clearly, serious issues remain for lawmakers and educators to resolve about the use of high-stakes tests. These include their questionable power to spark school reforms that make students better learners.

In view of its many problems, should intelligence testing in schools be suspended? Most experts reject this solution. Without testing, important educational decisions would be based only on subjective impressions, perhaps increasing discriminatory placement of minority children. Intelligence tests are useful when interpreted carefully by psychologists and educators who are sensitive to cultural influences on test performance. And despite their limitations, IQ scores continue to be valid measures of school learning potential for the majority of Western children.

APPLYING WHAT WE KNOW

Features of a High-Quality Home Life in Infancy and Toddlerhood, Early Childhood, and Middle Childhood: The HOME Subscales

INFANCY AND TODDLERHOOD	EARLY CHILDHOOD	MIDDLE CHILDHOOD
Emotional and verbal responsiveness of the parent	Cognitive stimulation through toys, games, and reading material	Parental emotional and verbal responsiveness
Parental acceptance of the child	Language stimulation	Emotionally positive parent–child relationship
Organization of the physical environment	Organization of the physical environment	Parental encouragement of social maturity
Provision of appropriate play materials	Emotional support: parental pride, affection, and warmth	Provision for active stimulation
Parental involvement with the child	Stimulation of academic behavior	Growth-fostering materials and experiences
Opportunities for variety in daily stimulation	Parental modeling and encouragement of social maturity	Family participation in developmentally stimulating experiences
	Opportunities for variety in daily stimulation	Parental involvement in child rearing
	Avoidance of physical punishment	Physical environment: safe, clean, and conducive to development

Home Environment and Mental Development

As noted earlier, children of the *same* ethnic and SES background vary greatly in mental test scores. Many studies support the conclusion that factors in the home environment contribute to these differences.

Researchers divide home influences into two broad types: **Shared environmental influences** pervade the general atmosphere of the home and, therefore, *similarly* affect siblings living in it. Examples include the availability of stimulating toys and books and parental modeling of cognitively challenging activities. **Nonshared environmental influences** make siblings *different* from one another. Unique treatment by parents, birth order and spacing, and special events that affect one sibling more than the other (such as moving to a new neighborhood) are examples.

Shared Environmental Influences

Two types of research shed light on the role of shared environmental influences: (1) studies in which researchers observe home environmental qualities and relate them to IQ; and (2) studies examining the impact of family beliefs about intellectual success on student performance.

Observations of Home Environmental Qualities. The **Home Observation for Measurement of the Environment (HOME)** is a checklist for gathering information about the quality of children's home lives through observation and parental interview (Caldwell & Bradley, 1994). Refer to Applying What We Know above for factors that HOME measures in infancy and toddlerhood, early childhood, and middle childhood.

Evidence on HOME confirms the findings of decades of research—that stimulation provided by parents is moderately linked to mental development. Regardless of SES and ethnicity, an organized, stimulating physical setting and parental encouragement, involvement, and affection repeatedly predict better language and IQ scores in toddlerhood and early childhood (Berger, Paxson, & Waldfogel, 2009; Foster et al., 2005; Fuligni, Han, & Brooks-Gunn, 2004; Klebanov et al., 1998; Linver, Martin, & Brooks-Gunn, 2004; Mistry et al., 2008). In a study in which researchers controlled for both SES and home environmental quality, the black–white disparity in preschoolers' IQ diminished to just a few points (Smith, Duncan, & Lee, 2003).

The extent to which parents talk to infants and toddlers contributes strongly to early language progress, which, in turn, predicts intelligence and academic achievement in elementary school (Hart & Risley, 1995). Recall from Chapter 7 that knowledge of the sound structure of language (phonological awareness), vocabulary and grammatical development, and wide-ranging general knowledge are vital for learning to read.

The HOME–IQ relationship declines in middle childhood, perhaps because older children spend increasing amounts of time in school and other out-of-home settings (Luster & Dubow, 1992). Nevertheless, two middle-childhood HOME scales are especially strong predictors of academic achievement: provision for active stimulation (for example, encouraging hobbies and organizational memberships) and family participation in developmentally stimulating experiences (visiting friends, attending theater performances) (Bradley, Caldwell, & Rock, 1988).

Yet we must interpret these correlational findings cautiously. In all the studies, children were reared by their biological parents, with whom they share not just a common environment but also a common heredity. Parents who are genetically more intelligent may provide better experiences as well as give birth to genetically brighter children, who evoke more stimulation from their parents. Research supports this hypothesis, which refers to *genetic–environmental correlation* (see Chapter 3, page 122). The HOME–IQ correlation is stronger for biological than for adopted children, suggesting that parent–child genetic similarity elevates the relationship (Saudino & Plomin, 1997).

But heredity does not account for the entire association between home environment and mental test scores. Family living conditions—both HOME scores and resources in the surrounding neighborhood—continue to predict children's IQ beyond the contribution of parental IQ and education (Chase-Lansdale et al., 1997; Klebanov et al., 1998). These findings highlight the vital importance of environmental quality.

Family Beliefs About Intellectual Success. Regardless of SES, newly arrived immigrant parents from Asia and Latin America emphasize the importance of intellectual success, and their children do remarkably well in school. (Return to the Cultural Influences box on page 53 in Chapter 2 to review these findings.) Parental support for achievement is greater in higher-SES families in which both parent and child IQs are higher, making it difficult to isolate the impact of family beliefs on children's performance. Is IQ responsible for immigrant families' high valuing of intellectual endeavors and their children's superior academic performance? Probably not; recent arrivals are unlikely to be more intelligent than American–born children whose parents arrived a decade or two earlier. Rather, immigrant parents' belief that education is the surest way to improve life chances seems to play a profound role (Cooper, Dominguez, & Rosas, 2005; Fuligni & Yoshikawa, 2003).

Parental beliefs are also linked to academic performance among nonimmigrant children. In a study of more than 1,300 U.S. Caucasian- and African-American families with school-age children, parental expectations for educational attainment predicted parents' involvement

© MICHAEL NEWMAN/PHOTOEDIT

A Mexican-American mother looks over examples of her third grader's assignments at a parent–teacher conference. Parents who highly value education are more involved in their children's school life, which is associated with higher achievement.

in their children's school activities, supervision of homework, and—two years later—children's reading and math achievement (Zhan, 2005). Similarly, an investigation of Asian-American, Hispanic, and Caucasian-American families revealed that within each group, the more education parents expected their fourth and fifth graders to attain, the higher the children's school grades (Okagaki & Frensch, 1998). Parental expectations were not merely responsive to their child's prior achievements. Rather, regardless of children's grades the previous year, parental beliefs predicted school performance.

Think back to James's father's conviction that academic success could transform James's life path, described in the opening to this chapter. Warm, appropriately demanding child rearing, cognitively stimulating parent–child activities, and parents' school involvement seem to be the major means through which parents convey such beliefs to their children (Davis-Kean, 2005; Okagaki, 2001). We will consider parenting and achievement further in Chapters 11 and 14.

Nonshared Environmental Influences The experiences of children growing up in the same family, while similar in some ways, differ in others. Parents may favor one child or assign children special roles—for example, one expected to achieve in school, a second to get along with others. Each child also experiences sibling relationships differently.

Kinship research suggests that nonshared environmental factors are more powerful than shared influences on IQ. Turn back to Figure 8.6 on page 335. Notice the relatively low IQ correlations between unrelated siblings living together—a direct estimate of the effect of shared environment. Recall, also, that in adolescence the IQ resemblance between fraternal twins declines (see page 336). This trend, which also characterizes nontwin siblings, is particularly marked for unrelated siblings, whose IQs at adolescence are no longer correlated. These findings indicate that the impact of the shared environment on IQ is greatest in childhood (Finkel & Pedersen, 2001; Loehlin, Horn, & Willerman, 1997). Thereafter, it gives way to nonshared influences, as young people spend more time outside the home, encounter experiences unlike those of their siblings, and seek environments consistent with their genetic makeup.

Nevertheless, few studies have examined nonshared environmental influences on IQ. The most extensively studied factors are sibling birth order and spacing. For years, researchers thought that earlier birth order and wider spacing might grant children more parental attention and stimulation and, therefore, result in higher IQs. But recent evidence indicates that birth order and spacing are unrelated to IQ (Rodgers, 2001; Rodgers et al., 2000; Wichman, Rodgers, & MacCallum, 2006). Why is this so? Parents' differential treatment of siblings appears to be far more responsive to children's personalities, interests, and behaviors than to these family-structure variables.

Finally, some researchers believe that the most potent nonshared environmental influences are unpredictable, unique events—an inspiring English teacher, a summer at a special camp, or perhaps a period of intense sibling rivalry (McCall, 1993). To understand the role of these nonshared factors in mental development, we need intensive case studies of children growing up in the same family.

LOOK and LISTEN

Ask several parents to describe a unique event, such as an inspiring teacher or a special experience, that seemed to boost their child's school performance. Then ask the children for their views of these nonshared influences.

ASK YOURSELF

Review ■ Why can't heritability estimates explain ethnic differences in IQ? Using research findings, describe environmental factors that contribute to these differences.

Connect ■ Explain how dynamic assessment is consistent with Vygotsky's zone of proximal development and with scaffolding (see Chapter 6, pages 267–268).

Apply ■ Josefina, a Hispanic fourth grader, does well on homework assignments. But when her teacher announces, "It's time for a test to see how much you've learned," Josefina usually does poorly. How might stereotype threat explain this inconsistency?

Reflect ■ Do you think that intelligence tests are culturally biased? What evidence and observations influenced your conclusions?

Early Intervention and Intellectual Development

▶ Discuss the impact of early intervention on intellectual development.

In the 1960s, as part of the "War on Poverty" in the United States, many intervention programs for economically disadvantaged preschoolers were initiated. Their goal was to offset the declines in IQ and achievement common among low-SES schoolchildren by addressing learning problems early, before formal schooling begins. The most extensive of these federal programs, **Project Head Start,** began in 1965. A typical Head Start center provides children with a year or two of preschool, along with nutritional and health services. Parent involvement is central to the Head Start philosophy. Parents serve on policy councils, contribute to program planning, work directly with children in classrooms, attend special programs on parenting and child development, and receive services directed at their own emotional, social, and vocational needs. Currently, Head Start serves about 904,000 children and their families across the nation (Head Start, 2010).

Benefits of Early Intervention

More than two decades of research have established the long-term benefits of early intervention. The most extensive of these studies combined data from seven interventions implemented by universities or research foundations. Results showed that poverty-stricken children who attended programs scored higher in IQ and achievement than controls during the first two to three years of elementary school. After that, differences declined (Lazar & Darlington, 1982). But on real-life measures of school adjustment, children and adolescents who had received intervention remained ahead. They were less likely to be placed in special education or retained in grade, and a greater number graduated from high school. They also showed lasting benefits in attitudes and motivation: They were more likely to give achievement-related reasons (such as school or job accomplishments) for being proud of themselves.

A separate report on one program, the High/Scope Perry Preschool Project, revealed benefits lasting well into adulthood. More than 100 African-American 3- and 4-year-olds were randomly assigned either to a cognitively enriching two-year preschool program or to no intervention. During weekly visits to the homes of the intervention group, teachers showed parents how to teach and read to their children. Besides improved school adjustment, preschool intervention was associated with increased employment and reduced pregnancy and delinquency rates in adolescence. At age 27, those who had attended preschool were more likely to have graduated from high school, to have enrolled in college, to have higher earnings, be married, and own their own home—and less likely to have ever been diagnosed as mentally impaired or to be on welfare or involved with the criminal justice system (see Figure 8.12 on page 348). The most recent follow-up, at age 40, revealed that the intervention group sustained its advantage on all measures of life success, including education, income, family life, and law-abiding behavior (Schweinhart, 2010; Schweinhart et al., 2005).

Do the effects on school adjustment of these well-designed and well-delivered interventions generalize to Head Start and other community-based preschool interventions? Gains are similar, though not as strong. Head Start preschoolers, who are more economically disadvantaged than children in other programs, have more severe learning and behavior problems. And quality of services in

© LAURA DWIGHT PHOTOGRAPHY

For these preschoolers, the benefits of early intervention are likely to include lasting advantages on real-life measures of school adjustment, including attitudes and motivation.

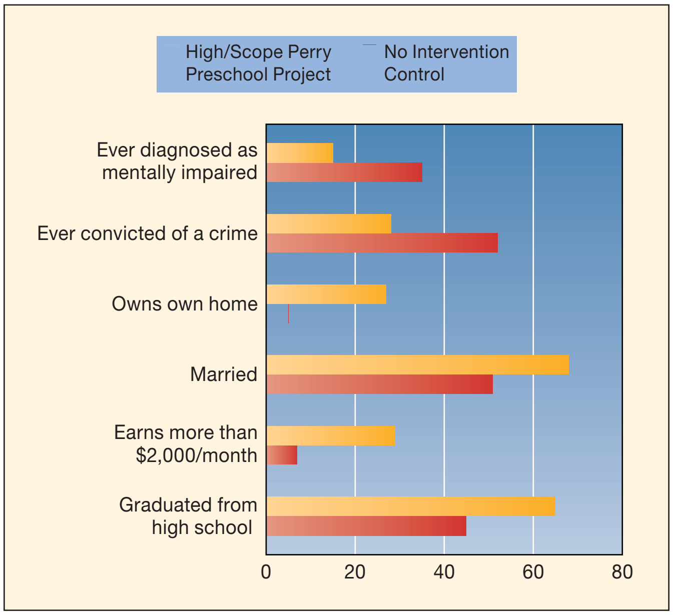

FIGURE 8.12 **Some outcomes of the High/Scope Perry Preschool Project on follow-up at age 27.** Although two years of a cognitively enriching preschool program did not eradicate the effects of growing up in poverty, children who received intervention were advantaged over no-intervention controls on all measures of life success when they reached adulthood. (Adapted from Schweinhart et al., 2005; Schweinhart, 2010.)

Head Start—though better than in most preschool education programs serving low-SES children—often does not equal that of model university-based programs (Resnick, 2010; U.S. Department of Health and Human Services, 2010e). But interventions of documented high quality are associated with diverse, long-lasting favorable outcomes, including higher rates of high school graduation and college enrollment and lower rates of adolescent drug use and delinquency (Garces, Thomas, & Currie, 2002; Love et al., 2006; Mashburn, 2008).

A consistent finding is that gains in IQ and achievement test scores from attending Head Start and other interventions quickly dissolve. In the Head Start Impact Study, a nationally representative sample of 5,000 Head Start–eligible 3- and 4-year-olds was randomly assigned to one year of Head Start or to a control group that could attend other types of preschool programs (U.S. Department of Health and Human Services, 2010e). By year's end, Head Start 3-year-olds had gained relative to controls in vocabulary, emergent literacy, and math skills; 4-year-olds in vocabulary, emergent literacy, and color identification. Head Start 3-year-olds also benefitted socially, displaying declines in overactivity and withdrawn behavior. But except for language skills, academic test-score advantages were no longer evident by end of first grade.

What explains these disappointing outcomes? Head Start children typically enter inferior public schools in poverty-stricken neighborhoods, which undermine the benefits of preschool education (Brooks-Gunn, 2003; Ramey, Ramey, & Lanzi, 2006). But in the Chicago Child–Parent Centers—a program emphasizing literacy intervention and parent involvement that began at age 3 and continued through third grade—gains in academic achievement were still evident in junior high school (Reynolds & Temple, 1998).

Furthermore, when high-quality intervention starts in infancy and extends through early childhood, children display cognitive and academic achievement advantages throughout childhood and adolescence (Brooks-Gunn, 2004; Ramey, Ramey, & Lanzi, 2006). The Carolina Abecedarian Project illustrates these positive outcomes. In the 1970s, more than 100 infants from poverty-stricken families, ranging in age from 3 weeks to 3 months, were randomly assigned to either a treatment group or a control group. Treatment infants were enrolled in full-time, year-round child care through the preschool years. There they received stimulation aimed at promoting motor, cognitive, language, and social skills and, after age 3, literacy and math concepts. All children received nutrition and health services; the primary difference between treatment and controls was the intensive child-care experience.

As Figure 8.13 shows, by 12 months of age, the IQs of the two groups diverged. Treatment children sustained their lead until last tested—at age 21. In addition, throughout their years of schooling, treatment youths achieved considerably higher scores than controls in reading and math. These gains translated into more years of schooling completed, higher rates of college enrollment and employment in skilled jobs, and lower rates of drug use and adolescent parenthood (Campbell et al., 2001, 2002; Campbell & Ramey, 2010).

Recognition of the greater power of intervening as early as possible led the U.S. Congress to provide limited funding for services directed at infants and toddlers, who already

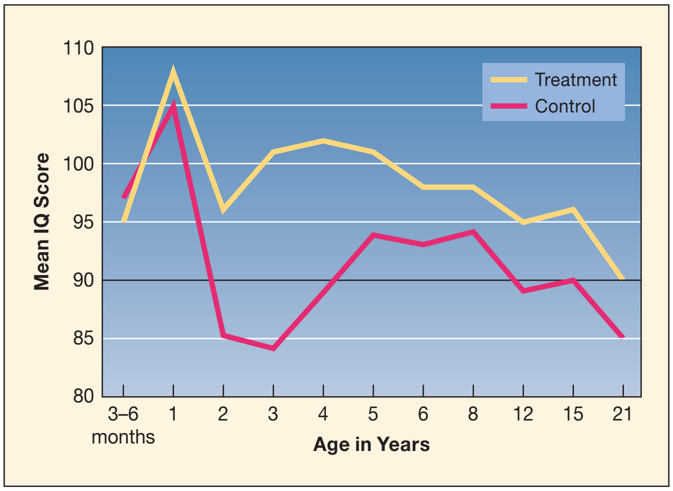

FIGURE 8.13 **IQ scores of treatment and control children from infancy to 21 years in the Carolina Abecedarian Project.** At 1 year, treatment children outperformed controls, an advantage consistently maintained through age 21. The IQ scores of both groups declined gradually during childhood and adolescence—a trend probably due to the damaging impact of poverty on mental development. (Adapted from Campbell et al., 2001.)

have serious developmental problems or who are at risk for problems because of poverty. **Early Head Start,** begun in 1995, currently has 700 sites serving 63,000 low-income families. It offers an array of coordinated services—child care, educational experiences for infants and toddlers, parenting education, family social support, and health care—delivered through a center-based, home-based, or mixed approach, depending on community needs. A recent evaluation, conducted when children reached age 3, showed that intervention led to warmer, more stimulating parenting, a reduction in harsh discipline, gains in cognitive and language development, and lessening of child aggression (Love et al., 2005; Love, Chazan-Cohen, & Raikes, 2007; Raikes et al., 2010). The strongest effects occurred at sites mixing center and home-visiting services—a combination that may intensify educational and family services.

Even when intervention is delayed until age 3 or 4, the improved school adjustment that results from attending a one- or two-year Head Start program is impressive. The comprehensiveness of Head Start—provision of health, nutrition, education, and family social services—along with its emphasis on parent involvement may be responsible. The more involved parents are in Head Start, the better their child-rearing practices and the more stimulating their home learning environments. These factors are positively related to preschoolers' independence and task persistence in the classroom and to their year-end academic, language, and social skills (Marcon, 1999b; McLoyd, Aikens, & Burton, 2006; Parker et al., 1999).

Strengthening Early Intervention

Excellent early intervention is highly cost effective when compared with the cost of providing special education, treating criminal behavior, and supporting unemployed adults. Economists estimate a lifetime return to society of $300,000 to $500,000 on an investment of about $17,000 per preschool child—a potential total savings of many billions of dollars if every poverty-stricken preschooler in the United States were enrolled (Heckman et al., 2010).

What factors contributed to the enduring impact of such outstanding programs as the High/Scope Perry Preschool Project, the Chicago Child–Parent Centers, and the Carolina Abecedarian Project? According to one analysis, they shared the following critical features:

- *Starting early.* The Abecedarian Program began in the first months of life, the High/Scope Perry Preschool Project and the Chicago Child–Parent Centers as early as age 3.
- *Employing well-educated, well-compensated teachers.* Most teachers in the three programs had at least a bachelor's degree in education, and they were paid competitively with public school teachers—factors resulting in low staff turnover and stability in teacher–child relationships.
- *Maintaining generous teacher–child ratios and small class sizes.* In the Abecedarian Program, the teacher–infant ratio was 1 to 3, the teacher–toddler ratio 1 to 4. Preschool ratios in the three programs ranged from 1 to 5 to 1 to 8.
- *Offering intensive intervention.* Each program included many hours of classroom contact with children in the early years—in the High/Scope Perry Preschool Project and Chicago Child–Parent Centers, full days for up to two school years; in the Abecedarian Project, full days, year-round, for five years.
- *Emphasizing parent involvement, education, and support.* The High/Scope Perry Preschool Project and the Chicago Child–Parent Centers made concerted efforts to involve parents in their children's learning.
- *Focusing on the whole child.* The three programs promoted all aspects of children's development—not just academic skills. They recognized that a child who is ill, hungry, weak in social skills, or suffering from emotional or behavior problems is unable to learn at his or her best.

In an Early Head Start classroom, mothers and toddlers gather for a picture-book reading session. The effects of intervention are more likely to endure when programs begin at very young ages and are intensive, involving many hours of child contact that extend through the early years.

© MICHAEL NEWMAN/PHOTOEDIT

To achieve lasting favorable results, designers of today's early intervention programs must include these key ingredients (Galinsky, 2006). Also, the number of children served must be greatly expanded. Unfortunately, because of limited funding, only 60 percent of poverty-stricken 3- and 4-year-olds attend some type of preschool program, with Head Start serving just half of these children (Magnuson & Shager, 2010). And many preschoolers whose parents' income just surpasses the Head Start income eligibility requirements also receive no intervention.

A few supplementary programs—such as Jumpstart, described at the beginning of this chapter—have responded to this shortage by delivering educational intervention to children in child-care centers, as well as strengthening intervention in Head Start and other preschool classrooms. Evaluations indicate that 3- to 5-year-olds who experience Jumpstart show greater year-end gains in language, literacy, task persistence, and social skills than non-Jumpstart children in the same Head Start or other early childhood settings (Harris & Berk, 2011; Jumpstart Evaluation Team, 2008). To find out about another highly successful supplementary intervention, see the Social Issues: Education box on the following page.

- Evaluate theories of creativity, and discuss ways to nurture creativity and talent.

Giftedness: Creativity and Talent

Throughout this chapter, we have seen that intelligence includes much more than mental abilities that predict success in school. Today, educators recognize that **gifted** children—those who display exceptional intellectual strengths—have diverse characteristics. Some have IQ scores above 130, the standard definition of giftedness based on intelligence test performance (Gardner, 1998b). High-IQ children, as we have seen, have keen memories and an exceptional capacity to solve challenging academic problems. Yet recognition that intelligence tests do not sample the entire range of human mental skills has led to an expanded conception of giftedness, which includes creativity.

Creativity is the ability to produce work that is *original* yet *appropriate*—something that others have not thought of but that is useful in some way (Kaufman & Sternberg, 2007; Sternberg, 2003b). Judgments of creativity reflect not only the uniqueness and quality of the product but also the process of arriving at it. Rather than following established rules, a creative work pulls together previously disparate ideas. Typically, it also involves hard work and the need to overcome obstacles on the way to the final product.

In addition to its value on the job and in daily life, creativity is vital for societal progress. Without it, there would be no new inventions, scientific findings, movements in art, or social programs. Therefore, understanding its ingredients and nurturing them from childhood are of paramount importance. As we will see in the following sections, ideas about creativity have changed radically during the past two decades.

The Psychometric View

Until recently, a purely cognitive perspective dominated research on creativity. Commonly used tests tapped **divergent thinking**—the generation of multiple and unusual possibilities when faced with a task or problem. Divergent thinking contrasts with **convergent thinking,** which involves arriving at a single correct answer and is emphasized on intelligence tests (Guilford, 1985).

Because highly creative children (like high-IQ children) are often better at some types of tasks than others, a variety of tests of divergent thinking are available (Runco, 1992a, 1993; Torrance, 1988). A verbal measure might ask children to name uses for common objects (such as a newspaper). A figural measure might ask them to come up with drawings based on a circular motif (see Figure 8.15 on page 352). A "real-world problem" measure requires students to suggest solutions to everyday problems. Responses to all these tests can be scored for the number of ideas generated and their originality. For example, on a verbal test, saying that a newspaper can be used "as handgrips for a bicycle" would be more original than saying it can be used "to clean things."

SOCIAL ISSUES: EDUCATION

The Head Start REDI Program: Strengthening School Readiness in Economically Disadvantaged Preschoolers

Preschoolers attending Head Start reap cognitive and social benefits, but gains are limited and dissipate over time. Most children from economically disadvantaged families enter kindergarten behind national norms in knowledge and skills essential for school success. Head Start programs typically have far fewer classroom resources than the model programs that have yielded stronger outcomes. And Head Start lead teachers—nearly 20 percent of whom have neither an associate's nor a bachelor's degree and only 40 percent of whom have state teaching certificates—are often not prepared to handle the developmental delays and problems of children in their classrooms (Hulsey et al., 2010).

Responding to these quality concerns, the Head Start REDI (Research-based Developmentally Informed) program is an enrichment curriculum designed to be integrated into existing Head Start classroom learning activities. Before school begins, Head Start teachers participate in workshops where they learn research-based strategies for enhancing language, literacy, and social skills known to predict school success. Then, throughout the school year, they receive several hours per week of one-to-one mentoring from master teachers, who model, coach, and provide ongoing feedback to ensure that they implement REDI effectively.

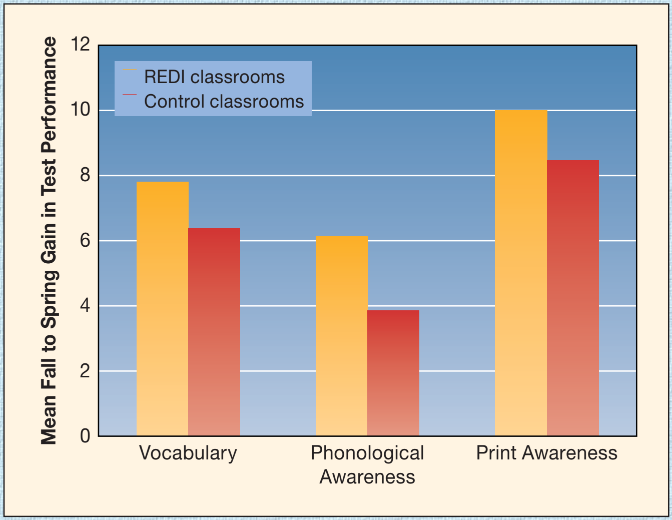

FIGURE 8.14 Fall to spring gains in language and emergent literacy skills in Head Start REDI and control classrooms. Head Start children receiving the REDI supplementary intervention exceeded children in typical Head Start classrooms in vocabulary, phonological awareness, and print awareness. Phonological awareness gains consist of two skills: combining parts of words, such as "b" and "air" (bear); and dividing compound words—for example, saying "snowshoe" without "snow." Print awareness gains involved identifying written letters of the alphabet. (Adapted from Bierman et al., 2008.)

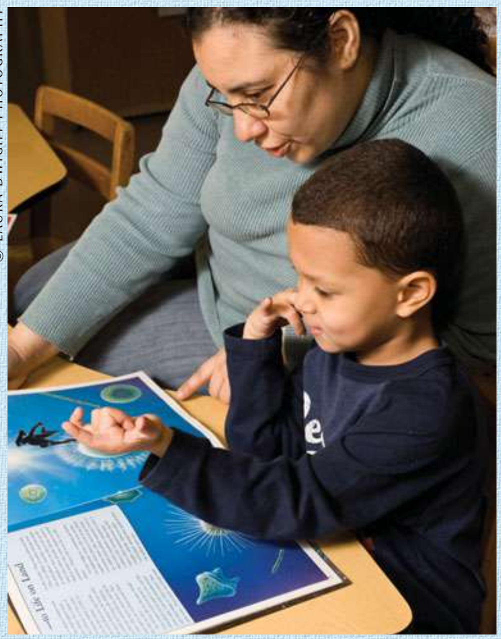
To foster language and emergent literacy, REDI emphasizes interactive reading. Teachers discuss two books per week with children, reinforcing new vocabulary words with pictures and other props and scaffolding children's conversation to increase the complexity of their oral language. Language sound games promote phonological awareness, and alphabet-letter learning is encouraged through specially designed materials in learning centers. (Return to Chapter 7, page 308, for evidence on the effectiveness of these techniques for advancing young children's emergent literacy skills.)



© LAURA DWIGHT PHOTOGRAPHY

A teacher trained in Head Start REDI strategies engages in interactive reading with a preschooler. The REDI program has succeeded in strengthening the impact of Head Start on children's school readiness.

In the social domain, REDI focuses on skills that enable children to participate fully in classroom social life: helping, sharing, taking turns, and resolving conflicts, which build rewarding teacher and peer relationships. REDI also includes experiences that help children focus attention, inhibit impulsive behavior, and organize their goal-directed activities—skills that predict academic achievement throughout elementary and high school (Blair & Razza, 2007; Duncan et al., 2007). For lessons in social skills, teachers use puppet characters and role-play demonstrations, and they provide children with opportunities to practice social skills in cooperative projects and games.

REDI is remarkably successful at strengthening Head Start children's school readiness. In a field experiment in which 44 Head Start classrooms were randomly assigned to either REDI or usual classroom practice, the REDI children made greater year-end gains in language and emergent literacy skills (see Figure 8.14) (Bierman et al., 2008). REDI children were also advantaged in social skills, including accurately recognizing other's emotions, resolving peer conflicts, inhibiting aggressive behavior, and actively engaging in learning activities.

In sum, REDI strengthens the immediate impact of Head Start—positive effects that are likely due to REDI's impact on teaching quality. End-of-year observations revealed that in Head Start REDI classrooms, compared with typical Head Start classrooms, teachers talked with children more often and in more cognitively complex ways, established a more positive classroom climate, and more often used management strategies that prevented disruptive behavior (Domitrovich et al., 2009).

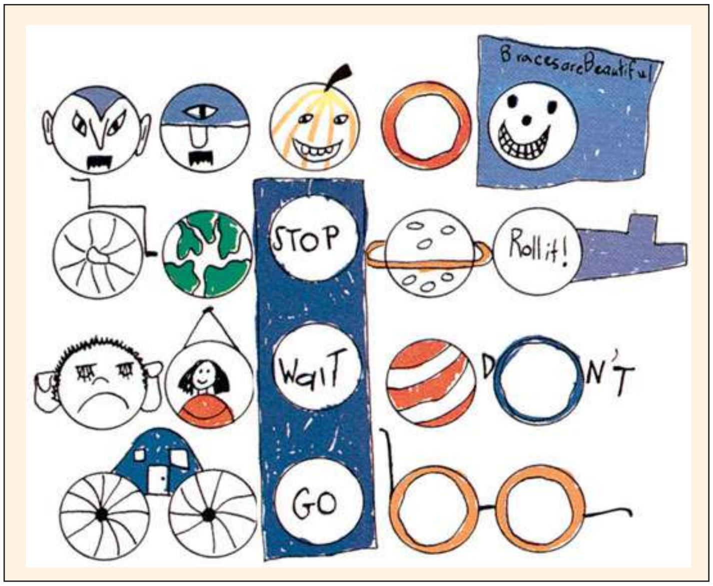


FIGURE 8.15 **Responses of an 8-year-old who scored high on a figural measure of divergent thinking.** This child was asked to make as many pictures as she could from the circles on the page. The titles she gave her drawings, from left to right, are as follows: "Dracula," "one-eyed monster," "pumpkin," "Hula-Hoop," "poster," "wheelchair," "earth," "stop-light," "moon," "planet," "movie camera," "sad face," "picture," "beach ball," "the letter *O*," "car," "glasses." Tests of divergent thinking tap only one of the complex cognitive contributions to creativity. (Reprinted by permission of Laura E. Berk.)

Tests of divergent thinking are known as the *psychometric approach to creativity* because they permit scores to be compared to the performance of standardization samples. Yet critics note that these measures are poor predictors of creative accomplishment in everyday life because they tap only one of the complex cognitive contributions to creativity (Plucker & Makel, 2010). And they say nothing about personality traits, motivation, and environmental circumstances that foster creative potential. Still, divergent-thinking tests do tap relevant skills, have been the major focus of research on creativity in children, and (as we will see shortly) have enhanced our understanding of the development of creativity.

A Multifaceted View

Recent theories agree that many elements must converge for creativity to occur (Kozbelt, Beghetto, & Runco, 2010; Renzulli, 2006). One influential multifaceted approach is Robert Sternberg and Todd Lubart's (1991, 1996) **investment theory of creativity.** According to Sternberg and Lubart, pursuing a novel project (one not being tackled by others) increases the chances of arriving at a creative, highly valued product. But whether a person invests in novelty—initiates an original project and brings it to fruition—depends on that person's cognitive, personality, motivational, and environmental resources, summarized in Table 8.2. Each must be present to catalyze creativity, although strength in one (such as perseverance) can compensate for weakness in another (an environment that is lukewarm toward novel ideas).

Contrary to popular belief, creativity is neither determined at birth nor the prized possession of an elite few. Many people can develop it to varying degrees, and it is likely to reach greater heights when nurtured from an early age. Let's look at the components of creativity and how to strengthen them in children.

Cognitive Resources

Creative work brings together a variety of high-level cognitive skills. It requires *problem finding*—detecting a gap in current knowledge, a need for a new product, or a deficiency in existing procedures. Once a problem is found, *the ability to define it*—to move it from a vague to a clearly specified state—becomes important. In both children and adults, the more effort devoted to defining the problem, the more original the final product (Runco & Okuda, 1988; Sternberg, 2003b).

TABLE 8.2 **Resources Necessary for Creativity**

COGNITIVE	PERSONALITY	MOTIVATIONAL AND ENVIRONMENTAL
Problem finding	Innovative style of thinking	Settings rich in stimulation
Divergent thinking	Curiosity	Emphasis on intellectual curiosity
Convergent thinking: evaluating competing ideas	Willingness to take intellectual risks	Systematic teaching that builds talent
Insight	Tolerance of ambiguity	Availability of time to reflect on ideas
Knowledge	Courage of one's convictions	Encouragement of original ideas and evaluation of those ideas
		Emphasis on intrinsic motivation

Days Left
World Turtle Day!!

As sixth graders rehearse a play that they have written, they gain experience with diverse cognitive resources that contribute to creativity, including problem finding, insight processes, and evaluating competing ideas.

Divergent thinking is essential for generating novel solutions to problems. But the successful creator must also choose the best responses, setting aside fruitless options. Therefore, creativity involves *alternating between divergent and convergent thinking* (Guignard & Lubart, 2006). In narrowing the range of possibilities, creative individuals rely on *insight processes*—combining and restructuring elements in sudden but useful ways. For example, the use of analogies and metaphors to identify unique connections is common among people who have made outstanding creative contributions (Barron, 1988). At an early age, children engage in this kind of thinking (see Chapter 6, page 246, and Chapter 9, page 380). Furthermore, *evaluating competing ideas* to select the most promising is vital. School-age children's evaluative ability can be enhanced by instructions to critically assess the originality of ideas (Runco, 1992b).

Finally, extensive *knowledge* is necessary to make a creative contribution to any field (Lubart, Georgsdottir, & Besançon, 2009). Without it, people cannot recognize or understand new ideas. Consider this cognitive ingredient, and you will see why high creativity is usually manifested as **talent**—outstanding performance in one or a few related fields. Case studies reveal that excellence in such endeavors as creative writing, mathematics, science, music, visual arts, athletics, and leadership have roots in specialized interests and skills that appear in childhood (Moran & Gardner, 2006). And research supports the *10-year-rule* in development of master-level creativity—a decade between initial exposure to a field and sufficient expertise to produce a creative work (Simonton, 2000). Furthermore, IQ and creativity correlate only modestly, typically around .20 to .40 (Lubart, 2003). Beyond an above-average general intelligence, other factors are necessary for creative giftedness.

Personality Resources Certain personality characteristics foster the cognitive components of creativity, ensuring that they are applied to best advantage:

- *Innovative style of thinking.* Creative individuals not only see things in new ways but also enjoy doing so. They prefer loosely structured activities involving innovative problem finding rather than already defined tasks.
- *Perseverance and tolerance of ambiguity.* Working toward creative goals brings periods when pieces of the problem do not fit together—prompting many children and adults to give up or pursue the first (but not the best) solution. Creativity requires patience and persistence in the face of obstacles.
- *Willingness to take risks.* Creativity requires a willingness to deviate from the crowd, to undertake challenges when outcomes are uncertain.
- *The courage of one's convictions.* Because their ideas are novel, creators may at times doubt them, especially when criticized by skeptical teachers or peers. People who think creatively often encounter resistance, ranging from puzzlement to hostility. Creative endeavors require independence of judgment and high self-esteem (Sternberg & Lubart, 1996).

Motivational Resources Motivation for creativity must be *task-focused* rather than *goal-focused.* Task-focusing motivators, such as the desire to meet a high standard, energize work and keep attention on the problem. Goal-focusing motivators, in contrast, often impair performance by diverting attention from the task to extrinsic rewards such as grades and prizes. In one study, 7- to 11-year-old girls worked on collages, some competing for prizes and others expecting that the prizes would be raffled off. The products of those in the first group were much less creative (Amabile, 1982).

Extrinsic rewards are not always detrimental to creativity. Teaching children how to engage in divergent thinking on a task and rewarding them for original responses increases the frequency of those responses (Collins & Amabile, 1999). And an occasional reward for a creative product can underscore the social value of creativity and encourage children to embark on innovative projects. But when rewards are overemphasized, children focus only on these goals, and creativity suffers.

© ST. PETERSBURG TIMES/CHERIE DIEZ/THE IMAGE WORKS

This 14-year-old attends a middle school with specialized courses in the performing arts. She benefits from opportunities to work with master teachers and to interact with peers who share her passion for dance.

Environmental Resources Studies of the backgrounds of talented children and highly accomplished adults often reveal a family life focused on the child's needs—warm, sensitive parents who provide a stimulating home life, are devoted to developing their child's abilities, and provide models of hard work and high achievement. These parents are reasonably demanding but not driving or overambitious (Winner, 2000, 2003). They arrange for caring teachers while the child is young and for more rigorous master teachers as the child's talent develops.

Many gifted children and adolescents are socially isolated, partly because their highly driven, nonconforming, and independent styles leave them out of step with peers and partly because they enjoy solitude, which is necessary to develop their talents. Still, gifted children desire gratifying peer relationships, and some—more often girls than boys—try to become better-liked by hiding their abilities. Compared with their ordinary agemates, gifted youths, especially girls, report more emotional and social difficulties, including low self-esteem and depression (Reis, 2004).

Classrooms in which gifted youths can interact with like-minded peers, choose topics for extended projects, take intellectual risks, and reflect on ideas without being rushed to the next assignment foster creativity (Besançon & Lubart, 2008). In classrooms where knowledge acquisition is stressed over using knowledge originally, children's thinking tends to become *entrenched*—limited to commonplace associations that produce correct answers. Talented students, when not sufficiently challenged, sometimes lose their drive to excel. But when pushed too hard by parents or teachers, by adolescence these students are likely to ask, "Why am I doing this?" If the answer is not "Because it interests me," they may decide not to pursue their gift (Winner, 2000, p. 166).

Refer to Applying What We Know on the following page for ways that parents and teachers can promote children's creativity. Although many schools offer programs for the gifted, debate about their effectiveness typically focuses on factors irrelevant to creativity—whether to offer enrichment in regular classrooms, pull children out for special instruction (the most common practice), or advance brighter pupils to a higher grade. Overall, gifted children fare well within each of these models, as long as the special activities foster the ingredients of creative thought (Guignard & Lubart, 2007).

LOOK and LISTEN

Interview an elementary school teacher about his or her teaching practices aimed at fostering children's creativity. In the teacher's view, what contemporary societal and school policies promote and/or impede educational efforts to enhance children's creativity?

Some societies focus so narrowly on high academic achievement as an index of success that they dampen the development of creativity. The collectivism characteristic of Asian cultures often leads teachers to emphasize mastery of knowledge and analytical skills over generating new ideas, which requires students to stand out from the crowd. In one study, Chinese college students' artwork was judged less creative than that of U.S. students by experts from both countries (Niu & Sternberg, 2001). In interventions aimed at promoting creative expression in high school art classes in Beijing, students were asked to make collages. One group received a general instruction to be creative, a second group specific instructions in *how* to be creative ("fold or tear materials so their shapes and sizes do not limit creative expression"), and a control group no creativity instructions. Students in the two creative conditions generated products that were more creative than those produced by students in the control group, with the specific-instruction group performing best (Niu & Sternberg, 2003). A brief prompt—especially, guidance in how to take a creative approach—readily enhanced artistic originality.

Gardner's theory of multiple intelligences has inspired several model school programs that provide enrichment to all students in diverse disciplines, so any child capable of high-level, creative performance can manifest it. Meaningful activities, each tapping a specific intelligence or set of intelligences, serve as contexts for assessing strengths and weaknesses

APPLYING WHAT WE KNOW

Promoting Children's Creativity

SUGGESTION	DESCRIPTION
Encourage idea generation and evaluation.	Offer opportunities for divergent thinking and praise it, even when some ideas are silly or irrelevant. Then engage children in constructive criticism: When an idea has little value, suggest new approaches that include aspects of the child's idea, thereby demonstrating that most ideas must be refined to be useful.
Encourage sensible risk taking.	Provide assignments and activities that include choices and that have more than one acceptable answer. Avoid praising children mainly for high test scores or papers based on one right answer, which may lead them to avoid new ways of thinking.
Encourage tolerance of ambiguity.	Point out that creative individuals often feel unsure of whether they are on the right track. Encourage children to accept these feelings and to spend time working through uncertainty. Emphasize that doing so will result in better ideas.
Help children believe in their ability to be creative.	Remind children that the value of a creative idea does not depend on teachers' or classmates' approval but, rather, on the idea's originality and usefulness.
Help children find what they love to do.	Encourage children to explore new fields rather than just accepting interests that you value. To help them uncover their true interests, ask each child to demonstrate an ability or talent for the class, and point out the diversity of worthwhile interests.
Model creative thinking.	Balance teaching knowledge with teaching how to think about that knowledge. Help children reason across subjects, pointing out that creative insights often result from integrating material across fields, not from memorizing information.

Source: Sternberg, 2003b.

and, on that basis, teaching new knowledge and original thinking (Gardner, 2000; Hoerr, 2004). For example, linguistic intelligence might be fostered through storytelling or playwriting; spatial intelligence through drawing, sculpting, or taking apart and reassembling objects; and kinesthetic intelligence through dance or pantomime.

Evidence is still needed on how well these programs nurture children's talents and creativity. But they have already succeeded in one way—by highlighting the strengths of some students who previously had been considered unexceptional or even at risk for school failure (Kornhaber, 2004). Consequently, they may be especially useful in identifying talented low-SES, ethnic minority children, who are often underrepresented in school programs for the gifted (McBee, 2006). How best to maximize the creative resources of the coming generation—the future poet and scientist as well as the everyday citizen—is a challenge for future research.

ASK YOURSELF

Review ■ Summarize the benefits of early intervention programs, such as Head Start, for poverty-stricken children. What program characteristics might contribute to and strengthen those benefits?

Connect ■ Using what you learned about brain development in Chapter 5 (see pages 186–192), explain why intensive intervention for poverty-stricken children starting in infancy and continuing through early childhood has a greater impact on IQ than intervention starting later.

Connect ■ How is high-stakes testing likely to affect encouragement of creativity in classrooms? Explain.

Reflect ■ Describe several childhood experiences that you believe enhanced your creativity, along with ones that might have discouraged it. In the latter instances, what would you do differently to foster children's creative potential? Use research to justify your recommendations.

SUMMARY

Definitions of Intelligence
(p. 320)

Describe changing definitions of intelligence on which mental tests are based.

- The **psychometric approach** to cognitive development is the basis for intelligence tests that assess individual differences in children's mental abilities. The first successful test, developed by Binet in 1905, provided a single, holistic measure of intelligence.
- Researchers used **factor analysis** to determine whether intelligence is a single trait or an assortment of abilities. Spearman proposed an underlying **general intelligence,** or g, though he acknowledged various types of **specific intelligence.** Thurstone, in contrast, viewed intelligence as a set of distinct primary mental abilities.

© BOB DAEMMRICH/PHOTOEDIT

- Contemporary theorists propose hierarchical models of mental abilities. Cattell's identification of **crystallized** and **fluid intelligence** has influenced attempts to reduce cultural bias in intelligence testing. Carroll's **three-stratum theory of intelligence** is the most comprehensive factor-analytic classification of mental abilities.

Recent Advances in Defining Intelligence **(p. 323)**

How do contemporary researchers use and expand componential analyses of intelligence test scores to define intelligence?

- **Componential analyses** of children's test scores have revealed relationships between aspects of information processing—processing speed, working-memory capacity, and flexible attention, memory, and reasoning strategies—and intelligence test performance. Extending these efforts, Sternberg's **triarchic theory of successful intelligence** views intelligence as an interaction of analytical intelligence (information-processing skills), creative intelligence (capacity to solve novel problems), and practical intelligence (application of intellectual skills in everyday situations).
- Gardner's **theory of multiple intelligences** identifies at least eight distinct intelligences, each with a unique biological basis and course of development. It has stimulated educational innovations, helped in understanding and nurturing children's special talents, and calls attention to abilities not measured by intelligence tests, such as **emotional intelligence.**

Measuring Intelligence **(p. 326)**

Describe commonly used intelligence tests for children, distinguish between aptitude and achievement tests, and discuss the usefulness of infant tests.

- The **Stanford-Binet Intelligence Scales, Fifth Edition,** and the **Wechsler Intelligence Scale for Children–IV (WISC–IV)** are most often used to identify highly intelligent children and diagnose those with learning problems. Each provides a measure of general intelligence and a profile of subtest scores; each has a downward extension, tailored for assessing the intelligence of preschoolers.
- Two related types of tests are **aptitude tests,** which assess potential to learn a specialized activity, and **achievement tests,** which assess actual knowledge and skill attainment. Both types of tests include items similar to those found on intelligence tests.
- Most infant tests, which consist largely of perceptual and motor responses, predict later intelligence poorly and are largely used for screening—helping to identify infants who are at risk for future problems. As a result, infant scores are called **developmental quotients (DQs)** rather than IQs.

PHOTO BY STEPHEN AUSMUS/USDA

How are IQ scores computed and distributed in large, representative samples?

- Intelligence tests are scored by computing an **intelligence quotient (IQ).** It compares the test-taker's raw score to the scores of a **standardization** sample of same-age individuals, whose performances form a **normal distribution,** with mean IQ set at 100. IQ reflects the extent to which test performance deviates from the standardization-sample mean.

What Do Intelligence Tests Predict, and How Well?
(p. 330)

Discuss the stability of IQ and its prediction of academic achievement, occupational attainment, and psychological adjustment.

- After age 6, IQ scores show substantial correlational stability. The older the child at time of first testing and the closer in time two testings are, the stronger the relationship between the scores. However, most children show substantial fluctuations in the absolute value of IQ as a result of personality traits, child-rearing practices, and living conditions.

© LAURA DWIGHT PHOTOGRAPHY

- IQ is moderately correlated with adult academic achievement, occupational attainment, and emotional and social adjustment, but the underlying causes of these findings are complex. Other traits, including education, family influences, motivation, and **practical intelligence,** also contribute substantially to life success.

Ethnic and Socioeconomic Variations in IQ **(p. 334)**

Describe ethnic and socioeconomic variations in IQ.

- Black children and children of low **socioeconomic status (SES)** score lower on intelligence tests than white and middle-SES children, respectively. These findings that have kindled the IQ nature–nurture debate.

Explaining Individual and Group Differences in IQ (p. 335)

Discuss the contributions of heredity and environment to individual and group differences in IQ.

- Heritability estimates support a moderate role for heredity in IQ individual differences. Kinship studies indicate that the greater the genetic similarity between family members, the more similar their IQ scores. However, heritabilities cannot be used to explain between-group ethnic and SES differences in test scores.
- Adoption studies indicate that advantaged rearing conditions can substantially raise IQ. But stronger correlations of the IQs of adopted children with biological relatives than with adoptive relatives provide evidence for a genetic contribution.
- African-American children reared in economically well-off white homes attain above-average IQs by middle childhood. A dramatic generational increase in IQ – known as the **Flynn effect**—also supports the role of environmental factors and challenges the assumption that racial and ethnic variations in IQ are mostly genetic.

Evaluate evidence on whether ethnic differences in IQ result from test bias, and discuss efforts to reduce cultural bias in testing.

- Experts disagree on whether ethnic differences in IQ result from test bias. Although IQ predicts academic achievement equally well for majority and minority children, culturally specific communication styles, knowledge, and **stereotype threat** can lead to test scores that underestimate minority children's intelligence.
- Combining test scores with assessments of children's adaptive behavior helps safeguard against test bias. **Dynamic assessment,** which introduces purposeful teaching into the testing situation to measure what the child can attain with social support, enhances minority children's performance.

Summarize the impact of shared and nonshared environmental influences on IQ.

- Research using the **Home Observation for Measurement of the Environment (HOME)** indicates that overall quality of the home—a **shared environmental influence**—consistently predicts language progress and IQ. Although parent–child genetic similarity plays a part in the HOME–IQ relationship, a warm, stimulating family environment promotes mental ability. Parental belief in the importance of intellectual endeavors also has a powerful impact on academic performance.
- Kinship research suggests that **nonshared environmental influences** are more powerful than shared influences and strengthen in adolescence and adulthood. The most potent nonshared factors may be unpredictable, one-time events.

Early Intervention and Intellectual Development (p. 347)

Discuss the impact of early intervention on intellectual development.

- **Project Head Start** is the most extensive federally funded preschool program for low-income children in the United States.
- Research on high-quality early interventions shows that immediate IQ and achievement score gains decline within a few years, while benefits in school adjustment persist. And one program yielded advantages for preschool intervention children on adulthood indicators of life success, including education, income, and law-abiding behavior.
- The earlier intervention starts, the longer it lasts, and the more intensive the program, the broader and more enduring the benefits. **Early Head Start** offers coordinated services for infants and toddlers and their families, with positive effects on parenting, cognitive and language development, and lessening of aggression.

Giftedness: Creativity and Talent (p. 350)

Evaluate theories of creativity, and discuss ways to nurture creativity and talent.

- Recognition that intelligence includes more than mental abilities that predict school success has expanded conceptions of **giftedness** to include **creativity.** The psychometric approach, emphasizing the distinction between **divergent** and **convergent thinking,** is too narrow to predict real-world creative accomplishment. New, multifaceted approaches, such as the **investment theory of creativity,** look at a wide variety of intellectual, personality, motivational, and environmental resources that are necessary to initiate creative projects and bring them to fruition.

© LAURA DWIGHT PHOTOGRAPHY

- High creativity is usually manifested as **talent,** and talented children typically have parents and teachers who nurture their exceptional abilities. However, many gifted children, especially girls, report emotional and social difficulties. They are best served by educational programs in which they can interact with like-minded peers, take intellectual risks, reflect on ideas, and acquire skills relevant to their talents.

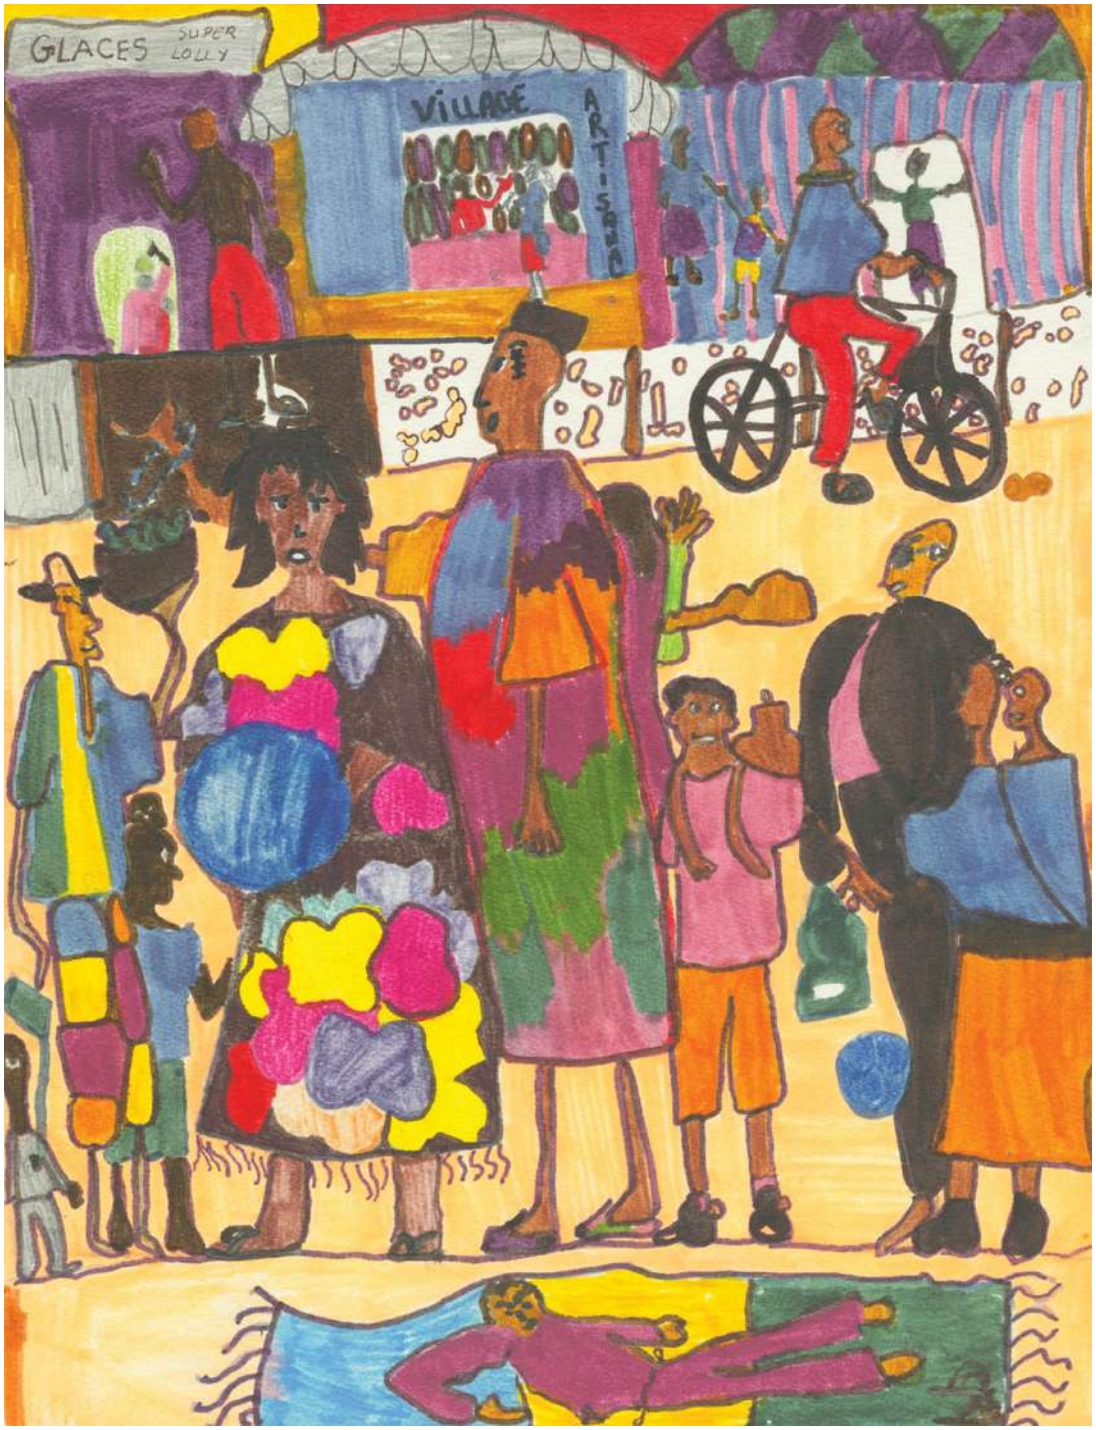
CHAPTER 9



"Gabonese Market Stalls"

Fabric Dossa
10 years, Gabon

A lively chorus of voices permeates this open-air market. Language is an astounding, distinctly human achievement. How does it develop so rapidly and easily in childhood?

Reprinted with permission from the World Awareness Children's Museum, Glens Falls, New York. Catalog #94569. www.worldchildrensmuseum.org

Language Development

“Done!” 1-year-old Erin said emphatically, wriggling in her highchair.

Oscar and Marilyn looked at each other and exclaimed in unison, “Did she say, ‘Done’?” Lifting Erin down, Marilyn responded, “Yes! You’re done,” to her daughter’s first clear word. In the next few weeks, more words appeared—among them “Mama,” “Dada,” “please,” “thanks,” and “sure.”

Marilyn spoke to Erin and her 11-year-old brother, Amos, in English. But Oscar, determined that his second child would become bilingual, used only Spanish, his native tongue. As Erin reached the 18-month mark, her vocabulary grew rapidly, and she mixed words from the two languages. “Book!” she called out, thrusting her favorite picture book toward Oscar in a gesture that meant, “Read this!” As father and daughter “read” together, Erin labeled: “*Nariz*” (“nose”). “*Boca*” (“mouth”). “Head.” “*Ojos*” (“eyes”). “Hippo.” “*Grande!*” (referring to the size of the hippo). On reaching the last page, she exclaimed, “*Gracias!*” and slipped off Oscar’s lap.

By her second birthday, Erin had a vocabulary of several hundred words and often combined them: “So big!” “*Muy grande*” (“very big”), “More cracker,” “*Dame galleta*” (“Give me cracker”), and “*No quiero*” (“I don’t want to”). Amused by Erin’s willingness to imitate almost anything, Amos taught her a bit of slang. During mealtime conversations, Erin would interject, “Geta picture” (“Get the picture”). And when asked a question, she sometimes casually answered, “Whatever.”

At age 2½, Erin conversed easily. After a family excursion to the aquarium, Marilyn asked, “What did you see?”

“A big turtle put his head in the shell,” Erin replied.

“Why did he do that?”

“He goed away. He’s sleepy.”

Language—the most awesome of universal human achievements—develops with extraordinary speed in early childhood. At age 1, Erin used single words to name familiar objects and convey her desires. Only a year and a half later, she had a diverse vocabulary and combined words into grammatically correct sentences. Even her mistakes (“goed”) revealed an active, rule-oriented approach to language. Before reaching her third birthday, Erin used language creatively to satisfy her desires, converse with others, and experiment with social roles. And she moved easily between her two native tongues, speaking English with her mother and brother and Spanish with her father.

Children’s amazing linguistic accomplishments raise puzzling issues about development. How do children acquire a vast vocabulary and intricate grammatical system in such a short time? Is language a separate capacity, with its own prewired, special-purpose neural system in the brain? Or is it governed by powerful general cognitive abilities that humans also apply to other aspects of their physical and social worlds? Do all children acquire language in the same way, or do individual and cultural differences exist?

Our discussion opens with prominent theories of language development that differ sharply in answers to these questions. Next we turn to infant preparatory skills that set the stage for the child’s first words. Then, to appreciate the diverse linguistic skills children master, we follow the common practice of dividing language into four components. For each, we consider, first, *what* develops, and then a more controversial question: *How* do children acquire so much in so little time? We conclude with a discussion of the challenges and benefits of bilingualism—mastering two languages—in childhood. ■

Bilingualism: Learning Two Languages in Childhood

■ **SOCIAL ISSUES: EDUCATION:** *Two Approaches to Bilingual Education: Canada and the United States*

- What are the four components of language?

Components of Language

Language consists of several subsystems that have to do with sound, meaning, overall structure, and everyday use. Language development entails mastering each of these aspects and combining them into a flexible communication system.

The first component, **phonology,** refers to the rules governing the structure and sequence of speech sounds. If you have ever visited a foreign country where you did not know the language, you probably wondered how anyone could analyze the rapid flow of speech into organized strings of words. Yet in English, you easily apply an intricate set of rules to comprehend and produce complicated sound patterns. How you acquired this ability is the story of phonological development.

Semantics, the second component, involves vocabulary—the way underlying concepts are expressed in words and word combinations. When young children first use a word, it often does not mean the same thing as it does to adults. To build a versatile vocabulary, children must refine the meanings of thousands of words and connect them into elaborate networks of related terms.

Once mastery of vocabulary is under way, children combine words and modify them in meaningful ways. **Grammar,** the third component of language, consists of two main parts: **syntax,** the rules by which words are arranged into sentences, and **morphology,** the use of grammatical markers indicating number, tense, case, person, gender, active or passive voice, and other meanings (the endings *-s* and *-ed* are examples in English).

Finally, **pragmatics** refers to the rules for engaging in appropriate and effective communication. To converse successfully, children must take turns, stay on the same topic as their conversational partner, and state their meaning clearly. They also must figure out how gestures, tone of voice, and context clarify meaning. Furthermore, because society dictates how language should be spoken, pragmatics involves *sociolinguistic knowledge*. Children must acquire certain interaction rituals, such as verbal greetings and leave-takings. They must adjust their speech to mark important social relationships, such as differences in age and status. And they must master their culture's narrative mode of sharing personally meaningful experiences with others.

As we take up the four components of language, you will see that they are interdependent. Acquisition of each facilitates mastery of the others.

© STEVEN RUBIN/THE IMAGE WORKS

To communicate effectively, these preschoolers must combine language subsystems of sound, meaning, structure, and everyday use. How they accomplish this feat raises puzzling—and fascinating—questions about development.

- Describe and evaluate major theories of language development.

Theories of Language Development

During the first half of the twentieth century, researchers identified language milestones that applied to children around the globe: All babbled around 6 months, said their first words at about 1 year, combined words at the end of the second year, and had mastered a vast vocabulary and most grammatical constructions by 4 to 5 years. The regularity and rapidity of these achievements suggested a process largely governed by maturation, inspiring the nativist perspective on language development. In recent years, new evidence has spawned the interactionist perspective, which emphasizes the joint roles of children's predispositions and communicative experiences in language acquisition.

The Nativist Perspective

Linguist Noam Chomsky (1957) proposed a *nativist* theory that regards language as a uniquely human accomplishment, etched into the structure of the brain. Focusing on grammar, Chomsky reasoned that the rules for sentence organization are too complex to be directly taught to or discovered by even a cognitively sophisticated young child. Rather, Chomsky proposed that all children have a **language acquisition device (LAD)**—an innate system that permits them, once they have acquired sufficient vocabulary, to combine words into grammatically consistent, novel utterances and to understand the meaning of sentences they hear.

How can a single LAD account for children's mastery of the world's diverse languages? According to Chomsky (1976, 1997), within the LAD is a **universal grammar,** a built-in storehouse of rules common to all human languages. Young children use this knowledge to decipher grammatical categories and relationships in any language to which they are exposed. Because the LAD is specifically suited for language processing, children master the structure of language spontaneously, with only limited language exposure (Pinker, 1999). In this way, the LAD ensures that language, despite its complexity, will be acquired early and swiftly.

Evidence Relevant to the Nativist Perspective

Are children innately primed to acquire language? Research reviewed in the Biology and Environment box on page 362, suggesting that children have a remarkable ability to invent new language systems, provides some of the most powerful support for this perspective. Three additional sets of evidence—efforts to teach language to animals, localization of language functions in the human brain, and investigations into whether a sensitive period for language development exists—are consistent with Chomsky's view. Let's look at each in turn.

Can Animals Acquire Language? Is the ability to master a grammatically complex language system unique to humans? To find out, many attempts have been made to teach language to animals, including dolphins, parrots, gorillas, orangutans, and chimpanzees. With extensive training, members of each of these species can acquire a vocabulary ranging from several dozen to several hundred symbols and can produce and respond to short, novel sentences, although they do so less consistently than a preschool child (Herman & Uyeyama, 1999; Pepperberg, 2000; Savage-Rumbaugh, Shanker, & Taylor, 1998).

Chimpanzees are closest to humans in the evolutionary hierarchy. Common chimps, the species studied most often, have been taught artificial languages (in which a computer keyboard generates visual symbols) and American Sign Language. Yet even after years of training, common chimps are unable to produce strings of three or more symbols that conform to a rule-based structure. Their language limitations may, in part, reflect a narrow understanding of others' mental states. Common chimps can accurately predict others' goals if those goals are readily apparent in behavior—for example, whether or not someone is willing to share food with them. But they may not recognize less obvious intentions, including ones that motivate use of language—for example, that others want to exchange knowledge and ideas (Tomasello, Call, & Hare, 2003).

Bonobo chimps are more intelligent and social than common chimps. The linguistic attainments of a bonobo named Kanzi are especially impressive (Savage-Rumbaugh, Shanker, & Taylor, 1998). While young, Kanzi picked up his mother's artificial language by observing trainers interact with her. To encourage his language development, Kanzi's caregivers communicated both in the artificial language and in English. Kanzi rarely combined words, preferring to join a word to a gesture—for example, "*carry* + [gesture to person]," meaning "you carry Kanzi." But through listening to fluent speech, he acquired remarkable comprehension of English, including the ability to discriminate hundreds of English words and to act out unusual sentences he had not heard before, such as "Put the money in the mushroom." And Kanzi could usually detect the difference between novel, reversed sentences—"Take the potato outdoors" and "Go outdoors and get the potato" (Savage-Rumbaugh et al., 1993; Shanker, Savage-Rumbaugh, & Taylor, 1999).

Still, researchers disagree on Kanzi's linguistic achievements. Some argue that he is a remarkable conversationalist (Greenspan & Shanker, 2004). Others claim that he uses language only to get what he wants (a strawberry to eat), not to share information (talk about strawberries) (Seidenberg & Petitto, 1987). And Kanzi's mastery of grammar does not exceed that of a human 2-year-old, who (as we will see) is not far along in grammatical development. Overall, the findings support Chomsky's assumption of a uniquely human capacity for an elaborate grammar. No evidence exists that even the brightest animals can comprehend and produce sentences that are both complex *and* novel.

A bonobo chimp points to visual symbols to communicate with researcher Sue Savage-Rumbaugh, who is tracking his language development.

BIOLOGY and ENVIRONMENT

Deaf Children Invent Language

Can children develop complex, rule-based language systems with only minimal language input, or with input so inconsistent that the rules of grammar are not readily apparent? If so, this evidence would support for Chomsky's idea that the human brain is prewired for language development (Goldin-Meadow, 2005b, 2006a). Research reveals that deaf children can generate an intricate natural language, even when reared in linguistically deficient environments.

Minimal Language Input

In a series of studies, Susan Goldin-Meadow (2009) and her colleagues followed deaf toddlers and preschoolers whose parents discouraged manual signing and addressed them verbally. None of the children made progress in acquiring spoken language or used even the most common gestures of their nation's sign language. Nevertheless, they spontaneously produced a gestural communication system, called *homesign,* strikingly similar in basic structure to hearing children's verbal language.

The deaf children developed gestural vocabularies with distinct forms for nouns and verbs, each of which stood for a class of objects or a class of actions (for example, a *twist* gesture to request that someone open a jar and to convey that a door knob will not open), similar to the meanings of spoken words. Furthermore, the children combined gestures into novel sentences conforming to basic grammatical rules that were not necessarily those of their parents' spoken language (Goldin-Meadow, Gelman, & Mylander, 2005; Goldin-Meadow et al., 1994). For example, to describe a large bubble he had just blown, one child first pointed at a bubble jar and then used two open palms with fingers spread to denote the act of "blowing up big."

The children did not pick up their gesture systems from parents, whose gestures were limited—no different from the gestures that hearing speakers produce while talking (Goldin-Meadow, 2003a). Rather, the children created homesign, and they used it for the same diverse purposes as any language—to comment on objects and events, to ask questions, to influence others' actions, to tell stories, to talk about their own and others' signs, and to talk to themselves (Goldin-Meadow, 2009).

© NICARAGUAN SIGN LANGUAGE PROJECTS, INC.

In Nicaragua, educators brought deaf children and adolescents together to form a community. Within two decades, they devised a new language—Nicaraguan Sign Language.

Language becomes a flexible means of communicating when it is used to talk about nonpresent objects and events. In referring to the nonpresent, the deaf children followed the same sequence of development as hearing children—first denoting objects and events in the recent past or anticipated but immediate future, next the more remote past and future, and finally hypothetical and fantasized events (Morford & Goldin-Meadow, 1997). One homesigning child pointed over his shoulder to signify the past, then pointed to a picture of a poodle, and finally pointed to the floor in front of him, saying, "I used to have a poodle!"

Hearing children reach language milestones earlier and acquire a far more complex grammar than children inventing homesign. These findings indicate that a rich language environment with partners who "speak" the same language fosters the attainments just mentioned. But without access to conventional language, deaf children generate their own language

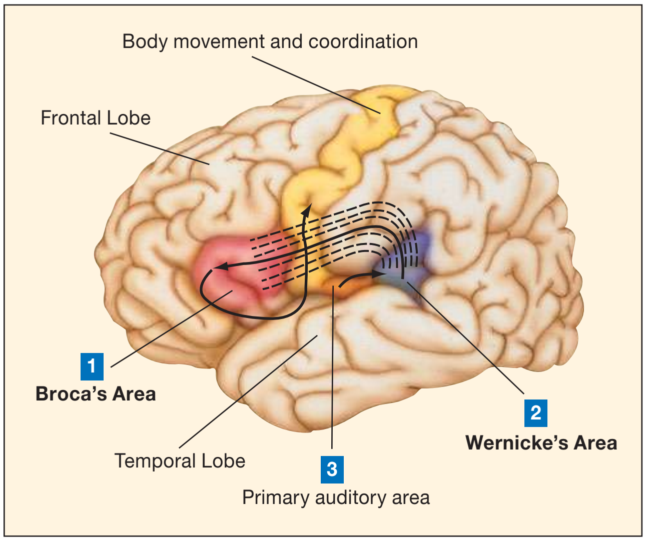

FIGURE 9.1 **Broca's and Wernicke's areas, in the left hemisphere of the cerebral cortex.** (1) Broca's area, located in the frontal lobe, supports grammatical processing and language production. (2) Wernicke's area, located in the temporal lobe, is involved in comprehending word meaning. Contrary to what was once believed, however, neither area is solely or even mainly responsible for these functions. Instead, each cooperates with many other regions of the left hemisphere. Wernicke's area and Broca's area communicate through a bundle of nerve fibers represented by dashed lines. Among the regions from which Wernicke's area receives impulses is (3) the primary auditory area, where sensations from the ears are sent. Broca's area communicates with motor areas involved in speaking.

Language Areas in the Brain. Recall from Chapter 5 that for most individuals, language is housed largely in the left hemisphere of the cerebral cortex. Within it are two important language-related structures (see Figure 9.1). To clarify their functions, researchers have, for several decades, studied adults who experienced damage to these structures and display *aphasias,* or communication disorders. The patients' linguistic deficits suggested system. In Nicaragua, educators brought deaf children and adolescents, each with a unique homesign, together to form a community. Although they had no shared language, in less than two decades they developed an elaborate one—Nicaraguan Sign Language—that matched other human languages in structural complexity (Senghas & Coppola, 2001).

Inconsistent Language Input

An unusual study of a rare child whose language environment was not the typical rich form also illustrates children's remarkable capacity to invent language. Simon, a deaf child, was born to deaf parents who did not start to learn American Sign Language (ASL) (which is as elaborate as any spoken language) until they were adolescents. As with the deaf children just described, Simon's parents were exposed only to oral language in childhood. They communicated with Simon in ASL from infancy, but because they were late ASL learners, they had not attained the grammatical complexity of native signers, and they used many ASL structures inconsistently. (See the section on a sensitive period for language development on page 364.) Simon has a hearing younger sibling and went to a school with hearing teachers and children; his only ASL input came from his parents.

When Simon was 7, researchers gave him a challenging ASL grammar task, which assessed his knowledge of the verb *to move* (Singleton and Newport, 2004). In ASL, accurately expressing motion requires up to seven grammatical markers, which indicate (1) the object's path, (2) the object's orientation, (3) the manner in which the object moves (for example, bouncing or rolling), (4) the object's location relative to a secondary object, (5) the position of the secondary object with respect to the path, (6) the features of the moving object (category, size, or shape), and (7) the features of the secondary object. The researchers compared Simon's performance with that of several reference groups: his parents, deaf school-age children of deaf native-signing parents, and deaf native-signing adults.

Findings confirmed that Simon's parents' ASL grammar was much weaker than that of native-signing adults. Yet Simon's language did not mirror his parents' error-ridden input. Instead, he introduced a level of regularity into his language that surpassed his parents' usage. As Figure 9.2 shows, his score on the "to move" task exceeded the average score of native-signing deaf children and approached the performance of native-signing deaf adults. Simon managed to extract the regularities from his parents' imperfect language and magnify them, arriving at a highly systematic grammar.

Deaf children's remarkable capacity to invent language, despite minimal or inconsistent input, is compatible with the existence of an innate LAD. As we will see, however, other theorists claim that nonlinguistic cognitive capacities, applied to the task of communicating, are responsible.

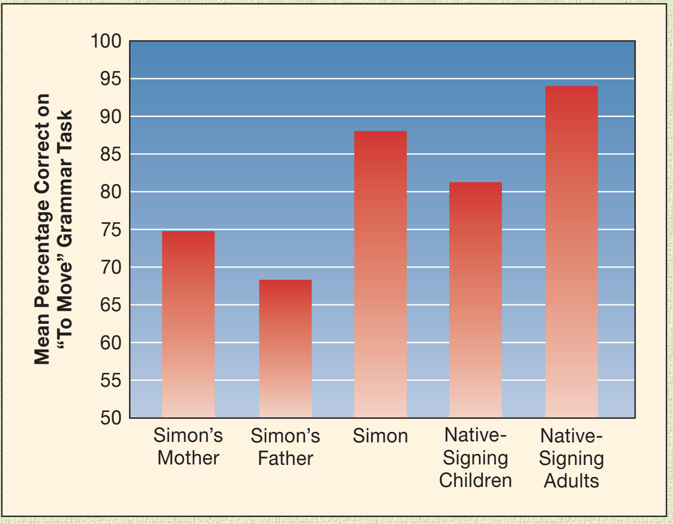

FIGURE 9.2 **Simon's performance on a challenging ASL grammar task, compared with the performance of his parents and native-signing children and adults.** Despite inconsistent input from his parents, 7-year-old Simon showed excellent mastery of ASL grammar, exceeding the average performance of native-signing deaf children and approaching of native-signing deaf adults. (Adapted from Singleton & Newport, 2004.)

that **Broca's area,** located in the left frontal lobe, supports grammatical processing and language production, while **Wernicke's area,** located in the left temporal lobe, plays a role in comprehending word meaning.

But recent brain-imaging research suggests more complicated relationships between language functions and brain structures. The impaired pronunciation and grammar of patients with Broca's aphasia and the meaningless speech streams of patients with Wernicke's aphasia involve the spread of injury to nearby cortical areas and widespread abnormal activity in the left cerebral hemisphere, triggered by the brain damage (Bates et al., 2003; Keller et al., 2009). Contrary to long-held belief, Broca's and Wernicke's areas are not solely or even mainly responsible for specific language functions. Nevertheless, depending on the site of injury to the adult left hemisphere, language deficits do vary predictably. Damage to frontal-lobe areas usually yields language production problems, damage to the areas in the temporal lobes comprehension problems—patterns that are highly consistent across individuals (Dick et al., 2004).

The broad association of language functions with left-hemispheric regions is consistent with Chomsky's notion of a brain prepared to process language. But recall from Chapter 5 that at birth, the brain is not fully lateralized; it is highly plastic. Language areas in the cerebral cortex *develop* as children acquire language (Mills & Conboy, 2005; Mareschal et al., 2007). Although the left hemisphere is biased for language processing, if it is injured in the first few years, other regions take over language functions, and most such children eventually attain normal language competence (see page 188 in Chapter 5). Thus, left-hemispheric localization is not necessary for effective language processing. For example, recall from Chapter 5 that deaf adults who as children learned sign language depend more on the right hemisphere. Additional research reveals that many parts of the brain participate in language activities to differing degrees, depending on the language skill and the individual's mastery of that skill (Shafer & Garrido-Nag, 2007).

Grammatical competence, however, may depend more on specific brain structures than the other components of language. When 2- to 2½-year-old children and adults listened to short sentences—some syntactically correct, others with phrase-structure violations—both groups showed similarly distinct ERP brain-wave patterns for each sentence type in the left frontal and temporal lobes (Oberecker & Friederici, 2006; Oberecker, Friedrich, & Friederici, 2005). This suggests that 2½-year-olds process sentence structures with the same neural system as adults do. Furthermore, in older children and adults with left-hemispheric brain damage, grammatical abilities are more impaired than semantic or pragmatic abilities, which seem to draw more on right-hemispheric regions (Baynes & Gazzaniga, 1988; Stromswold, 2000).

Finally, when the young brain allocates language to the right hemisphere after injury—as a result of left-hemispheric damage or learning of sign language—it localizes it in roughly the same regions that typically support language in the left hemisphere (Newman et al., 2002; Rosenberger et al., 2009). This suggests that those regions are uniquely disposed for language processing.

A Sensitive Period for Language Development. Must language be acquired early in life, during an age span in which the brain is particularly responsive to language stimulation? Evidence for a sensitive period coinciding with brain lateralization would support the nativist position that language development has unique biological properties.

To test this idea, researchers have examined the language competence of deaf adults who acquired their first language—American Sign Language (ASL)—at different ages. The later learners, whose parents chose to educate them through the oral method, which relies on speech and lip-reading and discourages signing, did not acquire spoken language because of their profound deafness. And consistent with the sensitive period notion, those who learned ASL in adolescence or adulthood never became as proficient at any aspect of language as those who learned in childhood (recall Simon's parents, in Figure 9.2, who scored lower on a test of complex grammar than he did because they had not acquired ASL until adolescence) (Mayberry, 2010; Newport, 1991; Singleton & Newport, 2004). Furthermore, the typical right-hemispheric localization of ASL functions, which require visual–spatial processing of hand, arm, and facial movements, is greatly reduced in individuals who learned ASL beyond childhood (Newman et al., 2002). However, a precise age cutoff for a decline in first-language competence has not been established.

Immigrant mothers read English with their children as part of a library literacy program. Because childhood is a sensitive period for optimum language development, these mothers may never become as proficient in English as their children.

© SUZANNE DECHILLO/THE NEW YORK TIMES/REDUX PICTURES

Is acquiring a second language also harder after a sensitive period has passed? In one study, researchers examined U.S. census data, selecting immigrants from Spanish- and Chinese-speaking countries who had resided in the United States for at least 10 years. The census form had asked the immigrants to rate how competently they spoke English, from "not at all" to "very well"—self-reports that correlate strongly with objective language measures. As age of immigration increased from infancy and early childhood into adulthood, English proficiency declined, regardless of respondents' level of education (see Figure 9.3) (Hakuta, Bialystok, & Wiley, 2003). Other research confirms an age-related decline beginning around age 5 to 6 in capacity to acquire a second language with a native accent

(Flege, Yeni-Komshian, & Liu, 1999; Flege et al., 2006). Furthermore, ERP and fMRI measures of brain activity indicate that second-language processing is less lateralized, and also overlaps less with brain areas devoted to first-language processing, in older than in younger learners (Neville & Bruer, 2001). But second-language competence does not drop sharply at a certain age. Rather, a continuous, age-related decrease occurs.

What factors underlie the younger-age language-learning advantage? Some researchers assign a key role to the narrowing of speech perception during the second half of the first year—from discrimination among nearly all language sounds to heightened sensitivity to sound distinctions in the language (or languages) the baby hears (see Chapter 4, page 156). As a result, neural networks become dedicated to processing native-language sounds, strengthening native-language learning while weakening capacity to acquire unfamiliar languages. As preliminary evidence for this view, 7-month-olds' skill at perceiving native-language sounds, along with their insensitivity to sound variations in languages they do not hear, predicts rapid vocabulary and grammatical development in the second and third years (Kuhl et al., 2005; Kuhl, 2009).

In sum, the more "committed" the brain is to native-language patterns, the better children's mastery of their native language and the less effectively they acquire foreign languages (Kuhl, 2006). This neural commitment increases with mastery of language and, thus, with age.

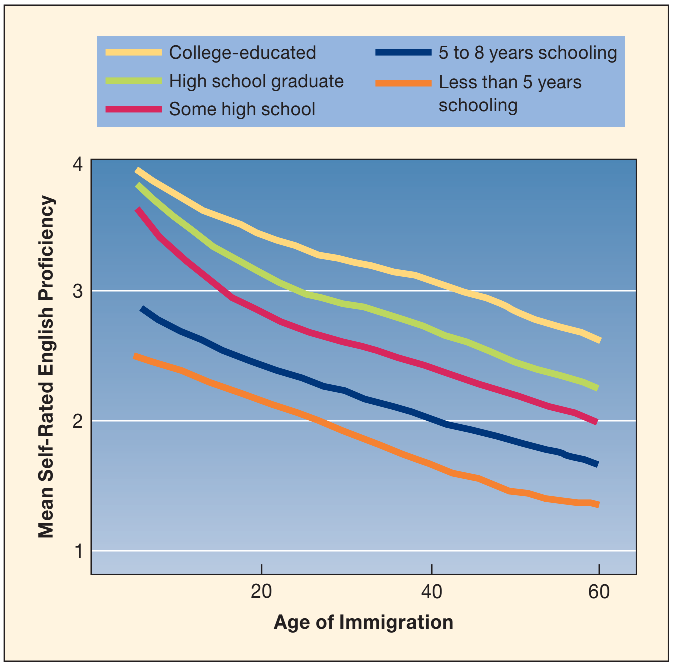

FIGURE 9.3 Relationship between age of immigration to the United States and self-rated English proficiency, illustrated for native Spanish speakers. As age of immigration increased, English proficiency decreased for individuals at all levels of education, from a few years of elementary school to a college education. Findings for native Chinese speakers were similar. (From K. Hakuta, E. Bialystok, & E. Wiley, 2003, "Critical Evidence: A Test of the Critical Period Hypothesis for Second-Language Acquisition," *Psychological Science,* Vol. 14, No. 1, p. 37, copyright © 2003, Association for Psychological Science. Reprinted by permission of SAGE Publications.)

Limitations of the Nativist Perspective

Chomsky's theory has had a major impact on current views of language development. But despite wide acceptance of Chomsky's belief in humans' unique, biologically based capacity to acquire language, his account of development has been challenged on several grounds.

First, researchers have had great difficulty specifying Chomsky's universal grammar. A persistent problem is the absence of a complete description of these abstract grammatical structures or even an agreed-on list of how many exist or the best examples of them. According to Chomsky's critics, one set of rules cannot account for the multiplicity of grammatical forms—indeed, variation in every structural way possible—among the world's 5,000 to 8,000 languages (Christiansen & Chater, 2008; Evans & Levinson, 2009; Tomasello, 2003, 2005). How children manage to link such rules with the extraordinary diversity in strings of words they hear is also unclear.

Second, Chomsky's assumption that grammatical knowledge is innately determined does not fit with certain observations of language development. Once children begin to use an innate grammatical structure, we would expect them to apply it to all relevant instances in their language. But later we will encounter evidence that children refine and generalize many grammatical forms gradually, engaging in much piecemeal learning and making errors along the way (Tomasello, 2000, 2003, 2006). Complete mastery of some forms (such as the passive voice) is not achieved until well into middle childhood (Tager-Flusberg & Zukowski, 2009). This suggests that more experimentation and learning are involved than Chomsky assumed.

Chomsky's theory also lacks comprehensiveness. For example, it cannot explain how children weave statements together into connected discourse and sustain meaningful conversations. Perhaps because Chomsky did not dwell on the pragmatic side of language, his theory grants little attention to the quality of language input or to social experience in supporting language progress. Furthermore, the nativist perspective does not regard children's cognitive capacities as important. Yet in Chapter 6, we saw that cognitive development is involved in children's early vocabulary growth. And studies of children with mental retardation (see the Biology and Environment box on page 366) show that cognitive competence also influences children's grammatical mastery.

BIOLOGY and ENVIRONMENT

Language Development in Children with Williams Syndrome

Williams syndrome, a rare disorder occurring in only one in 7,500 births, results from deletion of genetic material on the seventh chromosome. Affected individuals have facial, heart, and kidney abnormalities and mild to serious mental retardation. With IQ scores typically ranging from 50 to 70, they are just as mentally impaired as individuals with Down syndrome—yet they are far more advanced in language skills (Bellugi et al., 2000; Tager-Flusberg, 2007). For many years, researchers took this apparent "decoupling" of cognition and language as evidence that language is controlled by an innate LAD. But new evidence on language attainments associated with the disorder reveals that this conclusion is not warranted.

Infants with Williams syndrome are strongly oriented toward the social world—extremely gregarious and fascinated by faces and voices (Zitzer-Comfort et al., 2010). Their language development, though delayed, is impressive. During the preschool years, children with Williams syndrome have larger vocabularies and produce grammatically more complex sentences than children with Down syndrome (Mervis & Robinson, 2000). For example, the longest sentence of one 3-year-old with Williams syndrome was "Please have some grapes in my cup right now." Her counterpart with Down syndrome said, "Here-ya-go" and "Hold me" (Jarrold, Baddeley, & Hewes, 1998, p. 361). By adolescence, the vocabularies of young people with Williams syndrome contain many unusual words. When asked to name as many animals as possible, one teenager said, "weasel, newt, salamander, Chihuahua, ibex, yak" (Bellugi et al., 1992, p. 11).

Yet affected individuals have trouble with highly challenging grammatical rules. For example, French-speaking adolescents with Williams syndrome do poorly on grammatical gender assignment—matching masculine and feminine articles (such as *un* versus *une*) with nouns by attending to word endings and noting exceptions. Normally developing French children master this gender system by age 4 (Karmiloff-Smith et al., 1997). And a study of English-speaking adults revealed difficulties with subtle verb forms ("He struggle the dog" rather than "He struggled with the dog") (Karmiloff-Smith et al., 1998).

Why does Williams syndrome lead to an uneven language profile—areas of both strength and weakness? Growing evidence indicates that the cognitive deficits of Williams syndrome profoundly alter the course of language development. Children with the disorder are relatively good at memorizing but poor at rule learning (Karmiloff-Smith et al., 2003; Rowe & Mervis, 2006). To compensate, they capitalize on their social strengths, attending closely to faces and voices and acquiring as much language by rote as they can.

In support of this explanation, toddlers with Williams syndrome do not build their early vocabularies on intentional gestures (such as pointing) and advances in categorization, as typically developing children do (Laing et al., 2002). Instead, they more often mimic others, so much so that they frequently speak without comprehending what they are saying. Preschool and school-age children with Williams syndrome have pragmatic deficits: They make many irrelevant remarks during conversations and are poor at adapting what they say to others' needs (Asada et al., 2010a, 2010b). Furthermore, working-memory capacity is more strongly correlated with grammatical development in children with Williams syndrome than in typically developing children (Robinson, Mervis, & Robinson, 2003). All of these findings are consistent with a heavy reliance on memory to learn language.

In sum, although the language of individuals with Williams syndrome is impressive in view of their cognitive limitations, it is impaired in significant ways. The evidence indicates that language is not as separate from other human mental abilities as Chomsky's LAD assumes.

COURTESY OF WILLIAMS SYNDROME ASSOCIATION

Despite mental retardation, this child with Williams syndrome is likely to display impressive language skills. But his cognitive deficits will limit his ability to master complex language rules.

The Interactionist Perspective

Recent ideas about language development emphasize *interactions* between inner capacities and environmental influences. One type of interactionist theory applies the information-processing perspective to language development. A second type emphasizes social interaction.

Information-Processing Theories The most influential information-processing accounts are derived from research with *connectionist,* or *artificial neural network, models.* Connectionist researchers design computer systems to simulate the multilayered networks of neural connections in the brain and program them with basic learning procedures—for example, to respond to regularities in the speech stream. Then the artificial network is exposed to various types of language input and given feedback about the accuracy of its responses. When a response is correct, the connections that produced it strengthen; when incorrect, they weaken. If the network's overall pattern of responses resembles that of children of different ages, researchers conclude that the network is a good model of human learning and development.

Tests with certain language sounds, words, and basic grammatical forms show that these networks capture children's early errors and gradually detect adult linguistic patterns. In acquiring the past tense, for example, a network first constructed some simple rules—for example, "Retrieve the past-tense form from memory." "Add *-ed* to any verb"—which at times resulted in mistakes. With further experience, the network modified and combined rules to arrive at adult usage: "For frequently used verbs (such as *go*), retrieve the unique past-tense form from memory *(went)*." "For novel or infrequently used verbs, form the past tense by adding *–ed*" (Taatgen & Anderson, 2002). Notice that neural networks are not biased to learn language. Instead, their designers assume that children make sense of their complex language environments by applying powerful, analytic cognitive capacities of a general kind rather than capacities especially tuned to language (Bates, 1999; Elman, 2001; Munakata, 2006).

Other theorists blend Chomsky's nativist perspective with the information-processing proposal that the human brain is extraordinarily skilled at detecting patterns. Recall the research presented in Chapter 4 (see page 157), which showed that infants are amazing statistical analyzers of the sound stream, capable of detecting which adjacent sounds often occur together and which do not—a skill that helps them discriminate words in fluent speech. Using this *statistical learning capacity,* infants identify basic language patterns by applying the same strategies they use to make sense of their nonlinguistic experiences. At the same time, researchers recognize that such statistical computations are not sufficient to account for mastery of higher-level aspects of language—for example, intricate grammatical structures that require a grasp of distant relationships between words and phrases (Aslin & Newport, 2009). Currently, statistical learning theorists are investigating how sensitivity to statistical regularities might combine with other general-cognitive and language-specific processing abilities to explain children's acquisition of increasingly complex language structures (Saffran, 2009).

Proponents of information-processing approaches draw on biological evidence, pointing out that regions of the brain housing language also govern other similar perceptual, motor, and cognitive abilities. For example, ERP and fMRI studies reveal that damage to the left hemisphere, including Wernicke's area, results in difficulty comprehending both language and other patterned stimuli, such as music and series of moving lights that depict familiar shapes (Bates et al., 2003; Saygin et al., 2004; Saygin, Leech, & Dick, 2010). Indeed, Wernicke's area—once thought to be language-specific—is actually more strongly associated with comprehension of nonverbal than of verbal sound (Dick et al., 2004).

Information-processing theorists have tested their ideas mostly with simplified language stimuli, presented to artificial neural networks and to children in laboratories. In many instances, they cannot be certain that the learning strategies identified generalize to children's language acquisition in everyday social contexts. Other interactionist theorists believe that children's social skills and language experiences are centrally involved in language development.

Social Interactionist Theories

According to the social interactionist perspective, native capacity, a strong desire to understand others and to be understood by them, and a rich language environment combine to help children discover the functions and regularities of language. An active child, well-endowed for making sense of language, strives to communicate. In doing so, she cues her caregivers to provide appropriate language experiences, which in turn help her relate the content and structure of language to its social meanings (Bohannon & Bonvillian, 2009; Chapman, 2006).

Among social interactionists, disagreement continues over whether children make sense of their complex language environments by applying general cognitive capacities or capacities specially tuned to language (Lidz, 2007; Shatz, 2007; Tomasello, 2003, 2006). Nevertheless, as we chart the course of language development, we will encounter much support for their central premise—that children's social competencies and language experiences greatly affect language development. In reality, native endowment, cognitive-processing strategies, and social experience may operate in different balances with respect to each component of language. Today, we still know much more about the course of language development than about precisely how it takes place.

According to the social interactionist perspective, native capacity, a strong desire to communicate, and exposure to a rich language environment combine to help this preschooler discover the functions and regularities of language.

ASK YOURSELF

Review ■ Summarize outcomes of attempts to teach language to animals. Are results consistent with the nativist assumption that human children are uniquely endowed with an LAD? Explain.

Review ■ How do the two types of interactionist theories of language development differ from nativist views and from each other?

Connect ■ Cite research in this chapter and in Chapter 5 indicating that with age, areas of the cortex become increasingly specialized for language. Relate these findings to the concept of brain plasticity.

Apply ■ Describe evidence for the existence of a sensitive period for language learning. What are the practical implications of these findings for teaching children a second language?

- Discuss receptivity to language, development of speech sounds, and conversational skills during infancy.

Prelinguistic Development: Getting Ready to Talk

From the very beginning, infants are prepared to acquire language. During the first year, sensitivity to language, cognitive and social skills, and environmental supports pave the way for the onset of verbal communication.

Receptivity to Language

Recall from Chapter 4 that newborns are especially sensitive to the pitch range of the human voice and prefer speech—especially their mother's voice and their native tongue—to other sounds, perhaps because of repeated exposure to their mother speaking during pregnancy. We have also seen that newborns make fine-grained distinctions between virtually any human-language sounds. Because this skill may help them crack the phonological code of their native tongue, let's look at it more closely.

Learning Native-Language Sound Categories and Patterns As adults, we analyze the speech stream into **phonemes,** the smallest sound units that signal a change in meaning, such as the difference between the consonant sounds in "pa" and "ba." Phonemes are not the same across all languages. For example, "ra" and "la" are distinct sounds to English speakers but sound the same to speakers of Japanese. Similarly, English speakers have trouble perceiving the difference between two "p" sounds—a soft "p" and a sharp "p" with a burst of air—used to distinguish meaning in the Thai language. This tendency to perceive as identical a range of sounds that belong to the same phonemic class is called **categorical speech perception.** Newborns, like adults, are capable of it. And humans—as well as other primates and chinchillas—categorize not only speech but also nonspeech sounds (Burnham & Mattock, 2010). These findings indicate that categorical perception is not unique to linguistic input. Rather, it is a property of the auditory system, and human languages take advantage of it.

Young infants are sensitive to a much wider range of speech categories than exists in their own language. As they listen actively to the talk of people around them, they focus on meaningful sound variations. Between 6 and 8 months, they start to organize speech into the phonemic categories of their own language—that is, they stop attending to sounds that will not be useful in mastering their native tongue or, in the case of bilingual exposure, sounds not part of both languages they are about to learn (Burns et al., 2007; Kuhl et al., 1992; Mattock et al., 2008; Polka & Werker, 1994).

Interestingly, visual language discrimination—by monitoring a speaker's face and lip movements—changes similarly. At 4 to 6 months, infants can distinguish their native language (English) from an unfamiliar language (French) merely by watching silent video clips of adults saying sentences in each language. At 8 months, however, English-learning infants no longer make this visual distinction. But 8-month-olds from French–English bilingual homes continue to separate the two languages visually—a discrimination that helps them learn two languages at once (Weikum et al., 2007).

As older infants focus intently on language regularities, they soon recognize familiar words in spoken passages, listen longer to speech with clear clause and phrase boundaries, and divide the speech stream into wordlike units (see Chapter 4, page 157, to review). They also extend their sensitivity to speech structure to individual words. Using phoneme sequences and stress patterns, 7-month-olds can distinguish sounds that typically begin words from those that do not (Swingly, 2005; Thiessen & Saffran, 2007). For example, English and Dutch infant learners often rely on the onset of a strong syllable to indicate a new word, as in "*an*imal" and "*pud*ding." By 10 months, they can detect words that start with weak syllables, such as "sur*prise*" (Jusczyk, 2001; Kooijman, Hagoort, & Cutler, 2009). The reverse pattern—earlier detection of words starting with weak syllables—characterizes infants acquiring Canadian French, which includes more words with a weak–strong stress pattern (Polka & Sundara, 2003).

© LAURA DWIGHT PHOTOGRAPHY

This mother speaks to her 8-month-old using infant-directed speech—short, clearly pronounced sentences with high-pitched, exaggerated expression. This form of communication eases the task of understanding language.

Taken together, these findings reveal that in the second half of the first year, infants have begun to detect the internal structure of sentences and words—information that will be vital for linking speech units with their meanings. How do babies accomplish these feats? We have seen that they are vigilant *statistical analyzers* of sound patterns; in the second half of the first year, they can distinguish adjacent syllables that frequently occur together (signaling that they belong to the same word) from those that seldom occur together (signaling a word boundary). Research suggests that infants first use these statistical learning abilities to locate words in speech. Then they focus on the words, detecting regular patterns of syllable stress (Saffran & Thiessen, 2007). Furthermore, babies of this age are budding *rule learners.* At 7 months, they can distinguish an ABA from an ABB pattern in the structure of short, nonsense-word sequences—a capacity that may eventually help them grasp basic syntax (Marcus et al., 1999) (see page 157 in Chapter 4).

Clearly, infants acquire a great deal of language-specific knowledge before they start to talk around 12 months of age. As we will see, certain features of adult speech greatly assist them in detecting meaningful speech units.

Adult Speech to Young Language Learners

Adults in many countries speak to babies in **infant-directed speech (IDS),** a form of communication made up of short sentences with high-pitched, exaggerated expression, clear pronunciation, distinct pauses between speech segments, clear gestures to support verbal meaning, and repetition of new words in a variety of contexts ("See the *ball.*" "The *ball* bounced!") (Fernald et al., 1989; O'Neill et al., 2005). Deaf parents use a similar style of communicating when signing to their babies (Masataka, 1996).

Parents do not seem to be deliberately trying to teach infants to talk when they use IDS; many of the same speech qualities appear when adults communicate with nonnative speakers. Rather, IDS probably arises from adults' desire to hold babies' attention and ease their task of understanding, and it works effectively in these ways. From birth on, infants prefer IDS over other kinds of adult talk (Aslin, Jusczyk, & Pisoni, 1998). By 5 months, they are more emotionally responsive to it and can discriminate the tone quality of IDS with different meanings—for example, approving versus soothing utterances (Moore, Spence, & Katz, 1997; Werker, Pegg, & McLeod, 1994). Mothers' exaggerated pronunciation in IDS is strongly associated with 6- to 12-month-olds' increasing sensitivity to the phonemic categories of their native language and with detection of words in the speech stream (Liu, Kuhl, & Tsao, 2003; Thiessen, Hill, & Saffran, 2005). And in the second year, the short, simple phrases leading up to a noun ("*Where's the* kitty?" "*See the* kitty."), common in IDS, facilitate detection of word meanings (Fernald & Hurtado, 2006). Perhaps these phrases enable toddlers to anticipate that an important word is coming and, thus, listen closely for it.

Parents fine-tune IDS, adjusting the length and content of their utterances to fit babies' changing needs—adjustments that enable toddlers to join in and that foster language progress in the second and third years (Murray, Johnson, & Peters, 1990; Rowe, 2008). In addition, toddlers' first words and phrases are usually ones they hear often in their caregivers' IDS (Cameron-Faulkner, Lieven, & Tomasello, 2003).

LOOK and LISTEN

While observing a parent and baby playing, describe how the parent adapts his or her language to the child's needs. Did the parent use IDS?

© PICTURE PARTNERS/ALAMY

This 3-month-old's pleasant, vowel-like "oo" noises are known as cooing. Soon she will add consonants, and around 6 months, like babies everywhere, begin to babble.

First Speech Sounds

Around 2 months, babies begin to make vowel-like noises, called **cooing** because of their pleasant "oo" quality. Gradually, consonants are added, and around 6 months **babbling** appears, in which infants repeat consonant–vowel combinations, often in long strings such as "babababababa" and "nanananana."

Babies everywhere (even those who are deaf) start babbling at about the same age and produce a similar range of early sounds. But for babbling to develop further, infants must hear human speech. In hearing-impaired babies, these speechlike sounds are delayed and limited in diversity of sounds produced over time (Bass-Ringdahl, 2010; Moeller et al., 2007). And a deaf infant not exposed to sign language will stop babbling entirely (Oller, 2000).

In one case, a deaf-born 5-month-old received a *cochlear implant*—an electronic device inserted into the ear that converts external sounds into a signal to stimulate the auditory nerve. She showed typical babbling in infancy and resembled her hearing agemates in language development at 3 to 4 years (Schauwers et al., 2004). But if auditory input is not restored until after age 2 (the usual time for cochlear implant surgery), children remain behind in language development. And if implantation occurs after age 4, language delays are severe and persistent (Govaerts et al., 2002; Svirsky, Teoh, & Neuburger, 2004). These outcomes suggest an early sensitive period in which exposure to speech is essential for the brain to develop the necessary organization for normal speech processing.

Babies initially produce a limited number of sounds and then expand to a much broader range (Oller et al., 1997). Around 7 months, babbling includes consonant–vowel syllables common in spoken languages. And as caregivers respond contingently to infant babbles, infants modify their babbling to include sound patterns like those in the adult's speech (Goldstein & Schwade, 2008). By 8 to 10 months, babbling reflects the sounds and intonation of children's language community, some of which are transferred to their first words ("Mama," "Dada") (Boysson-Bardies & Vihman, 1991).

TAKE A MOMENT... The next time you hear an older baby babbling, notice how certain sounds appear in particular contexts—for example, when exploring objects, looking at books, or walking upright (Blake & Boysson-Bardies, 1992). Infants seem to be experimenting with the sound system and meaning of language before they speak in conventional ways. Toddlers continue babbling for four or five months after they say their first words.

Deaf infants exposed to sign language from birth babble with their hands much as hearing infants do through speech (Petitto & Marentette, 1991). Furthermore, hearing babies of deaf, signing parents produce babblelike hand motions with the rhythmic patterns of natural sign languages (Petitto et al., 2001, 2004). This sensitivity to language rhythm, evident not just in perception of speech but also in babbling, whether spoken or signed, supports both discovery and production of meaningful language units.

Becoming a Communicator

At birth, infants are prepared for some aspects of conversational behavior. For example, newborns initiate interaction through eye contact and terminate it by looking away. By 3 to 4 months, infants start to gaze in the same general direction adults are looking—a skill that becomes more accurate at 10 to 11 months. Around this time, babies become sensitive to adults' precise direction of gaze, suggesting that they realize that others' focus provides information about their communicative intentions (to talk about an object) or other goals (to obtain an object) (Brooks & Meltzoff, 2005; Senju, Csibra, & Johnson, 2008). Indeed, 12-month-olds look where an adult is looking only when the adult's eyes are open. And 12- to 14-month-olds are more likely to engage in gaze following when no obstacles block an adult's line of sight to an object (Brooks & Meltzoff, 2002; Dunphy-Lelii & Wellman, 2004). Around their first birthday, babies realize that a person's visual gaze signals a vital connection between the viewer and his or her surroundings, and they want to participate.

This **joint attention,** in which the child attends to the same object or event as the caregiver, who often labels it, contributes greatly to early language development. Infants and toddlers who frequently experience it sustain attention longer, comprehend more language, produce meaningful gestures and words earlier, and show faster vocabulary development through 2 years of age (Brooks & Meltzoff, 2008; Carpenter, Nagell, & Tomasello, 1998b; Flom & Pick, 2003; Silvén, 2001). Gains in joint attention at the end of the first year enable babies to establish a "common ground" with the adult, through which they can figure out the meaning of the adult's verbal labels.

Between 4 and 6 months, interactions between caregivers and babies begin to include *give-and-take,* as in pat-a-cake and peekaboo games. At first, the parent starts the game and the baby is an amused observer. But even 4-month-olds are sensitive to the structure and timing of these interactions, smiling more at an organized than a disorganized peekaboo exchange (Rochat, Querido, & Striano, 1999). By 12 months, babies participate actively, trading roles with the caregiver. As they do so, they practice the turn-taking pattern of human conversation, a vital context for acquiring language and communication skills. Infants' play maturity and vocalizations during games predict advanced language progress in the second year (Rome-Flanders & Cronk, 1995).

Around the first birthday, babies extend their joint attention and social interaction skills: They *point* toward an object or location while looking back toward the caregiver, in an effort to direct the adult's attention and influence their behavior. One-year-olds also grasp the communicative function of others' pointing. They interpret pointing to indicate the location of a hidden toy only when the adult also makes eye contact, not when the adult looks down at his finger (Liszkowski, Carpenter, & Tomasello, 2007; Tomasello, Carpenter, & Liszkowski, 2007).

© S. FELD/ROBERTSTOCK

This baby uses a preverbal gesture to draw his father's attention to the birdhouse. A verbal response from his father promotes the transition to spoken language.

Infant pointing leads to two communicative gestures. The first is the **protodeclarative,** in which the baby points to, touches, or holds up an object while looking at others to make sure they notice. In the second, the **protoimperative,** the baby gets another person to do something by reaching, pointing, and often making sounds at the same time (Carpenter, Nagell, & Tomasello, 1998a). Over time, some of these gestures become explicitly symbolic—much like those in children's early make-believe play (see Chapter 6). For example, a 1- to 2-year-old might flap her arms to indicate "butterfly" or raise her palms to signal "all gone" (Goldin-Meadow, 1999).

Besides using communicative gestures to serve their own goals, 12-month-olds adapt these gestures to the needs of others. In one study, they pointed more often to an object whose location a searching adult did not know than to an object whose location the adult did know (Liszkowski, Carpenter, & Tomasello, 2008). Already, the cooperative processes essential for effective communication—modifying messages to suit others' intentions and knowledge—are under way. Soon toddlers integrate words with gestures, using the gesture to expand their verbal message, as in pointing to a toy while saying "give" (Capirci et al., 2005). Gradually, gestures recede, and words become dominant.

Toddlers' use of preverbal gestures predicts faster early vocabulary growth in the second and third years (Brooks & Meltzoff, 2008; Rowe, Özçalişkan, & Goldin-Meadow, 2008). And the earlier toddlers form word–gesture combinations and the greater number they use, the sooner they produce two-word utterances at the end of the second year and the more complex their sentences at age 3½ (Özçalişkan & Goldin-Meadow, 2005; Rowe & Goldin-Meadow, 2009). Clearly gesture is at the cutting edge of early language development, serving as a steppingstone to more advanced constructions.

We have seen that caregivers who respond sensitively and involve infants in dialogue-like exchanges encourage early language progress. Yet in some cultures, such as the Kaluli of Papua New Guinea, the people of Western Samoa, and the Maya of southern Mexico, adults rarely communicate with young children and never play social games with them. Not until infants crawl and walk do siblings take charge, talk to toddlers, and respond to their vocalizations.

LOOK and LISTEN

Observe a 12- to 18-month-old for 30 to 60 minutes at home or child care, jotting down descriptions of preverbal gestures and word–gesture combinations. Does the toddler's use of gestures fit with research findings?

SOCIAL ISSUES: EDUCATION

Parent–Child Interaction: Impact on Language and Cognitive Development of Deaf Children

About 2 to 3 out of every 1,000 American infants is born profoundly or fully deaf (ASHA, 2011). When a deaf child cannot participate fully in communication with caregivers, development is severely compromised. Yet the consequences of deafness for children's language and cognition vary with social context, as revealed by comparing deaf children of hearing parents with deaf children of deaf parents.

Over 90 percent of deaf children have hearing parents who are not fluent in sign language. In toddlerhood and early childhood, these children often are delayed in development of language and make-believe play. In middle childhood, many achieve poorly in school, are deficient in social skills, and display impulse-control problems (Arnold, 1999; Edmondson, 2006). Yet deaf children of deaf parents escape these difficulties! Their language (use of sign), play maturity, and impulse control are on a par with hearing children's. After school entry, deaf children of deaf parents learn easily and get along well with adults and peers (Bornstein et al., 1999; Spencer & Lederberg, 1997).

These differences can be traced to early parent–child communication. Children with limited and less sensitive parental communication lag behind their agemates in achieving control over their behavior—in thinking before they act. Beginning in infancy, hearing parents of deaf children are less positive, less responsive to the child's efforts to communicate, less effective at achieving joint attention and turn-taking, less involved in play, and more directive and intrusive (Spencer, 2000; Spencer & Meadow-Orlans, 1996). In contrast, the quality of interaction between deaf children and deaf parents resembles that of hearing children and hearing parents.

Hearing parents are not to blame for their deaf child's problems. Rather, they lack experience with visual communication, which enables deaf parents to respond readily to a deaf child's needs. Deaf parents know they must wait for the child to turn toward them before interacting (Loots & Devise, 2003). Hearing parents tend to speak or gesture while the child's attention is directed elsewhere—a strategy that works with a hearing but not with a deaf partner. When the child is confused or unresponsive, hearing parents often feel overwhelmed and become overly controlling (Jamieson, 1995).

The impact of deafness on language and cognitive development can best be understood by considering how it affects parents and other significant people in the child's life. Deaf children need access to language models—deaf adults and peers—to experience natural language learning. And their hearing parents benefit from social support along with training in how to interact sensitively with a nonhearing partner.

Screening techniques can identify deaf babies at birth. Many U.S. states and an increasing number of Western nations require that every newborn be tested, enabling immediate enrollment in programs aimed at fostering effective parent–child interaction. When children with profound hearing loss start to receive intervention within the first year of life, they show much better language, cognitive, and social development (Vohr et al., 2008; Yoshinaga-Itano, 2003).

© ELLEN B. SENISI PHOTOGRAPHY

Unlike many hearing parents of deaf children, this mother is fluent in sign language. Using visual communication, she responds readily to her 3-year-old's efforts to communicate. Consequently, the child displays language progress typical for her age.

Yet Kaluli, Samoan, and Mayan children acquire language within the normal time frame (de León, 2000; Ochs, 1988).

These findings suggest that adult molding of communication during the first year is not essential. But by the second year, caregiver–child interaction contributes greatly to the transition to language. In observations of mother–child play at 9 and 13 months, the frequency with which mothers joined in the child's activity, offered verbal prompts, and imitated and expanded on the child's vocalizations predicted how early children attained major language milestones, including first words, a 50-word vocabulary, two-word combinations, and use of language to talk about the past. The relationship of maternal responsiveness to language progress was particularly strong at 13 months (Tamis-LeMonda, Bornstein, & Baumwell, 2001).

As the Social Issues: Education box above illustrates, when a child's disability makes it difficult for parents to engage in responsive communication, children show profound delays in both language and cognitive development. For ways that caregivers can support early language learning, see Applying What We Know on the following page.

APPLYING WHAT WE KNOW

Supporting Early Language Learning

STRATEGY	CONSEQUENCE
Respond to infants' coos and babbles with speech sounds and words.	Encourages experimentation with sounds that can later be blended into first words. Provides experience with the turn-taking pattern of human conversation.
Establish joint attention and comment on what the child sees.	Predicts earlier onset of language and faster vocabulary development.
Play social games, such as pat-a-cake and peekaboo, with infants and toddlers.	Provides experience with the turn-taking pattern of human conversation.
Engage children in frequent conversations.	Predicts faster early language development and later academic success.
Expand slightly on what the child just said, adding new information.	Saying something like, "You want juice? I have some juice. It's apple juice!" to a toddler models use of language just ahead of the child's current level, thereby promoting language progress.
Read to children often, engaging them in dialogues about picture books.	Provides exposure to many aspects of language, including vocabulary, grammar, communication skills, and information about written symbols and story structures important for literacy progress.

ASK YOURSELF

Review ■ Cite findings indicating that both infant capacities and caregiver communication contribute to prelinguistic development.

Connect ■ Explain how parents' use of infant-directed speech illustrates Vygotsky's zone of proximal development (see Chapter 6, pages 267–268).

Apply ■ Fran frequently corrects her 17-month-old son Jeremy's attempts to talk and—fearing that he won't use words—refuses to respond to his gestures. How might Fran be contributing to Jeremy's slow language progress?

Reflect ■ Find an opportunity to speak to an infant or toddler. How did your manner of speaking differ from the way you typically speak to an adult? What features of your speech are likely to promote early language development, and why?

Phonological Development

▶ Describe the course of phonological development.

TAKE A MOMENT... Listen in on a 1- to 2-year-old trying out her first handful of words. You will probably hear an assortment of interesting pronunciations ("nana" for "banana," "oap" for "soap," "weddy" for "ready"), as well as some wordlike utterances that do not resemble adult forms—for "translations," you must ask the toddler's parent. Phonological development is a complex process that depends on the child's ability to attend to sound sequences, produce sounds, and combine them into understandable words and phrases. Between 1 and 4 years, children make great progress at this task. In trying to talk like people around them, they draw on their impressive capacity to distinguish the phonemic categories of their native language, which is well developed by the end of the first year. They also adopt temporary strategies for producing sounds that bring adult words within their current range of physical and cognitive capabilities (Menn & Stoel-Gammon, 2009). Let's see how they do so.

The Early Phase

Children's first words are influenced in part by the small number of sounds they can pronounce (Stoel-Gammon, 2011; Stoel-Gammon & Sosa, 2007). The easiest sound sequences start with consonants, end with vowels, and include repeated syllables, as in "Mama," "Dada," "bye-bye," and "nigh-nigh" (for "night-night"). Sometimes young speakers use the same sound to represent a variety of words, making their speech hard to understand (Ingram, 1999). For example, one toddler substituted "bat" for as many as 12 different words, including "bad," "bark," "bent," and "bite."

Research confirms that toddlers and young preschoolers with more words in their spoken vocabularies can pronounce more speech sounds and syllable structures (Smith, McGregor, & Demille, 2006; Stoel-Gammon, 2011). Fortunately, languages cater to young children's phonological limitations. Throughout the world, sounds resembling "Mama," "Dada," and "Papa" refer to parents, so it is not surprising that these are among the first words produced by children everywhere. Also, in infant-directed speech, adults often use simplified words to talk about things of interest to toddlers—"bunny" for rabbit, "choo-choo" for train. These word forms support the child's first attempts to talk.

One-year-olds first learning to talk know how familiar words—such as *dog, baby,* and *ball*—are supposed to sound, even when they mispronounce them. Researchers showed 14-month-olds pairs of objects (such as a baby and a dog), accompanied by a voice speaking the word for one of the objects, with either correct pronunciation ("baby"), slight mispronunciation ("vaby"), or considerable mispronunciation ("raby") (Swingley & Aslin, 2002). The toddlers easily detected the correct pronunciation: They looked longer at the appropriate object when a word was pronounced correctly than when it was either mildly or extremely mispronounced (see Figure 9.4). And they respond this way to mispronunciations of either beginning or ending consonants (Swingley, 2009).

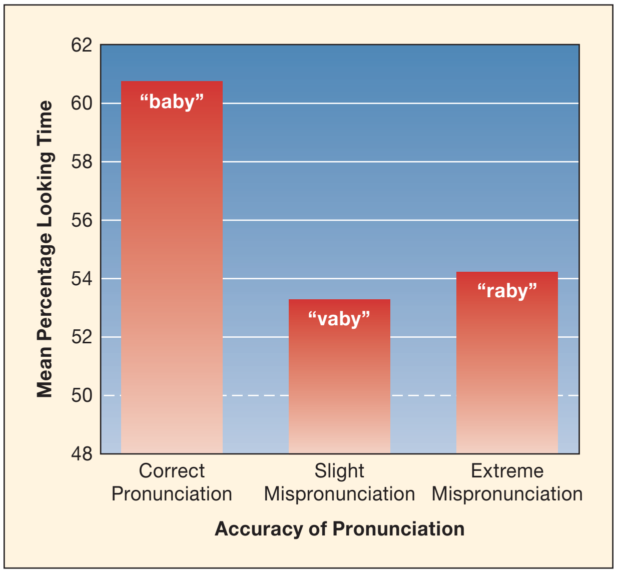

FIGURE 9.4 **One-year-olds know the correct pronunciation of familiar words.** Babies viewed pairs of familiar objects (such as a baby and a dog) accompanied by a voice speaking the word for one of the objects with either correct pronunciation ("baby"), slight mispronunciation ("vaby"), or considerable mispronunciation ("raby"). They looked longest at the appropriate object when a word was pronounced correctly. In each condition, time spent looking at the correct object exceeded 50 percent, indicating that babies recognized the words whether or not they were pronounced correctly. (Adapted from Swingley & Aslin, 2002.)

Nevertheless, when learning a new word, toddlers often do not pick up the fine details of its sounds, which contributes to their pronunciation errors. In several studies, 14-month-olds were unable to associate two similar-sounding nonsense words ("bih" and "dih") with different objects, despite easily detecting the "b"–"d" contrast in sound discrimination tasks (Fennell & Werker, 2003; Stager & Werker, 1997). Why don't toddlers apply their impressive sensitivity to speech sounds when acquiring new words? Associating words with their referents places extra demands on toddlers' limited working memories. Intent on communicating, they focus on the word–referent pairing while sacrificing the word's sounds, which they encode imprecisely.

As toddlers' vocabularies increase, they become better at using their perceptual abilities to distinguish similar-sounding new words. Once they acquire several sets of words that sound alike, they may be motivated to attend more closely to fine-grained distinctions between others.

Phonological Strategies

By the middle of the second year, children move from trying to pronounce whole syllables and words to trying to pronounce each individual sound within a word. As a result, they can be heard experimenting with phoneme patterns. One 21-month-old pronounced "juice" as "du," "ju," "dus," "jus," "sus," "zus," "fus," "tfus," "jusi," and "tfusi" within a single hour (Fee, 1997). This marks an intermediate phase of development in which pronunciation is partly right and partly wrong. Because young children get more practice perceiving and producing phoneme patterns that occur frequently in their language, they pronounce words containing those patterns more accurately and rapidly (Majorano & D'Odorico, 2011; Zamuner, Gerken, & Hammond, 2004). Unique-sounding words are generally difficult to pronounce. A close look reveals that children apply systematic strategies to challenging words so that these words fit with their pronunciation capacities yet resemble adult utterances. Although individual differences exist in the precise strategies that children adopt (see Table 9.1 for examples), they follow a general developmental pattern (Vihman, 1996).

At first, children produce *minimal words,* focusing on the stressed syllable and trying to pronounce its consonant–vowel combination ("du" or "ju" for "juice"). Soon they add ending consonants ("jus"), adjust vowel length ("beee" for "please"), and add unstressed syllables ("mae-do" for "tomato"). Finally, they produce the full word with a correct stress pattern, although they may still need to refine its sounds ("timemba" for "remember," "pagetti" for "spaghetti") (Demuth, 1996; Salidis & Johnson, 1997).

Children's errors are similar across a range of languages, including Cantonese, Czech, English, French, Italian, Quiché (a Guatemalan Mayan language), Spanish, and Swedish. But rate of phonological progress depends on the complexity of a language's sound system and the importance of certain sounds for conveying meaning. Cantonese-speaking children, for example, develop more quickly than English-speaking children. Many Cantonese words are single syllables, but a change in a syllable's tone can change its meaning. Chinese children master this tone system by age 2 (So & Dodd, 1995). Among children acquiring English, "v" is a late-appearing sound, whereas Swedish children master it early. In English, "v" is relatively infrequent; in Swedish, it is common and vital for distinguishing words (Ingram, 1999).

TABLE 9.1 Common Phonological Strategies Used by Young Children to Simplify Pronunciation of Adult Words

STRATEGY	EXAMPLE
Repeating the first consonant-vowel in a multisyllable word	"TV" becomes "didi," "cookie" becomes "gege."
Deleting unstressed syllables in a multisyllable word	"Banana" becomes "nana," "giraffe" becomes "raffe."
Replacing fricatives (hissing sounds) with stop consonant sounds	"Sea" becomes "tea," "say" becomes "tay."
Replacing consonant sounds produced in the rear and palate area of the vocal tract with ones produced in the frontal area	"Kid" becomes "tid," "goose" becomes "doose."
Replacing liquid sounds ("l" or "r") with glides ("y" or "w")	"Lap" becomes "yap," "ready" becomes "weddy."
Deleting the final consonant of a word	"Bike" becomes "bai," "more" becomes "muh," "bottom" becomes "bada."
Reducing a consonant cluster to a single consonant	"Clown" becomes "cown," "play" becomes "pay."

Source: Ingram, 1986.

Over the preschool years, children's pronunciation improves greatly. Maturation of the vocal tract and the child's active problem-solving efforts are largely responsible, since children's phonological errors are resistant to adult correction. One father tried repeatedly to get his 2½-year-old daughter to pronounce the word "music," but she persisted with "ju-jic." When her father made one last effort, she replied, "Wait 'til I big. Then I say 'ju-jic,' Daddy!"

Later Phonological Development

Although phonological development is largely complete by age 5, a few syllable stress patterns signaling subtle differences in meaning are not acquired until middle childhood or adolescence. For example, when shown pairs of pictures and asked to distinguish the "greenhouse" from the "green house," most children recognized the correct label by third grade and produced it between fourth and sixth grade (Atkinson-King, 1973). Changes in syllabic stress when certain abstract words take on endings ("humid" to "humidity," "method" to "methodical") are not mastered until adolescence (Camarata & Leonard, 1986).

These late attainments are probably affected by the semantic complexity of the words, in that hard-to-understand words are also more difficult to pronounce. Even at later ages, working simultaneously on the sounds and meaning of a new word may overload the cognitive system, causing children to sacrifice pronunciation temporarily until they better grasp the word's meaning.

ASK YOURSELF

Review ■ Why do young toddlers often fail to pick up the fine details of a new word's sounds, even though they can perceive those sounds?

Apply ■ As his father placed a bowl of pasta on the dinner table, 2-year-old Luke exclaimed, "So 'licious!" Explain Luke's phonological strategy.

Reflect ■ For one week, keep a log of words you mispronounce or do not pronounce fluently (you slow down to say them). Are they words that convey complex concepts or words with sounds that are relatively infrequent in English or in your native tongue? Research indicates that these factors, which affect children's pronunciation, also affect the pronunciation of adults.

- Summarize the course of semantic development, noting individual differences.
- Discuss ideas about how semantic development takes place, including the influence of memory and strategies for word learning.

Semantic Development

Word comprehension begins in the middle of the first year. When 6-month-olds listened to the words "Mommy" and "Daddy" while looking at side-by-side videos of their parents, they looked longer at the video of the named parent (Tincoff & Jusczyk, 1999). At 9 months, after hearing a word paired with an object, babies looked longer at other objects in the same category than at those in a different category (Balaban & Waxman, 1997). On average, children say their first word around 12 months. By age 6, they understand the meaning of about 10,000 words (Bloom, 1998). To accomplish this feat, children learn about five new words each day.

As these achievements reveal, children's **comprehension,** the language they understand, develops ahead of **production,** the language they use. For example, toddlers follow many simple directions ("Bring me your book," "Don't touch the lamp") even though they cannot yet express all these words in their own speech. A five-month lag exists between the time English-speaking toddlers comprehend 50 words (around 13 months) and the time they produce that many (around 18 months) (Menyuk, Liebergott, & Schultz, 1995).

Think back to the distinction made in Chapter 7 between two types of memory—recognition and recall. Comprehension requires only that children *recognize* the meaning of a word. But for production, children must *recall,* or actively retrieve from their memories, not only the word but also the concept for which it stands. Still, the two capacities are related. The speed and accuracy of toddlers' comprehension of spoken language increase dramatically over the second year. And toddlers who are faster and more accurate in comprehension tend to show more rapid growth in words understood and produced as they approach age 2 (Fernald, Perfors, & Marchman, 2006). Quick comprehension frees space in working memory for picking up new words and for the more demanding task of using them to communicate.

TABLE 9.2 Rank-Ordered Top 20 Earliest Words Produced by U.S. and Chinese (Mandarin- and Cantonese-Speaking) Toddlers

ENGLISH (UNITED STATES)	MANDARIN (HONG KONG)	CANTONESE (BEIJING)
Daddy	**Daddy**	**Mommy**
Mommy	Aah	**Daddy**
BaaBaa	**Mommy**	*Grandma (paternal)*
Bye	*YumYum*	*Grandpa (paternal)*
Hi	Sister (older)	**Hello**
UhOh	**UhOh**	*Hit*
Grr	Hit	Uncle (paternal)
Bottle	**Hello**	Grab/Grasp
YumYum	Milk	*Auntie (maternal)*
Dog	Naughty	**Bye**
No	*Brother (older)*	**UhOh**
WoofWoof	*Grandma (maternal)*	Ya/Wow
Vroom	*Grandma (paternal)*	*Sister (older)*
Kitty	**Bye**	**WoofWoof**
Ball	Bread	*Brother (older)*
Baby	*Auntie (maternal)*	Hug/Hold
Duck	Ball	Light
Cat	*Grandpa (paternal)*	*Grandma (maternal)*
Ouch	Car	Egg
Banana	**WoofWoof**	*Vroom*

Note. All words translated into English equivalents. Boldface words are common across all three languages. Italicized words are common across two languages.

Source: T. Tardif, P. Fletcher, W. Liang, Z. Zhang, N. Kaciroti, & V. A. Marchman, 2008, "Baby's First 10 Words," *Developmental Psychology, 44,* p. 932, Copyright © 2008 by the American Psychological Association. Reprinted with permission of the American Psychological Association.

The Early Phase

To learn words, children must identify which concept each label picks out in their language community. **TAKE A MOMENT...** Ask several parents to list their toddlers' first spoken words. Notice how these words build on the sensorimotor foundations Piaget described and on categories infants have formed (see Chapter 6). In a study tracking the first 10 words used by several hundred U.S. and Chinese (both Mandarin- and Cantonese-speaking) babies, important people ("Mama," "Dada"), common objects ("ball," "bread"), and sound effects ("woof-woof," "vroom") were mentioned most often. And as Table 9.2 shows, action words ("hit," "grab," "hug") and social routines ("hi," "bye"), though also appearing frequently in all three groups, were more often produced by Chinese than U.S. babies, who also named more important people—cultural differences we will consider shortly (Tardif et al., 2008). Other investigations concur that earliest words usually include people, objects that move, foods, animals (in families with pets), familiar actions ("hug"), outcomes of such actions ("hot," "ouch"), and social terms (Hart, 2004; Nelson, 1973). In their first 50 words, toddlers rarely name things that just sit there, like "table" or "vase."

Young toddlers add to their vocabularies slowly, at a pace of one to three words per week. Gradually, the number of words learned accelerates. The increase is much more rapid in comprehension than in production, as illustrated by English and Italian learners' vocabulary growth between 8 and 16 months, shown in Figure 9.5 (Caselli et al., 1995). Because rate of word learning between 18 and 24 months is so impressive (one or two words per day), many researchers concluded that toddlers undergo a *spurt in vocabulary*—a transition between a slow and a faster learning phase once the number of words produced reaches 50 to 100. But recent evidence indicates that most children do not experience a vocabulary spurt (Ganger & Brent, 2004). Rather, they show a steady, continuous increase in rate of word learning that persists through the preschool years, when children add as many as nine new words per day.

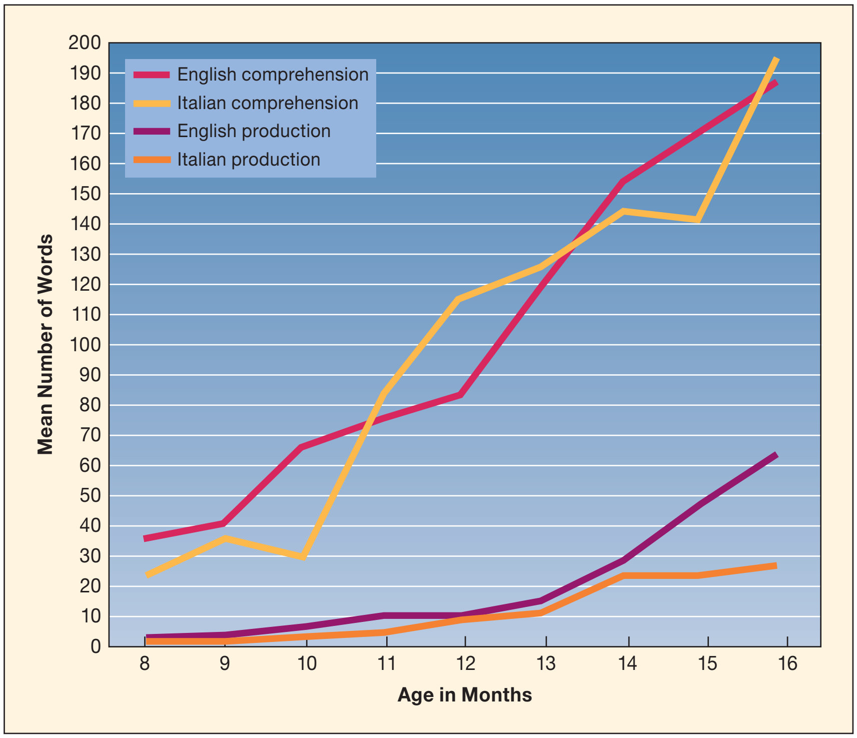

FIGURE 9.5 English and Italian learners' vocabulary growth between 8 and 16 months. Rate of word learning gradually accelerates. The increase in vocabulary size is far more rapid in comprehension than in production. (Reprinted from *Cognitive Development,* Vol. 10, No. 2, M. C. Caselli, et al., "A Cross-Linguistic Study of Early Lexical Development," p. 172, copyright 1995, with permission from Elsevier.)

How do young children build their vocabularies so quickly? An improved ability to categorize experience (see Chapter 6), recall words, and pronounce new words is involved (Dapretto & Bjork, 2000; Stoel-Gammon, 2011). In addition, a better grasp of others' intentions, evident in toddlers' imitation around 18 months (see page 233), supports rapid vocabulary growth because it helps toddlers figure out what others are talking about (Golinkoff & Hirsh-Pasek, 2006; Tomasello, 2003). Furthermore, as toddlers' experiences broaden, they have a wider range of interesting objects and events to label. For example, children approaching age 2 more often mention places to go ("park," "store"). And as they construct a clearer self-image, they add more words that refer to themselves ("me," "mine," "Katy"), to their own and others' bodies and clothing ("eyes," "mouth," "jacket"), and to their attitudes, desires, and emotions ("like," "want," "happy," "mad,") (Hart, 2004).

Researchers have discovered that children can connect a new word with an underlying concept after only a brief encounter, a process called **fast-mapping.** Even 15- to 18-month-olds comprehend new labels remarkably quickly, but they need more repetitions of the word's use across several situations than preschoolers, who process speech-based information faster and are better able to categorize and recall it (Akhtar & Montague, 1999; Fernald, Perfors, & Marchman, 2006).

Toddlers' understanding of a fast-mapped word is incomplete at first, deepening with repeated exposure (Swingley, 2010). They start to form networks of related concepts and words, which help them fast-map new words, contributing to the age-related increase in rate of word learning. In one study, researchers gave 18-month-olds extended training on a set of novel words in 12 weekly sessions by showing the child pictures and talking about word meanings ("See the *crab.* The *crab* lives in the ocean"). Compared with no-practice controls, trained toddlers acquired a second set of novel words far more rapidly (Gershkoff-Stowe & Hahn, 2007). And preschoolers become adept at fast-mapping two or more new words encountered in the same situation (Wilkinson, Ross, & Diamond, 2003).

Individual and Cultural Differences

Although children typically produce their first word around their first birthday, the range is large, from 8 to 18 months—variation due to a complex blend of genetic and environmental influences. Many studies show that girls are slightly ahead of boys in early vocabulary growth (Fenson et al., 1994; Van Hulle, Goldsmith, & Lemery, 2004). The most common biological explanation is girls' faster rate of physical maturation, which is believed to promote earlier development of the left cerebral hemisphere.

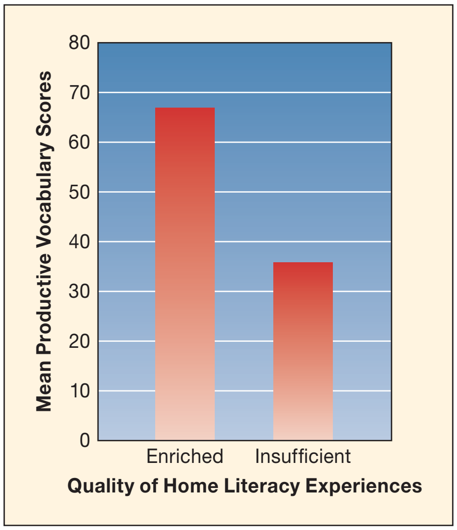

FIGURE 9.6 **Relationship of quality of home literacy experiences to productive vocabulary scores at age 2.** In families diverse in SES, 2-year-olds with rich home literacy experiences (access to many age-appropriate books and frequent participation in joint adult–child book-reading) had vocabularies that were far larger than those of 2-year-olds with insufficient literacy experiences. (Adapted from Tamis-LeMonda et al., 2006.)

Temperament matters, too. Shy toddlers often wait until they understand a great deal before trying to speak. Once they do speak, their vocabularies increase rapidly, although they remain slightly behind their agemates in language skills during the preschool years (Spere et al., 2004). Temperamentally negative toddlers also acquire language more slowly (Salley & Dixon, 2007). Their high emotional reactivity diverts them from processing linguistic information, and their relationships with caregivers are often conflict-ridden and, therefore, poorly suited to promoting language progress.

The quantity of caregiver–child conversation and richness of adults' vocabulary also play a strong role (Zimmerman et al., 2009). Commonly used words for objects appear early in toddlers' speech (refer again to Table 9.2), and the more often caregivers use a particular noun, the earlier that noun will become part of young children's productive vocabularies (Goodman, Dale, & Li, 2008). Mothers talk more to toddler-age girls than to boys, and parents converse less often with shy than with sociable children (Leaper, Anderson, & Sanders, 1998; Patterson & Fisher, 2002).

Low-SES children, who receive less verbal stimulation in their homes than higher-SES children, usually have smaller vocabularies (Hoff, 2006). In addition to amount and quality of parent–child interaction, limited parent–child book reading contributes substantially (see page 308 in Chapter 7). As Figure 9.6 shows, as early as 2 years of age, quality of children's home literacy experiences strongly predicts vocabulary size (Tamis-LeMonda et al., 2006).

Furthermore, properties of the child's native language are influential. Two-year-olds' spoken vocabularies vary substantially across languages—for example, about 180 to 200 words for children acquiring Swedish, 250 to 300 words for children acquiring English, and 500 words for children acquiring Mandarin Chinese (Bleses et al., 2008; Tardif et al., 2009). In Swedish, a complicated phonology makes syllable and word boundaries challenging to discriminate and pronounce. In contrast, Mandarin Chinese presents children with many short words that have easy-to-pronounce initial consonants. Within Mandarin words, each syllable is given one of four distinct tones, aiding discrimination.

Young children also have unique styles of early language learning, which affect early vocabulary development. Most toddlers use a **referential style;** their vocabularies consist mainly of words that refer to objects. A smaller number of toddlers use an **expressive style;** compared with referential children, they initially produce many more social formulas and pronouns ("thank you," "done," "I want it"), uttered as compressed phrases that sound like single words ("Iwannit"). Recall, from the opening to this chapter, Erin's early use of largely expressive-style words. These language styles reflect early ideas about the functions of language. Referential-style toddlers think words are for naming things, whereas expressive-style toddlers believe words are for talking about people's feelings and needs. The vocabularies of referential-style children grow faster because all languages contain many more nouns than social terms (Bates et al., 1994).

What accounts for a toddler's language style? Rapidly developing referential-style children often have an especially active interest in exploring objects. They also eagerly imitate their parents' frequent naming of objects, and their parents imitate back—a strategy that supports swift vocabulary growth by helping children remember new labels (Masur & Rodemaker, 1999). Expressive-style toddlers tend to be highly sociable, and their parents more often use verbal routines ("How are you?" "It's no trouble") that support social relationships (Goldfield, 1987).

The two language styles are also linked to culture. Nouns are particularly common in the vocabularies of English-speaking toddlers, but Chinese, Japanese, and Korean toddlers have more words for social routines. Mothers' speech in each culture reflects this difference (Choi & Gopnik, 1995; Fernald & Morikawa, 1993; Tardif, Gelman, & Xu, 1999). American mothers frequently label objects when interacting with their babies. Asian mothers, perhaps because of a cultural

This Chinese mother's communication with her toddler probably includes many words for social routines. As a result, the toddler is likely to display an expressive style of early language learning, focused on building social relationships.

emphasis on the importance of group membership, teach social routines as soon as their children begin to speak.

Notice how these findings support the social interactionist perspective: Children's inner dispositions and their linguistic and social worlds combine to influence both rate and makeup of early language progress.

Types of Words

Three types of words—object, action, and state—are most common in young children's vocabularies. Each provides important information about the course of semantic development.

Object and Action Words. Young language learners in many cultures have more object than action words in their beginning vocabularies (Bornstein & Cote, 2004; Kern, 2007). If actions are an especially important means through which infants learn about their world, why this early emphasis on naming objects?

One reason is that nouns refer to concepts (such as *table, bird,* or *dog*) that are easy to perceive (Gentner & Namy, 2004). When adults point to, label, and talk about an object, they help the child discern the word's meaning. In contrast, verbs require more complex understandings—of relationships between objects and actions. And when adults use a verb, the selected action usually is not taking place (Poulin-Dubois & Forbes, 2006). A parent who says the word *move* is probably referring to a past event ("Someone *moved* the bowl") or a future event ("Let's *move* the bowl"). Because learning verbs is more cognitively challenging, preschoolers speaking quite different languages take longer to extend a new verb ("*push* the bike") to other instances of the same action ("*push* the box") than they do to extend a novel noun to other objects in the same category (Imai et al., 2008). In mastering verb meanings, they benefit from many examples of the same verb used in different contexts.

Nevertheless, young children learning Chinese, Japanese, and Korean—languages in which nouns are often omitted from adults' sentences, while verbs are stressed—acquire verbs more readily than their English-speaking agemates (Kim, McGregor, & Thompson, 2000; Tardif, 2006). Besides increased exposure to verbs, Chinese-speaking children hear a greater variety of verbs denoting physical actions, which are easiest to master—for example, several verbs for *carry,* each referring to a different way of carrying, such as on one's back, in one's arms, or with one's hands (Ma et al., 2009).

© ELLEN B. SENISI PHOTOGRAPHY

As this mother labels objects, her daughter adds those words to her growing vocabulary. In young language learners, acquisition of nouns often precedes verbs because nouns refer to easy-to-perceive concepts.

State Words. Between 2 and 2½ years, children's use of *state* (or modifier) words expands to include labels for attributes of objects, such as size and color ("big," "red") and possession ("my toy," "Mommy purse"). Words referring to the functions of objects ("dump truck," "pickup truck") appear soon after (Nelson, 1976).

When state words are related in meaning, general distinctions (which are easier) appear before more specific ones. Thus, among words referring to the size of objects, children first acquire *big–small,* then *tall–short, high–low,* and *long–short,* and finally *wide–narrow* and *deep–shallow.* The same is true for temporal terms. Between ages 3 and 5, children first master *now–then* and *before–after,* followed by *today–yesterday* and *today–tomorrow* (Stevenson & Pollitt, 1987).

State words referring to object location provide additional examples of how cognition influences vocabulary development. Before age 2, children can easily imitate an adult's action in putting an object *in* or *on* another object, but they have trouble imitating the placement of one object *under* another. These terms appear in children's vocabularies in just this order, with all three achieved around age 2½ (Clark, 1983).

Because state words refer to qualities of objects and actions, children can use them to express a wide variety of concepts. As preschoolers master these words, their language becomes increasingly flexible.

LOOK and LISTEN

Ask several parents of 15- to 20-month-olds to list all the words their child uses. Are the relative numbers of object, action, and state words consistent with research evidence? Ask the parents for examples of underextensions and overextensions.

Underextensions and Overextensions

When young children first learn words, they often do not use them just as adults do. They may apply words too narrowly, an error called **underextension.** At 16 months, my younger son used the word "bear" to refer only to a special teddy bear to which he had become attached. A more common error between 1 and 2½ years is **overextension**—applying a word to a wider collection of objects and events than is appropriate. For example, a toddler might use the word “car” for buses, trains, trucks, and fire engines.

Toddlers’ overextensions reflect their remarkable sensitivity to categorical relations. They apply a new word to a group of similar experiences, such as “dog” for any furry, four-legged animal or “open” to mean opening a door, peeling fruit, and untying shoe laces. Furthermore, the toddler who refers to trucks, trains, and bikes as “cars” is likely to point to these objects correctly when given their names in comprehension tasks (Naigles & Gelman, 1995). This suggests that children often overextend deliberately because they have difficulty recalling or have not acquired a suitable word. And when a word is hard to pronounce, toddlers frequently substitute a related one they can say (Bloom, 2000). As vocabulary and pronunciation improve, overextensions disappear.

© ELLEN B. SENISI PHOTOGRAPHY

When asked to name items their teacher removes from the can, these toddlers are likely to make the error of overextension—for example, call all the vehicles “cars.” But they identify the objects accurately when the teacher names them.

Word Coinages and Metaphors Children as young as age 2 fill in for words they have not yet learned by coining new words based on ones they know—for example, “plant-man” for a gardener, or “crayoner” for a child using crayons. These early expressions reveal a remarkable, rule-governed approach to language.

Preschoolers also extend language meanings through metaphor—like the 3-year-old who described a stomachache as a “fire engine in my tummy” (Winner, 1988). Young preschoolers’ metaphors involve concrete, sensory comparisons: “Clouds are pillows,” “Leaves are dancers.” As their vocabulary and knowledge of the world expand, children appreciate nonsensory comparisons: “Friends are like magnets,” “Time flies by” (Keil, 1986; Özçalişkan, 2005). Metaphors permit children to communicate in especially vivid and memorable ways.

Later Semantic Development

During the elementary school years, vocabulary increases fourfold, eventually exceeding comprehension of 40,000 words (Anglin, 1993). On average, children learn about 20 new words each day, a rate of growth greater than in early childhood (see Figure 9.7). In addition to fast-mapping, older school-age children, especially those with excellent reading comprehension, enlarge their vocabularies by analyzing the structure of complex words. From *happy* and *decide,* they can derive the meanings of *happiness* and *decision* (Larsen & Nippold, 2007). They also figure out many more word meanings from context (Nagy & Scott, 2000).

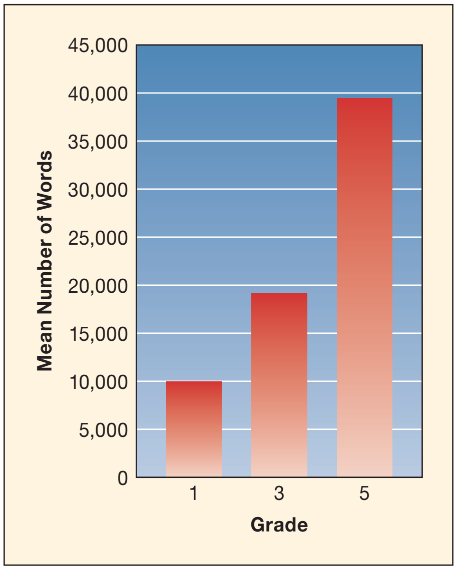

FIGURE 9.7 **Estimated increase in vocabulary during the school years.** Increase in word comprehension from grades 1 to 5 exceeds that of early childhood. (Adapted from Anglin, 1993.)

As at earlier ages, children benefit from engaging in conversation with more expert speakers, especially when their partners use and explain complex words (Weizman & Snow, 2001). But because written language contains a far more diverse and complex vocabulary than spoken language, reading contributes enormously to vocabulary growth. Children who engage in as little as 21 minutes of independent reading per day are exposed to nearly 2 million words per year (Cunningham & Stanovich, 1998).

As their knowledge expands and becomes better organized (see Chapter 7), older school-age children think about and use words more precisely: In addition to the verb *fall,* for example, they also use *topple, tumble,* and *plummet* (Berman, 2007). Word definitions also illustrate this change. Five- and 6-year-olds offer concrete descriptions referring to functions or appearance—*knife:* “when you’re cutting carrots”; *bicycle:* “it’s got wheels, a chain, and handlebars.” By the end of elementary school, synonyms and explanations of categorical relationships appear—*knife:* “Something you could cut with. A saw is like a knife. It could also be a weapon” (Wehren, De Lisi, & Arnold, 1981). This advance reflects older children’s ability to deal with word meanings on an entirely verbal plane. They can add new words to their vocabulary simply by being given a definition.

School-age children's more reflective and analytical approach to language permits them to appreciate the multiple meanings of words—to recognize, for example, that many words, such as *cool* or *neat,* have psychological as well as physical meanings: "What a cool shirt!" or "That movie was really neat!" This grasp of double meanings permits 8- to 10-year-olds to comprehend subtle metaphors, such as "sharp as a tack" and "spilling the beans" (Nippold, Taylor, & Baker, 1996; Wellman & Hickling, 1994). It also leads to a change in children's humor. Riddles and puns that alternate between different meanings of a key word are common: "Hey, did you take a bath?" "Why, is one missing?"

As they transition to adolescence, young people add a variety of abstract words—*counterintuitive, revolutionized, philosophy*—to their vocabularies. They also master sarcasm and irony and appreciate the difference between the two—that sarcasm is a critical comment directed at a specific target, whereas irony expresses unmet expectations that are not the fault of anyone in particular (Glenwright & Pexman, 2010; Winner, 1988). After his mother prepares a dish for dinner that he dislikes, an 11-year-old might quip sarcastically, "Oh boy, my favorite!" School-age children sometimes realize that a sarcastic remark is insincere if it is said in an exaggerated, mocking tone of voice. But adolescents need only notice the discrepancy between a statement and its context to grasp the intended meaning (Capelli, Nakagawa, & Madden, 1990).

Similarly, grasp of figurative language improves greatly in adolescence. Proverbs—especially those that express subtle attitudes—are especially challenging. They can be used to comment ("Blood is thicker than water"), interpret ("His bark is worse than his bite"), advise ("Humility often gains more than pride"), warn ("Of idleness comes no goodness"), and encourage ("Every cloud has a silver lining"). As with other aspects of semantic development, reading proficiency fosters understanding of proverbs (Nippold, Allen, & Kirsch, 2001). And a better grasp of figurative language enables teenagers to appreciate adult literary works.

LOOK and LISTEN

Record examples of 8- to 10-year-olds' humor, or examine storybooks for humor aimed at second through fourth graders. Does it require a grasp of the multiple meanings of words?

Ideas About How Semantic Development Takes Place

Research shows that adult feedback facilitates semantic development. When adults go beyond correcting and explain ("That's not a car. It's a truck. See, it has a place to put things in"), toddlers are more likely to move toward conventional word meanings (Chapman, Leonard, & Mervis, 1986). Still, adults cannot tell children exactly what concept each new word picks out. If an adult points to a dog and says, "doggie," the word may refer to any four-legged animal, the dog's shaggy ears, or its barking sound. Therefore, the child's cognitive processing must play a major role.

The Influence of Memory Young children's fast-mapping is supported by a special part of short-term memory, a **phonological store** that permits us to retain speech-based information. The faster preschoolers can recall a just-presented sequence of nonsense words (a measure of phonological memory skill), the larger their current vocabulary and the greater their vocabulary growth over the following year (Gathercole et al., 1999; Parra, Hoff, & Core, 2010). This suggests that a child with good phonological memory has a better chance of transferring new words to long-term memory and linking them with relevant concepts.

By the end of the second year, phonological memory is so good that toddlers can recognize familiar words on the basis of their initial sounds. When given only the first two or three phonemes of a word they know ("ba" for "baby," "daw" for "doggie"), 18- to 24-month-olds looked at the correct object, responding as accurately and quickly as they did to the whole word. Furthermore, toddlers with better verbal recognition scores had larger productive vocabularies (Fernald, Swingley, & Pinto, 2001). Early in development, phonological memory is linked to advanced vocabulary development. Being able to identify a word rapidly on the basis of initial sounds has clear advantages: It frees working memory for other language tasks, such as comprehending longer and more complex strings of words.

But phonological memory does not provide a full account of word learning. After age 5, semantic knowledge influences the speed with which children form phonological traces, and both factors affect vocabulary growth (Gathercole et al., 1997). Even at younger ages (as we will see next), children rely heavily on words they know to detect the meanings of new ones.

Strategies for Word Learning Young children figure out the meanings of words by contrasting them with words they already know and assigning the new label to a gap in their vocabulary. On hearing a new word in conversation, 2-year-olds repeat the word or acknowledge it with "yeah" or "uh-huh" in their next verbalization more than 60 percent of the time (Clark, 2007). These findings suggest that they assign the word a preliminary meaning and start to use it right away. Over time, they refine the word's meaning, striving to match its conventional use in their language community.

When learning a new noun, toddlers and preschoolers acquiring diverse languages tend to assume it refers to an object category at the basic level—an intermediate level of generality (see page 247 in Chapter 6). This preference helps young children narrow the range of possible meanings. Once they acquire a basic-level name *(dog),* they add names at other hierarchical levels, both more general *(animal)* and more specific *(beagle, greyhound)* (Imai & Haryu, 2004; Waxman & Lidz, 2006).

How do children discover which concept each word picks out? This process is not yet fully understood. One speculation is that early in vocabulary growth, children adopt a **mutual exclusivity bias**—the assumption that words refer to entirely separate (nonoverlapping) categories (Markman, 1992). Two-year-olds seem to rely on mutual exclusivity when the objects named are perceptually distinct—for example, differ clearly in shape. After hearing the names for two distinct novel objects (a clip and a horn), they assign each word correctly, to the whole object and not to a part of it (Waxman & Senghas, 1992).

Indeed, children's first several hundred nouns refer mostly to objects well-organized by shape. Once toddlers have acquired about 75 words, a **shape bias** is clearly evident: Previous learning of nouns based on shape heightens attention to the shape properties of additional objects. In research in which toddlers repeatedly played with and heard names for novel objects of different shapes ("That's a *wif* ") over a nine-week period, they soon formed the generalization that only similarly shaped objects have the same name (Smith et al., 2002; Yoshida & Smith, 2003). Toddlers with this training added more than three times as many object names to their vocabularies outside the laboratory as did untrained controls. Because shape is a perceptual property relevant to most object categories for which young preschoolers have already learned names, the shape bias helps them master additional names of objects, and vocabulary accelerates.

Once the name of a whole object is familiar, on hearing a new name for the object, 2- and 3-year-olds set aside the mutual exclusivity assumption. For example, if the object *(bottle)* has a part that stands out *(spout),* children readily apply the new label to it (Hansen & Markman, 2009). In these instances, mutual exclusivity helps limit the possibilities the child must consider. Still, mutual exclusivity and object shape cannot account for preschoolers' remarkably flexible responses when objects have more than one name.

© LAURA DWIGHT PHOTOGRAPHY

As her sister says, "It's a bus!," this 17-month-old points at a picture of a school bus while holding a toy bus in her hand. Heightened attention to object shape helps toddlers master object names rapidly.

By age 3, preschoolers' memory, categorization, and language skills have expanded, and they readily assign multiple labels to many objects (Deák, Yen, & Pettit, 2001). For example, they refer to a sticker of a gray goose as "sticker," "goose," and "gray." Children often call on other components of language for help in these instances. According to one proposal, preschoolers discover many word meanings by observing how words are used in syntax, or the structure of sentences—a hypothesis called **syntactic bootstrapping** (Gleitman et al., 2005; Naigles & Swenson, 2007). Consider an adult who says, "This is a *citron* one," while showing a child a yellow car. Two- and 3-year-olds conclude that a new word used as an adjective for a familiar object (car) refers to a property of that object (Hall & Graham, 1999; Imai & Haryu, 2004). As preschoolers hear the word in various sentence structures ("That lemon is bright *citron*"), they use syntactic information to refine the word's meaning and generalize it to other categories.

Young children also take advantage of the rich social information that adults frequently provide when they introduce new words. For example, they often draw on their expanding ability to infer others' intentions and perspectives (Akhtar & Tomasello, 2000). In one study, an adult performed an action on an object and then used a new label while looking back and forth between the child and the object, as if to invite the child to play. Two-year-olds concluded that the label referred to the action, not the object (Tomasello & Akhtar, 1995). Toddlers can even accurately interpret an adult's ambiguous request for an object ("Where's the ball?") by referring to their recent experience with that adult. They retrieve the particular object the adult had just played with (ball in a red bucket), not an identical object that another adult played with (ball in a blue bucket) (Saylor & Ganea, 2007). And 3-year-olds use information about a speaker's recently expressed desires (recalling which of two novel objects an adult said she liked) to figure out a word referent ("I really want to play with the *riff*") (Saylor & Troseth, 2006).

Adults also inform children directly about word meanings. Parents commonly highlight the meaning of adjectives by using the new label with several objects (a "red car," a "red truck")—information that helps children infer that the word refers to an object property (Hall, Burns, & Pawluski, 2003). And adults often explain which of two or more words to use, saying, for example: "You can call it a sea creature, but it's better to say *dolphin*." Parents who provide such clarifying information have preschoolers whose vocabularies grow more quickly (Callanan & Sabbagh, 2004; Deák, 2000).

Explaining Vocabulary Development

Children acquire vocabulary so efficiently and accurately that some theorists believe that they are innately biased to induce word meanings using certain principles, such as mutual exclusivity and syntactic bootstrapping (Lidz, Gleitman, & Gleitman, 2004; Woodward & Markman, 1998). But critics observe that a small set of built-in, fixed principles is not sufficient to account for the varied, flexible manner in which children master vocabulary (Deák, 2000). And many word-learning strategies cannot be innate because children acquiring different languages use different approaches to mastering the same meanings. For example, English-speaking children rely on syntactic bootstrapping to tell the difference between one object ("This is *a dax*"), multiple objects of the same category ("Those are *daxes*"), and a proper name ("This is *Dax*") (Hall, Lee, & Belanger, 2001). In Japanese, all nouns are treated the same syntactically ("This is *dax*"). But Japanese preschoolers find ways to compensate for the missing syntactic cues, learning just as quickly as their English-speaking agemates (Imai & Haryu, 2001).

An alternative perspective is that vocabulary growth is governed by the same cognitive strategies that children apply to nonlinguistic stimuli. A recent account, called the **emergentist coalition model,** proposes that word-learning strategies *emerge* out of children's efforts to decipher language. Children draw on a *coalition* of cues—perceptual, social, and linguistic—that shift in importance with age (see Figure 9.8) (Golinkoff & Hirsh-Pasek, 2006). Infants rely solely on perceptual cues—for example, a parent shaking a toy while naming it. Toddlers, while still sensitive to perceptual features (such as object shape and physical action), increasingly attend to social cues—the speaker's direction of gaze and gestures (Hollich, Hirsh-Pasek, & Golinkoff, 2000; Pruden et al., 2006). And as language develops further, linguistic cues—syntax and intonation (stress, pitch, and loudness)—play larger roles.

Preschoolers are most successful at figuring out new word meanings when several kinds of information are available (Saylor, Baldwin, & Sabbagh, 2005). Researchers have just begun to study the multiple cues they use for different types of words and how their combined strategies change with development. We still have much to discover about how children's inner capacities join with patterns of information in the environment to yield the phenomenal pace of semantic development.

ASK YOURSELF

Review ■ Using your knowledge of phonological and semantic development, explain why "Mama" and "Dada" are usually among children's first words.

Connect ■ Explain how children's strategies for word learning support an interactionist perspective on language development.

Apply ■ Katy's first words included "see," "give," and "thank you," and her vocabulary grew slowly during the second year. What style of language learning did she display, and what factors might have contributed to it?

Apply ■ At age 20 months, Nathan says "candy" when he sees buttons, pebbles, marbles, cough drops, and chocolate kisses. Are Nathan's naming errors random or systematic? Why are they an adaptive way of communicating?

- Describe the course of grammatical development.
- Discuss ideas about how grammatical development takes place, including strategies and communicative support for mastering new structures.

Grammatical Development

Studying children's grammar requires that they use more than one word in an utterance. Researchers have puzzled over the following questions about grammatical development: Do children build a consistent grammar resembling that of adults relatively easily and quickly, or do they acquire complex forms little by little? Are language-specific strategies, general cognitive strategies, or both involved in children's progress? What is the role of adult teaching—in particular, corrective feedback for grammatical errors? As we chart the course of grammatical development, we will consider evidence on these issues.

First Word Combinations

Sometime between 1½ and 2½ years, as productive vocabulary reaches 200 to 250 words, children transition from word–gesture combinations to joining two words: "Mommy shoe," "go car," "more cookie." These two-word utterances are called **telegraphic speech** because, like a telegram, they focus on high-content words and omit smaller, less important ones, such as *can, the,* and *to.* For children learning languages that emphasize word order, such as English and French, endings like *-s* and *-ed* are not yet present. In languages in which word order is flexible and small grammatical markers are stressed, children's first sentences include them from the start (de Villiers & de Villiers, 1999).

Children the world over use two-word utterances to express a wide variety of meanings (see Table 9.3). Are they applying a consistent grammar? According to one view, a more complete, and perhaps adult-like, grammar lies behind these two-word sentences (Gleitman et al., 1988; Lidz, 2007; Valian, 1991, 2005). Indeed, children often use the same construction to express different propositions. For example, a child might say, "Mommy cookie" when he sees his mother eating a cookie and also when he wants her to give him a cookie. Perhaps the more elaborate structures are present in the child's mind, but because of limited space in working memory, he cannot yet produce the longer word string.

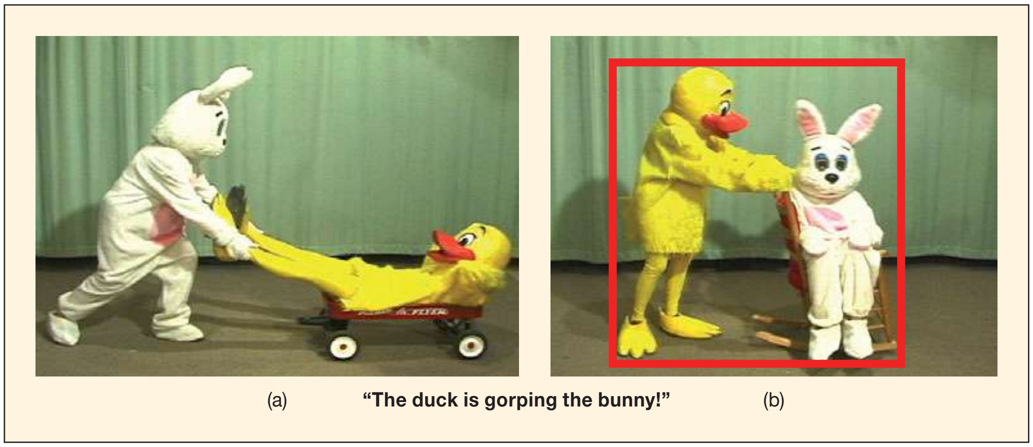
Consistent with this idea, children seem more knowledgeable about grammar in comprehension than in production (Lidz, 2007). In one study, 18- and 24-month-olds listened to grammatical sentences in which the article *the* preceded a noun, as well as three types of ungrammatical sentences: *the* was dropped, replaced by a nonsense word *(el),* or replaced by an alternate English word *(and),* as follows: *"Can you see the/and/el ball?"* (Kedar, Casasola, & Lust, 2006). When presented with video images of objects, toddlers of both ages oriented more quickly and more accurately toward the correct object following grammatical sentences. Similarly, when shown two videos—one in which a duck acts on a bunny, the other in which a bunny acts on a duck—2-year-olds looked

TABLE 9.3 Common Meanings Expressed by Children's Two-Word Utterances

MEANING	EXAMPLE
Agent–action	"Tommy hit"
Action–object	"Give cookie"
Agent–object	"Mommy truck" (meaning "Mommy, push the truck")
Action–location	"Put table" (meaning "Put X on the table")
Entity–location	"Daddy outside"
Possessor–possession	"My truck"
Attribution–entity	"Big ball"
Demonstrative–entity	"That doggie"
Notice–noticed object	"Hi mommy"; "Hi truck"
Recurrence	"More milk"
Nonexistence–nonexistent or disappeared object	"No shirt"; "No more milk"

Source: Brown, 1973.

longer at the video event that correctly matched a sentence containing a novel verb ("The duck *is gorping* the bunny") (see Figure 9.9) (Gertner, Fisher, & Eisengart, 2006). This suggests that 2-year-olds have some awareness of subject-verb-object word order, which they generalize to comprehension of new verbs.



(a)
"The duck is gorping the bunny!"
(b)

FIGURE 9.9 Are English-learning 2-year-olds aware of subject–verb–object word order? Two-year-olds viewed two side-by-side videos accompanied by a sentence with a novel verb—for example, "The duck is *gorping* the bunny." They spent more time looking at the event that matched the sentence—in this case, the duck acting on the bunny rather than the bunny acting on the duck. But this conclusion is controversial; practice during the training phase of the study may have primed 2-year-olds to look in the correct direction. (From Y. Gertner, C. Fisher, & J. Eisengart, 2006, "Learning Words and Rules: Abstract Knowledge of Word Order in Early Sentence Comprehension," *Psychological Science, 17,* p. 686. Reprinted by permission.)

But other researchers point out that the study depicted in Figure 9.9 had a training phase, in which the same characters and nouns (*duck* and *bunny)* were presented with familiar verbs in subject-verb-object constructions. This may have primed 2-year-olds to look in the correct direction when tested with a novel verb (Dittmar et al., 2008). In subsequent research that eliminated any syntactic cues during training, 2-year-olds showed no preference for either video during testing (Chan et al., 2010). Not until close to age 3 did children show some evidence of looking more often at the correct illustration of the novel-verb sentence.

Additional findings confirm that toddlers do not yet have a consistent, flexible grammar. Rather, their two-word sentences are largely made up of simple formulas, such as "more + *X*" and "eat + *X*," with many different words inserted in the *X* position. Toddlers rarely make gross word-order errors, such as saying "chair my" instead of "my chair." But their word-order regularities are usually copies of adult word pairings: "How about *more sandwich?*" or "Let's see if you can *eat the berries?*" (Tomasello & Brandt, 2009). When children entering the two-word phase were taught several noun and verb nonsense words (for example, *meek* for a doll and *gop* for a snapping action), they easily combined the new nouns with words they knew well, as in "more meek." But they seldom produced word combinations with the new verbs (Tomasello, 2000; Tomasello et al., 1997).

Much evidence shows that children younger than age 3 do poorly when asked to use newly learned verbs in constructions in which they have not heard the verbs used before (Tomasello, 2003). Their inability to use verbs flexibly implies that they do not yet grasp subject–verb and verb–object relations—the foundation of English grammar. According to this alternative view, young children first acquire "concrete pieces of language" from frequent word pairings that they hear. Only gradually do they generalize from those pieces to construct the word-order and other grammatical rules of their native tongue (Bannard, Lieven, & Tomasello, 2009; Tomasello, 2006).

From Simple Sentences to Complex Grammar

In the third year, three-word sentences appear in which English-speaking children clearly follow a subject–verb–object word order. Children learning other languages adopt the word order of the adult speech they hear. For "It is broken," a German child says, "*Kaputt ist der*" (literally, "Broken is it"). Between ages 2½ and 3, children create sentences in which adjectives, articles, nouns, verbs, and prepositional phrases start to conform to an adult structure, indicating that they have begun to master the grammatical categories of their language.

Gradual Mastery of Grammatical Structures Nevertheless, studies of children acquiring diverse languages, including Dutch, English, Hebrew, Inuktitut (spoken by the Inuit of Arctic Canada), Italian, Portuguese, and Russian, reveal that their first use of grammatical rules is piecemeal—applied to only one or a few verbs, not across the board. As children listen for familiar verbs in adult discourse, they expand their own utterances containing those verbs, drawing on adult usage as their model (Allen, 1996; Gathercole, Sebastián, & Soto, 1999; Lieven, Pine, & Baldwin, 1997; Stoll, 1998). One child, for example, added the preposition *with* to the verb *open* ("You open with scissors") but not to the word *hit* ("He hit me stick").

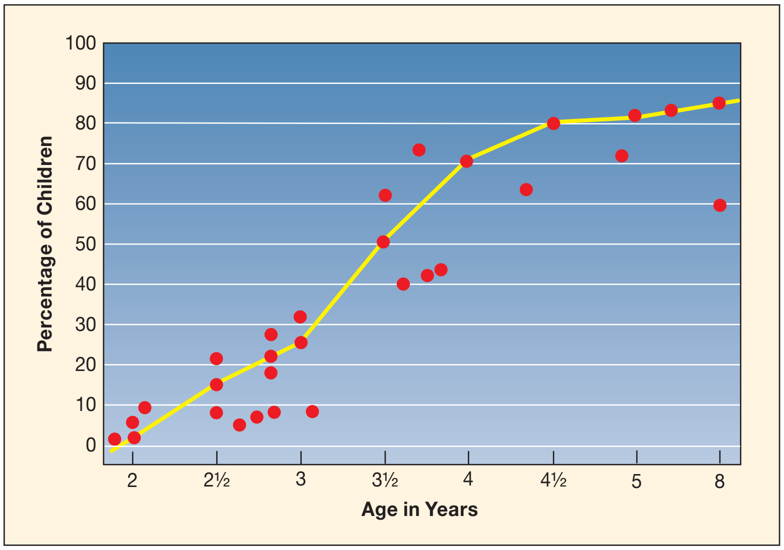


FIGURE 9.10 **Percentage of children in different studies who could use a new verb in the subject–verb–object form after hearing it in another construction.** Each dot in the graph represents the findings of one study. Ability to use the new verb—an indicator of the child's capacity to apply the subject–verb–object structure broadly—rose steadily with age. Children master this fundamental grammatical construction gradually. (Reprinted from *Cognition,* Vol. 74, No. 3, M. Tomasello, "Do Young Children Have Adult Syntactic Competence?" p. 223, copyright 2000, with permission from Elsevier.)

Only gradually do preschoolers refine and generalize their early grammatical forms. In a number of investigations, English-learning children were tested for their ability to produce novel sentences that conformed to basic English syntax. They had to use a new verb in the subject–verb–object form after hearing it in a different construction, such as passive ("Ernie is getting *gorped* by the dog"). The percentage of children who performed well (when asked what the dog was doing, they responded, "He's gorping Ernie") rose steadily with age. But as Figure 9.10 shows, not until 3½ to 4 could the majority of children apply the fundamental subject–verb–object structure broadly, to newly acquired verbs (Chan et al., 2010; Tomasello, 2003, 2006).

Because English relies on word order to express basic meanings, English-speaking preschoolers grasp unusual subject–verb–object expressions—an inanimate subject acting on an animate object, as in "The cup *meeks* the chicken," where *meek* means push—between ages 3 and 4. In languages where word order often deviates from the subject–verb–object construction, such as German and Cantonese Chinese, many 3½-year-olds prefer the reverse interpretation; they assume the animate noun (chicken) to be the agent (the chicken *meeks* the cup) (Chan, Lieven, & Tomasello, 2009). As these findings indicate, the age at which children flexibly grasp subject–verb–object word order depends on how available and consistent the form is in the child's language environment.

Development of Grammatical Morphemes Once children form three-word sentences, they add **grammatical morphemes**[1]—small markers that change the meaning of sentences, as in "John'*s* dog" and "he *is* eating." English-speaking 2- and 3-year-olds acquire these morphemes in a regular sequence, shown in Table 9.4 (Brown, 1973; de Villiers & de Villiers, 1973). Given the difficulty of the task, however, their errors are surprisingly few (Maratsos, 1998).

What explains this sequence of development? Two characteristics of morphemes play important roles. The first is *structural complexity.* For example, adding the ending *-ing* or *-s* is structurally less complex than using forms of the verb *to be.* In the latter, the child must express correct tense and also make the subject and verb agree ("*I am* coming" versus "*They are* coming"). Second, grammatical morphemes differ in *semantic complexity,* or the number and difficulty of the meanings they express. Adding *-s* to a word requires only one semantic distinction—the difference between one and more than one. In contrast, using *to be* involves many more, including an understanding of person, number, and time of occurrence (Slobin, 1982).

Look again at Table 9.4, and you will see that some morphemes with irregular forms are acquired before those with regular forms. For example, children use past-tense irregular verbs, such as *ran* and *broke,* before they acquire the regular *-ed* ending. But once children apply a regular morphological rule, they extend it to words that are exceptions, a type of error called **overregularization.** Expressions like "My toy car *breaked*" and "We each have two *foots*" appear between 2 and 3 years of age and persist into middle childhood (Marcus et al., 1992). Children less often make this error on frequently used irregular verbs, such as the past tense of *go (went)* and *say (said).* For rarely used verbs such as *grow* and *sing,* the error rate can be higher than 50 percent (Maratsos, 2000).

---

[1] A *morpheme* is the smallest unit of meaning in speech; any further division violates the meaning or produces meaningless units. Both "dog" and "-s" are morphemes; "-s" is a *grammatical morpheme.*

Why do children show this inconsistent pattern? Because they hear frequently used irregular forms often in adult speech, they probably learn those by rote memory. For less common irregulars, children alternate between correct and overregularized forms for months or even several years. According to one view, as children hear more instances in others' speech, the irregular form eventually wins out (Elman, 2003; Maratsos, 2000). At times, however, preschoolers do overregularize frequently used exceptions, as when they say "ated," "felled," or "feets." In these instances, perhaps their memory for the irregular morpheme fails, so they call on the *–ed* or *–s* rule, and overregularization results.

TABLE 9.4 **Order of Acquisition of English Grammatical Morphemes**

MORPHEME	EXAMPLE
1. Verb present progressive ending ("-ing")	"He singing."
2. Preposition "on"	"On horsie."
3. Preposition "in"	"In wagon."
4. Noun plural ("-s")	"Cats."
5. Verb irregular past tense	"He ran." "It broke."
6. Noun possessive	"Daddy's hat."
7. Verb uncontractible "be" form used with adjective, preposition, or noun phrase	"Are kitties sleepy?"
8. Articles "a and "the"	"A cookie." "The bunny."
9. Verb regular past tense ending ("-ed")	"He kicked it."
10. Verb present tense, third person singular regular ending	"He likes it."
11. Verb present tense, third person singular irregular ending	"She has [from *have*] a cookie." "He does [from *do*] a good job."
12. Auxiliary verb uncontractible "be" forms	"Are you eating?"
13. Verb contractible "be" forms used with adjective, preposition, or noun phrase	"He's inside." "They're sleepy."
14. Auxiliary verb contractible "be" forms	"He's coming." "Doggie's eating."

Development of Complex Grammatical Forms

Once children master the auxiliary verb *to be,* the door is open to a variety of new expressions. Negatives and questions are examples.

Negatives

Three types of negation appear in the following order in 2½- to 3-year-olds learning languages as different as Cantonese, English, and Tamil (spoken in India): (1) *nonexistence,* in which the child remarks on the absence of something ("No cookie," "All gone crackers"); (2) *rejection,* in which the child expresses opposition to something ("No take bath"); and (3) *denial,* in which the child denies the truthfulness of something ("That not my kitty") (Clancy, 1985; Tam & Stokes, 2001; Vaidyanathan, 1991).

These early constructions probably result from imitating parental speech. When parents express nonexistence or rejection, they often put *no* at the beginning of the sentence: "No more cookies" or "No, you can't have another cracker." Around 3 to 3½ years, as children add auxiliary verbs and become sensitive to the way they combine with negatives, correct negative forms appear: "There aren't any more cookies" (nonexistence), "I don't want a bath" (rejection), and "That isn't my kitty" (denial) (Tager-Flusberg & Zukowski, 2009).

Questions

Like negatives, questions first appear during the early preschool years and develop in an orderly sequence. English-speaking children, as well as those who speak many other languages, can use rising intonation to convert an utterance into a yes/no question: "Mommy baking cookies?" As a result, they produce such expressions quite early.

Correct question form in English requires that children invert the subject and auxiliary verb. In *wh-* questions—ones that begin with *what, where, which, who, when, why,* and *how*—the *wh-* word must also be placed at the beginning of the sentence. When first creating questions, 2-year-olds use many formulas: "Where's *X?*" "What's *X?*" "Can I *X?*" (Dabrowska, 2000; Tomasello, 1992, 2003). Preschoolers' question asking remains variable for a couple of years. A common error is to omit the auxiliary verb ("What he doing?"). Another is to fail to invert the subject and auxiliary verb when asking certain questions ("What she will do?" "Why he can go?") but not others ("How do you like it?" "What do you want?") (Rowland et al., 2005; Rowland & Pine, 2000). The correct expressions tend to be those that occur most often in caregivers' speech. And sometimes children produce errors in subject–auxiliary verb agreement ("Where does the dogs play?") and

As she sorts berries with her mother, this 3-year-old is acquiring Bhoti, the language of her community in India. Like English-speaking preschoolers, she is likely to master yes/no questions before *wh-* questions, which are semantically and structurally more difficult.

© ACHIM POHL/PETER ARNOLD INC.

in subject case ("Where can me sit?"). These diverse errors are difficult to reconcile with the existence of a built-in universal grammar (Rowland, 2007). As with other grammatical constructions, children seem to produce accurate questions piecemeal and gradually.

Among English-, Korean-, and Tamil-speaking preschoolers, correct question form appears first for yes/no and later for *wh-* constructions (Clancy, 1989; Vaidyanathan, 1988). Among *wh-* questions, which are semantically and structurally more difficult, *what, where,* and *who* tend to precede *how, why,* and *when,* which are harder to understand and answer (de Villiers, 2000).

Other Complex Constructions Between ages 3½ and 6, children produce more intricate constructions. First, connectives appear, joining whole sentences ("Mom picked me up, *and* we went to the park") and verb phrases ("I got up *and* ate breakfast"). The most general connective, *and,* is used first, followed by connectives expressing more specific meanings: *then* and *when* for temporal relations, *because* and *so* for causal relations, *or* for exclusion, *if* for conditionals, and *but* for opposition (Bloom et al., 1980). As with other grammatical forms, first use of connectives is piecemeal, largely limited to imitations of parental use (Morris, 2008). Over time, preschoolers' use increasingly conforms to the rules of their language.

Later, children produce embedded sentences ("I think *he will come*"), tag questions ("Dad's going to be home soon, *isn't he?*"), indirect object–direct object structures ("He showed *his friend* the present"), and passive sentences ("The dog *was patted by* the girl"). As the preschool years draw to a close, children use most grammatical structures of their native language competently (Tager-Flusberg & Zukowski, 2009).

Later Grammatical Development

During the school years, mastery of complex constructions improves. For example, English-speaking children use the passive voice more frequently, and they more often extend it from an abbreviated structure ("It got broken") into full statements ("The glass was broken by Mary") (Israel, Johnson, & Brooks, 2000; Tomasello, 2006). Older children also apply the passive voice to a wider range of nouns and verbs. Preschoolers comprehend the passive best when the subject of the sentence is an animate being and the verb is an action word ("The *boy is kissed* by the girl"). Over the school years, children extend the passive form to inanimate subjects ("The *hat* was worn by the man") and experiential verbs ("The dog *was seen* by the cat") (Lempert, 1990; Pinker, Lebeaux, & Frost, 1987).

Although the passive form is challenging, once again language input makes a difference. English-speaking adults rarely use full and experiential passives in everyday conversation. In languages in which adults use these forms often, such as Inuktitut (spoken by the Inuit people), children produce them earlier (Allen & Crago, 1996). And exposure to adult speech containing a variety of passive-sentence types (as opposed to just one type) prompts 4- and 5-year-olds to produce more passive utterances (Savage et al., 2006). Varied input seems to foster a general representation of the passive construction.

Another later grammatical achievement is advanced understanding of infinitive phrases—the difference between "John is eager to please" and "John is easy to please" (Berman, 2007; Chomsky, 1969). Like gains in vocabulary, appreciation of these subtle grammatical distinctions in middle childhood and adolescence is supported by an improved capacity to analyze and reflect on language and to attend to multiple linguistic and situational cues.

Ideas About How Grammatical Development Takes Place

Preschoolers' mastery of most of the grammar of their language is an astounding feat. How to explain it is perhaps the most disputed issue in the study of language development.

Strategies for Acquiring Grammar Evidence that grammatical development is an extended, learned process, beginning with knowledge of specific instances and building toward general categories and rules, has raised questions about Chomsky's nativist account. Some experts have concluded that grammar is a product of general cognitive development—children's tendency to search for consistencies and patterns of all sorts (Bloom, 1999; MacWhinney, 2005; Maratsos, 1998; Tomasello, 2003, 2006). Yet among these theorists, debate continues over just how children master grammar.

According to one view, young children rely on other properties of language to detect basic grammatical regularities. In **semantic bootstrapping,** for example, they use word meanings to figure out sentence structure. Children might begin by grouping together words with "agent qualities" (things that cause actions) as *subjects* and words with "action qualities" as *verbs.* Then they merge these categories with observations of how words are used in sentences (Bates & MacWhinney, 1987; Braine, 1994). In this way, children lay down a basic grammatical framework, which they modify over time to account for exceptions. In some languages, however, semantic categories (such as "agent") and basic grammatical structures (such as "subject") do not match up—a major problem for semantic bootstrapping. In Tagalog, a language spoken in the Philippines, certain agents can be subjects, but others cannot. Yet Tagalog-speaking children acquire the main grammar of their language within a typical time frame (Maratsos, 1998).

Other theorists believe that children master grammar through direct observation of the structure of language: They notice which words appear in the same positions in sentences, take the same morphological endings, and are similarly combined with other words. Over time, from exposure to many instances, they group words into grammatical categories and use them appropriately in sentences (Bannard, Lieven, & Tomasello, 2009; Bloom, 1999; Chang, Dell, & Bock, 2006; Tomasello, 2003, 2011).

Still other theorists agree with the essence of Chomsky's position. One idea accepts semantic bootstrapping but proposes that the grammatical categories into which children group word meanings are innate—present at the outset (Pinker, 1989, 1999). Another theory holds that children do not start with innate knowledge but have a special *language-making capacity*—a set of procedures for analyzing the language they hear that supports the discovery of grammatical regularities. Research on children learning more than 40 different languages reveals common patterns, consistent with a basic set of strategies (Slobin, 1985, 1997). Yet controversy persists over whether a universal language-processing device exists or whether children who hear different languages devise unique strategies (Lidz, 2007; Marchman & Thal, 2005).

Communicative Support for Grammatical Development

Besides investigating the child's capacities, researchers have examined features of adult–child communication that might ease the task of mastering grammar. Previous research reported that although adults frequently correct children's mistaken inferences about word meaning ("That's not a bird, it's a butterfly"), they rarely provide direct feedback about grammar (Brown & Hanlon, 1970). Yet parents often correct their child's grammatical errors *indirectly*—in ways that inform the child about conventional usage while keeping the conversation going.

In a study in which three English-learning and two French-learning children were followed from ages 2 to 4, researchers coded thousands of utterances for errors in pronunciation, word choice, and grammar, along with parents' immediate responses and children's reactions to those responses (Chouinard & Clark, 2003). Findings revealed that parents reformulated as many as two-thirds of children's erroneous expressions—a rate that was similar across the error types and the five children.

Many adult reformulations inform children about grammar through two techniques, often used in combination: **recasts**—restructuring inaccurate speech into correct form; and **expansions**—elaborating on children's speech, increasing its complexity (Bohannon & Stanowicz, 1988). For example, if a child says, "I gotted new red shoes," the parent might respond, "Yes, you got a pair of new red shoes," *recasting* the incorrect features of the child's statement while also *expanding* its complexity. After such corrective input, 2- to 4-year-olds often shift to correct forms—improvements still evident several months later (Saxton, Backley, & Gallaway, 2005).

Other grammatical prompts ask children to clarify what they mean so interaction can continue. For example, when a 2½-year-old said, "I

© ELLEN B. SENISI PHOTOGRAPHY

Responding to these 2-year-olds, a preschool teacher expands their brief sentences and recasts them into grammatically correct form—techniques that inform children about correct grammar.

want hugging Ava," his mother queried, "What do you want?" In one study, such error-contingent clarifying questions led 2½-year-olds to shift from an incorrect to a correct form 16 percent of the time, and 4-year-olds 34 percent of the time (Saxton, Houston-Price, & Dawson, 2005). Clarifying questions may encourage children to reflect on their utterances and apply what they know about correct grammar more consistently.

Nevertheless, the impact of such feedback has been challenged. The techniques are not used in all cultures and, in a few investigations, did not affect children's grammar (Strapp & Federico, 2000; Valian, 1999). But in some societies, older siblings may take over the task of providing young children with feedback, and parents may do so in other culturally prescribed ways. For example, on certain occasions, New Guinean Kaluli and Western Samoan adults tell children what to say by facing the child toward her listener, speaking for the child, and commanding, "*Elema,*" which means, "Say like that" (Ochs, 1988). Low-SES Western parents engage in similar practices (Hart & Risley, 1995).

In sum, virtually all investigators agree that young children are amazing processors of linguistic structure. But the extent to which adult communication helps children correct errors and take the next grammatical step forward remains a contested issue in child language research.

LOOK and LISTEN

In a 30- to 60-minute observation of a 2- to 4-year-old and his or her parent, note grammatical errors the child makes and adult feedback. How often does the parent reformulate child errors or ask clarifying questions? How does the child respond?

▶ Describe the course of pragmatic development.

Pragmatic Development

Besides mastering phonology, vocabulary, and grammar, children must learn to use language effectively in social contexts—by taking turns, staying on the same topic, stating their messages clearly, and conforming to cultural rules for interaction. During the preschool years, children make considerable headway in mastering the pragmatics of language.

Acquiring Conversational Skills

Young children are already skilled conversationalists. In face-to-face interaction, they make eye contact, respond appropriately to their partner's remarks, and take turns (Pan & Snow, 1999). With age, the number of turns over which children can sustain interaction and their ability to maintain a topic over time increase, but even 2-year-olds converse effectively (Snow et al., 1996).

In early childhood, additional conversational strategies are added. In the **turnabout,** the speaker not only comments on what has just been said but also adds a request to get the partner to respond again. Because 2-year-olds cannot generate many words in each turn, they seldom use turnabouts, but children do so increasingly over the next few years (Goelman, 1986). Between ages 5 and 9, more advanced conversational strategies appear, such as **shading,** in which a speaker initiates a change of topic gradually by modifying the focus of discussion (Wanska & Bedrosian, 1985).

Effective conversation also depends on understanding **illocutionary intent**—what a speaker means to say, even if the form of the utterance is not perfectly consistent with it. By age 3, children comprehend a variety of requests for action not directly expressed as requests:

"I need a pencil" or "Why don't you tickle me?" (Garvey, 1974). During middle childhood, illocutionary knowledge develops further. For example, an 8-year-old who has forgotten to do his chores understands that when his mother says, "The garbage is beginning to smell," she really means, "Take that garbage out!" (Ackerman, 1978). Appreciating form–intention pairings like this one requires children to make subtle inferences that are beyond preschoolers' cognitive capacities.

Still, surprisingly advanced conversational abilities are present early, and adults' patient, sensitive interactions with young children encourage and sustain them. Throughout this chapter, we have seen examples of how adult–child conversation fosters language development. Whether observed at home or in preschool, it is consistently related to general measures of language progress (Hart & Risley, 1995; NICHD Early Child Care Research Network, 2006). Dialogues with caregivers about storybooks are particularly effective (Hoff, 2010). They expose children to great breadth of language knowledge, including how to communicate in a clear, coherent narrative style—a skill that undoubtedly contributes to the association between joint storybook reading and literacy development (see Chapter 7, page 308).

Finally, the presence of a sibling enhances young children's conversational skills. Toddlers closely monitor conversations between their twin or older siblings and parents, and they often try to join in. When they do, these verbal exchanges last longer, with each participant taking more turns (Barton & Strosberg, 1997; Barton & Tomasello, 1991). As they listen to these conversations, younger siblings pick up important skills, such as use of personal pronouns ("I" versus "you"), which are more common in the early vocabularies of later-born than of first-born siblings (Pine, 1995). Furthermore, older siblings' remarks to a younger brother or sister often focus on regulating interaction: "Do you like Kermit?" "OK, your turn" (Oshima-Takane & Robbins, 2003). This emphasis probably contributes to younger siblings' conversational skills.

When his mother exclaims, "It's trash pickup day!" this 10-year-old comprehends her statement as an indirect request to wheel the trash can out to the curb. Understanding of illocutionary intent improves in middle childhood.

Communicating Clearly

To communicate effectively, we must produce clear verbal messages and recognize when messages we receive are unclear so we can ask for more information. These aspects of language are called **referential communication skills.**

Typically, laboratory tasks designed to assess children's ability to communicate clearly present them with challenging situations in which they must describe to a listener one object among a group of similar objects. For example, in one study, 3- to 10-year-olds were shown several eight-object arrays. In each, the objects were similar in size, shape, and color. Most 3-year-olds gave ambiguous descriptions. When asked for clarification, they relied heavily on gestures, such as pointing (Deutsch & Pechmann, 1982). The ability to send clear messages improved steadily with age.

When preschoolers are given simpler tasks or engage in face-to-face interaction with familiar people, they adjust their speech to their listener's perspective quite well. **TAKE A MOMENT...** But try engaging a preschooler in conversation on the telephone, jotting down what you and the child say. Here is an excerpt of one 4-year-old's phone conversation with his grandfather:

> *Grandfather:* How old will you be?
> *John:* Dis many. *[Holding up four fingers.]*
> *Grandfather:* Huh?
> *John:* Dis many. *[Again holding up four fingers.]* (Warren & Tate, 1992, pp. 259–260)

Young children's conversations appear less mature in highly demanding situations in which they cannot see their listeners' reactions or rely on typical conversational aids, such as gestures and objects to talk about. But when asked to tell a listener how to solve a simple puzzle, 3- to 6-year-olds give more specific directions over the phone than in person, indicating that they realize the need for more verbal description on the phone (Cameron & Lee, 1997). Between ages 4 and 8, both conversing and giving directions over the phone improve greatly. Telephone talk provides an excellent example of how preschoolers' communication skills depend on the demands of the situation.

Children's ability to evaluate the adequacy of messages they receive also improves with age. Around age 3, preschoolers start to ask others to clarify ambiguous messages. At first, children recognize when a message provides a poor description of a concrete object (Ackerman, 1993). Only later can they tell when a message contains inconsistencies. For example, when researchers showed 4- and 5-year-olds the scene in Figure 9.11 and instructed, "Put the frog on the book in the box," preschoolers could not resolve the ambiguity. Most put a frog on the empty book rather than in the box, even though they used similar embedded phrases in their own speech ("The frog *on the book* went to Mrs. Squid's house") (Hurewitz et al., 2000).

Notice how this task requires children to *inhibit* attention from being drawn to the empty book in the scene, which increases the salience of the first part of the directive, "Put the frog *on the book*." When asked to listen to the instruction with their back to the display, which temporarily blocked the scene's distracting features, almost all 4- and 5-year-olds processed the entire message and responded correctly (Meroni & Crain, 2003).

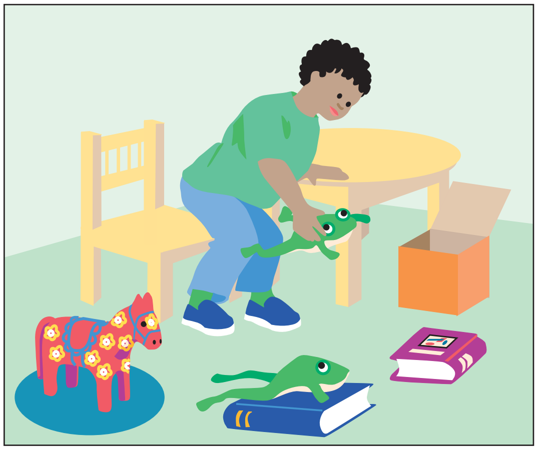

FIGURE 9.11 Testing for referential communication skills. When an adult instructed, "Put the frog on the book in the box," 4- and 5-year-olds could not resolve the ambiguity between the phrases "on the book" and "in the box." They stuck to their first inference and put one of the frogs on the empty book. Not until middle childhood can children integrate the two competing representations by selecting the frog on the book and placing it in the box. (Adapted from Hurewitz et al., 2000.)

Narratives

Conversations with adults about past experiences contribute to dramatic gains in children's ability to produce well-organized, detailed, expressive narratives (see page 299 in Chapter 7). When asked to relate a personally important event, 4-year-olds typically produce brief renditions called *leapfrog narratives,* jumping from one event to another in a disorganized fashion. Between 4½ and 5, children start to produce *chronological narratives,* placing events in temporal sequence and building to a high point: "We went to the lake. We fished and waited. Paul waited, and he got a huge catfish." Around age 6, chronological narratives extend into *classic narratives,* in which children add a resolution: "After Dad cleaned the catfish, we cooked it and ate it all up!" (McCabe & Bliss, 2003).

Preschoolers' limited working memories are partly responsible for their restricted narratives. In addition, young children often presume more shared knowledge than their listener has, so they offer little orienting information about events, such as time, place, and participants. Preschoolers' narratives also contain few *evaluations*—comments about how and why events took place or about their own and others' thoughts, feelings, and intentions. During middle childhood, orienting information, detailed descriptions, and connectives that lend coherence to the story ("next," "then," "so," "finally") increase. And evaluative comments rise steadily in middle childhood and adolescence (Melzi & Ely, 2009). When parents use the elaborative strategy discussed in Chapter 7 to help young children construct narratives, preschoolers produce more organized, detailed, and evaluative personal stories (see page 299).

Like narrative, make-believe play requires children to organize events around a plot, constructing a connected, meaningful story line. Pretend-play and narrative competence support each other (Nicolopoulou, 2006). When 4-year-olds created narratives in a make-believe context ("Tell me a story using these toys"), they generated more complex, coherent stories than agemates who were directly prompted (Ilgaz & Aksu-Koç, 2005). The pretend props and actions served as powerful cues for narrative events, reducing memory demands during storytelling. And in a school program, 5- to 7-year-olds who participated in 14 weeks of joint adult–child dramatization of a work of children's literature showed greater gains in narrative development than agemates who merely listened to an adult read the story over 14 sessions, with no playacting (Baumer, Ferholt, & Lecusay, 2005).

Because children pick up the narrative styles of parents and other significant adults in their lives, their narrative forms vary widely across cultures. As noted in Chapter 8, instead of relating a

A class of preschoolers reenacts the first Thanksgiving as Pilgrims and Indians. Make-believe experiences with props that cue story events reduce memory demands, enabling young children to generate more complex, coherent narratives.

© ELLEN B. SENISI PHOTOGRAPHY

single experience from beginning to end, African-American children often use a *topic-associating style,* blending several similar anecdotes. As a result, their narratives are usually longer and more complex than those of American white children (Champion, 2003b). Japanese children also connect events with a common theme, using a structure that resembles *haiku,* a culturally valued poetic form (Minami, 1996).

The ability to generate clear oral narratives contributes to literacy development, enhancing reading comprehension and preparing children for producing longer, more explicit written narratives. In families who regularly eat meals together, children are advanced in language and literacy development, perhaps because mealtimes offer many opportunities to listen to and relate personal stories (Snow & Beals, 2006).

Sociolinguistic Understanding

As early as the preschool years, children are sensitive to language adaptations to social expectations, known as **speech registers.** In one study, 4- to 7-year-olds were asked to act out roles with hand puppets. Even the youngest children showed that they understood the stereotypic features of different social positions. They used more commands when playing socially dominant and male roles, such as teacher, doctor, and father. When playing less dominant and feminine roles, such as student, patient, and mother, they spoke more politely and used more indirect requests (Andersen, 1992, 2000).

© MIXA/GETTY IMAGES

This Japanese kindergartner uses the correct expression of respect when addressing her teacher, thereby acknowledging his high social status. She is well on her way to mastering her culture's elaborate system of polite forms.

The importance of register adjustments is evident in how often parents teach social routines, such as politeness. Before infants can grasp the gesture's meaning, parents encourage them to wave "bye-bye." By age 2, when children fail to say "please" and "thank you," or "hi" and "good-bye," parents often model and demand an appropriate response.

Some cultures have elaborate systems of polite language. In Japan, for example, politeness affects many aspects of verbal and nonverbal communication, which vary with gender, age, social status, and familiarity of speaker and listener. Japanese mothers and preschool teachers constantly model and teach these expressions as a means of promoting in children a kind, considerate attitude toward others. As a result, preschoolers acquire a large repertoire of polite forms (Burdelski, 2010; Nakamura, 2001). When greeting customers in a make-believe store, even 1-year-olds use the greeting *"Irasshaimase!"* ("Welcome!"). Two- and 3-year-olds use more complicated polite speech, such as *"Mata oide-kudasai"* ("Please come again"). And 3- and 4-year-olds make considerable headway in acquiring the complex honorific/humble language of Japanese society, which is fully mastered in middle childhood.

Adolescence brings dramatic gains in capacity to adapt language style to social context, in part because teenagers enter many more situations than they did at younger ages. To succeed on the debate team, they must speak in a persuasive, well-organized, rapid-fire fashion. At work, they must respond to customers cheerfully and courteously. On a date, they must communicate with heightened sensitivity and intimacy. Greater skill at reflecting on the features of language and engaging in cognitive self-regulation also supports effective use of speech registers (Obler, 2008). Teenagers are far more likely than school-age children to practice what they want to say in an expected situation, review what they did say, and figure out how they could say it better.

ASK YOURSELF

Review ■ Summarize findings indicating that adult–child conversations promote preschoolers' pragmatic skills.

Connect ■ What cognitive advances contribute to the development of referential communication?

Apply ■ What pragmatic skills are evident in Erin's utterances, presented in the introduction to this chapter? How did Erin's parents and brother encourage her pragmatic development?

Reflect ■ List examples of speech registers you use in daily life. What childhood experiences might have influenced your mastery of these registers?

Describe the development of metalinguistic awareness and its role in language-related attainments.

Development of Metalinguistic Awareness

Consider the following exchange between a mother and her 5-year-old child:

Child: What's that?
Mother: It's a food processer.
Child: [*frowning*] No, you're the food processer, that's a food process.

This preschooler, conscious of word endings, expected *-er* to signify an animate agent, like *baker* or *dancer.* The child shows the beginnings of **metalinguistic awareness**—the ability to think about language as a system. Researchers have been especially interested in when metalinguistic awareness emerges and the role it plays in a variety of language-related accomplishments.

Around age 4, children know that word labels are arbitrary and not part of the objects to which they refer. When asked if an object could be called by a different name in a new language, they say "yes." They can also make some basic syntactic judgments—for example, that a puppet who says, "Nose your touch" or "Dog the pat," is saying his sentences backwards (Chaney, 1992). And by age 5, children have a good sense of the concept of "word." When an adult reading a story stops to ask, "What was the last word I said?" they almost always answer correctly for all parts of speech—they do not say "on-the-floor" instead of "floor" or "is-a" instead of "a" (Karmiloff-Smith et al., 1996). These early metalinguistic understandings are good predictors of vocabulary and grammatical development (Smith & Tager-Flusberg, 1982).

Nevertheless, full flowering of metalinguistic skills does not occur until middle childhood, as cognition advances and teachers point out features of language in reading and writing activities. Between ages 4 and 8, children make great strides in *phonological awareness* (Homer, 2009). Whereas preschoolers are sensitive to rhyme and other changes in word sounds, third graders can identify all the phonemes in a word. Recall from Chapter 7 that phonological awareness strongly predicts reading progress. Then literacy promotes further metalinguistic development by enabling language to become an object of thought that can be analyzed and dissected.

Consistent with this view, school-age children also make strides in morphological awareness, including the ability to manipulate word endings and generalize them to novel contexts (as in the example at the beginning of this section) (Duncan, Casalis, & Cole, 2009). And around age 8, children can judge the grammatical correctness of a sentence even if its meaning is false or senseless (Bialystok, 1986). Furthermore, metalinguistic knowledge is evident in elementary school children's improved ability to define words and appreciate their multiple meanings in puns, riddles, and metaphors—skills that continue to improve in adolescence (Berman, 2007).

As we will see next, bilingual children are advanced in metalinguistic awareness, as well as other cognitive skills. But before we conclude with this topic, refer to the Milestones table on the following page, which provides an overview of language development.

How do children become bilingual, and what are the advantages of bilingualism?

Bilingualism: Learning Two Languages in Childhood

Throughout the world, many children grow up *bilingual,* learning two languages and sometimes more than two. Recall from Chapter 2 that both the United States and Canada have large immigrant populations. An estimated 20 percent of U.S. children—10 million in all—speak a language other than English at home (U.S. Census Bureau, 2011b).

Children can become bilingual in two ways: (1) by acquiring both languages at the same time in early childhood, as Erin did, or (2) by learning a second language after mastering the first. Children of bilingual parents who teach them both languages in infancy and early childhood separate the language systems from the start (see page 368), distinguishing

Milestones

Language Development

AGE	PHONOLOGY	SEMANTICS	GRAMMAR	PRAGMATICS
Birth–1 year	● Coos, then babbles ● Organizes speech sounds into phonemic categories of native language ● Babbles using sound and intonation patterns of native language	● Prefers to listen to mother's voice and to native language ● Analyzes speech stream for words and syllable stress patterns ● Begins to comprehend words, and recognizes familiar words ● Uses communicative gestures	● Notices the structure of word sequences, distinguishing ABA from ABB patterns ● Develops sensitivity to clause and phrase boundaries	● Establishes joint attention ● Engages in vocal exchanges and turn-taking games
1–2 years	● Recognizes correct pronunciation of familiar words ● Uses systematic strategies to simplify word pronunciation	 ● Says first words ● Vocabulary grows to several hundred words	● Combines two words in telegraphic speech ● As three-word sentences appear, gradually adds grammatical morphemes	● Engages in conversational turn taking and topic maintenance
3–5 years	● Improves in phonological awareness ● Improves in word pronunciation 	● Coins words to fill in for words not yet mastered ● Understands metaphors based on concrete, sensory comparisons	● Gradually generalizes grammatical forms ● Continues to add grammatical morphemes in a regular order	● Masters additional conversational strategies, such as the turnabout ● Begins to grasp illocutionary intent ● Adjusts speech to listener's perspective and to social expectations ● Asks for clarification of ambiguous messages ● Produces chronological narratives
6–10 years	● Extends phonological awareness to all phonemes in words ● Masters syllable stress patterns signaling subtle differences in meaning	● At school entry, understands the meaning of about 10,000 words ● Acquires meanings of new words from context and from definitions ● Appreciates the multiple meanings of words, as indicated by metaphors and humor	 ● Refines complex grammatical structures, such as the passive voice and infinitive phrases	● Uses advanced conversational strategies, such as shading ● Refines understanding of illocutionary intent ● Communicates clearly in demanding situations, such as on the telephone ● Produces classic narratives rich in orienting information and evaluations
11 years–adulthood	 ● Masters syllable stress patterns of abstract words	● Comprehends over 40,000 words, including many abstract terms ● Understands subtle, nonliteral word meanings, as in sarcasm, irony, and proverbs	● Continues to refine complex grammatical structures	● Ability to communicate clearly and in accord with social expectations in diverse situations improves

Note: These milestones represent overall age trends. Individual differences exist in the precise age at which each milestone is attained.

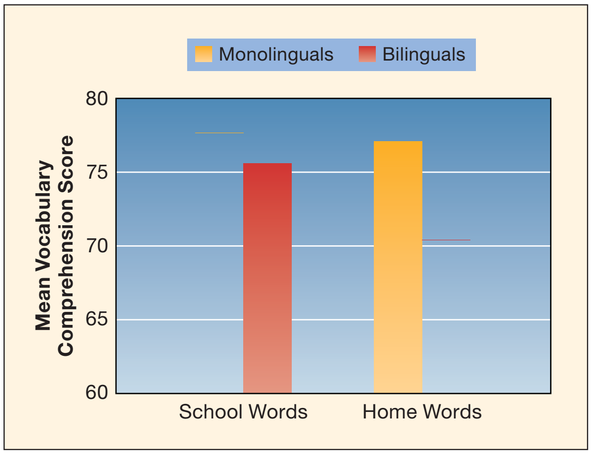

FIGURE 9.12 Monolingual and bilingual 6-year-olds' English vocabulary comprehension scores for "school" words and "home" words. Although bilingual schoolchildren's English vocabularies were smaller than those of their monolingual agemates, the difference applied only to words often used at home, where bilinguals' native language is spoken. The two groups were equivalent in comprehension of words often used at school, which bilingual children had ample opportunity to learn. (Adapted from Bialystok et al., 2009.)

their sounds, saying their first word, producing 50 words across the two languages (around age 1½), and attaining other early language milestones according to a typical timetable (Bialystok et al., 2009a; Conboy & Thal, 2006; Genesee & Nicoladis, 2007). Preschoolers acquire normal native ability in the language of their surrounding community and good-to-native ability in the second language, depending on their exposure to it (Genesee, 2001). When school-age children acquire a second language, they generally take five to seven years to attain speaking and writing skills on a par with those of native-speaking agemates (Paradis, 2007).

Like many bilingual adults, bilingual children sometimes engage in **code switching**—producing an utterance in one language that contains one or more "guest" words from the other—without violating the grammar of either language. Children may engage in code switching because they lack the vocabulary to convey a particular thought in one language, so they use the other. But children who code-switch the most are those whose parents often do so. Bilingual adults frequently code-switch to express cultural identity, and children may follow suit—as when a Korean child speaking English switches to Korean on mentioning her piano teacher, a sign of respect for authority (Chung, 2006). Opportunities to listen to code switching may facilitate bilingual development (Gawlitzek-Maiwald & Tracy, 1996). For example, a child accustomed to hearing French sentences with English guest words may rely on sentence-level cues to figure out English word meanings.

Compared to their monolingual agemates, bilingual children have somewhat smaller vocabularies in each language. But the difference seems largely due to opportunity to acquire certain words. For example, a close look at bilingual 6-year-olds who spoke a minority language at home but attended English-speaking schools revealed that they did not differ from monolinguals in comprehension of English words often used at school (such as animals, plants, and shapes) (see Figure 9.12) (Bialystok et al., 2009a). The bilingual children scored lower only in English words likely to be used at home (foods, household items), where they heard and spoke their other language.

A large body of research shows that children who become fluent in two languages are advanced in cognitive development. Brain-imaging research reveals that individuals who acquire two languages earlier and to greater proficiency develop denser neuronal connections in language areas of the left hemisphere (Mechelli et al., 2004). Bilingual children outperform others on tests of selective attention, inhibition of irrelevant information, analytical reasoning, concept formation, and cognitive flexibility (Bialystok, 2001; Bialystok & Martin, 2004; Carlson & Meltzoff, 2008). They are also advanced in certain aspects of metalinguistic awareness, such as detection of errors in grammar, meaning, and conventions of conversation (responding politely, relevantly, and informatively). And children transfer their phonological awareness skills in one language to the other, especially if the two languages share phonological features and letter–sound correspondences, as Spanish and English do (Bialystok, McBride-Chang, & Luk, 2005; Siegal, Iozzi, & Surian, 2009; Snow & Kang, 2006). These capacities, as noted earlier, enhance reading achievement.

If these children become fluent in both of their parents' native languages, they are likely to be advanced in many aspects of cognitive development and in metalinguistic awareness.

© LAURA DWIGHT PHOTOGRAPHY

The advantages of bilingualism provide strong justification for bilingual education programs in schools. The Social Issues: Education box on the following page describes the vastly differing approaches to bilingual education in the United States and Canada. In both countries, however, many immigrant children do not receive support for their native language in classrooms. Currently, some schools are trying a new approach—*two-way bilingual programs,* in which children with limited proficiency in English who speak a common native language and children who are fluent in English are assigned in equal numbers to the same classroom. Teaching is aimed at helping all children become fluent in both languages and at increasing cross-cultural understanding (Padilla, 2006). The goal is to foster the linguistic, cognitive, and cultural enrichment of the entire nation.

SOCIAL ISSUES: EDUCATION

Two Approaches to Bilingual Education: Canada and the United States

Canadian national education policies actively promote bilingual education. Children with an official minority-language background (French in the English-speaking provinces, English in French-speaking Quebec) have the right to elementary and secondary education in their respective languages. In addition, schools are encouraged to provide programs that maintain the languages and cultures of immigrants to Canada and also to promote First Nations languages. Although such programs are in short supply, funding for them is increasing. Overall, Canada places a high value on bilingual education that enhances minority children's native-language competence.

Nationally, French–English bilingualism has increased by 12 percent since the mid-1990s (Statistics Canada, 2007f). A major reason is Canada's *language immersion programs,* in which English-speaking elementary school children are taught entirely in French for several years. Currently, about 7 percent of Canadian elementary school students are enrolled. The immersion strategy succeeds in developing children who are proficient in both languages, and who, by grade 6, achieve as well in reading, writing, and math as their counterparts in the regular English program (Harley & Jean, 1999; Holobow, Genesee, & Lambert, 1991; Turnbull, Hart, & Lapkin, 2003). The Canadian government is taking steps to expand language immersion opportunities, in hopes of increasing the percentage of 15- to 19-year-olds who speak both English and French (Government of Canada, 2009).

In the United States, fierce disagreement exists over how to educate minority children with limited English proficiency. Some believe that time spent communicating in the child's native tongue detracts from English-language achievement, which is crucial for success in the worlds of school and work. Other educators, committed to developing minority children's native language while fostering mastery of English, note that providing instruction in the native tongue lets minority children know that their heritage is respected. It also prevents inadequate proficiency in both languages. Minority children who gradually lose their first language as a result of being taught the second end up limited in both languages for a time (Ovando & Collier, 1998). This circumstance leads to serious academic difficulties and is believed to contribute to the high rates of school failure and dropout among low-SES Hispanic young people, who make up nearly 50 percent of the U.S. language-minority population.

At present, public opinion and educational practice favor English-only instruction. Many U.S. states have passed laws declaring English to be their official language, creating conditions in which schools have no obligation to teach minority students in languages other than English. Yet in classrooms where both Spanish and English are integrated into the curriculum, U.S. minority students are more involved in learning, participate more actively in class discussions, and acquire speaking and reading skills in the second language more easily—gains that predict better academic achievement, increased likelihood of college attendance and graduation, and greater occupational attainment (Guglielmi, 2008). In contrast, when teachers speak only in a language that children can barely understand, minority children display frustration, boredom, withdrawal, and escalating academic difficulties (Kieffer, 2008). This downward spiral in achievement is greatest in high-poverty schools, where resources to support the needs of language-minority children are especially scarce.

© ROBIN SACHS/PHOTOEDIT

In this English–Spanish bilingual classroom, children are more involved in learning, participate more actively in class discussions, and acquire the second language more easily than they would in an English-only classroom.

Supporters of U.S. English-only education often point to the success of Canadian language immersion programs, in which classroom lessons are conducted in the second language. But Canadian parents enroll their children in immersion classrooms voluntarily, and both French and English are majority languages that are equally valued in Canada. Furthermore, teaching in the child's native language is merely delayed, not ruled out. For U.S. non–English-speaking minority children, whose native languages are not valued by the larger society, a different strategy seems necessary: one that promotes children's native-language skills while they learn English.

ASK YOURSELF

Review ■ Explain why metalinguistic awareness expands greatly in middle childhood. What might account for bilingual children's advanced metalinguistic skills?

Connect ■ How can bilingual education promote ethnic minority children's cognitive and academic development?

Apply ■ Reread the examples of Erin's language at the beginning of this chapter. Were Marilyn and Oscar wise to teach Erin both English and Spanish? Does Erin's mixing of the two languages indicate confusion? Justify your answers with research findings.

Reflect ■ Did you acquire a second language at home or study one in school? If so, when did you begin, and how proficient are you in the second language? Considering research on bilingualism, what changes would you make in your second-language learning, and why?

SUMMARY

Components of Language (p. 360)

What are the four components of language?

- Language consists of four subsystems: (1) **phonology,** the rules governing the structure and sequence of speech sounds; (2) **semantics,** the way underlying concepts are expressed in words; (3) **grammar,** consisting of **syntax,** the rules by which words are arranged in sentences, and **morphology,** markers that vary word meaning; and (4) **pragmatics,** the rules for engaging in appropriate and effective conversation.

Theories of Language Development (p. 360)

Describe and evaluate major theories of language development.

- Chomsky's nativist theory proposes a **language acquisition device** (**LAD**) containing a **universal grammar,** or storehouse of rules common to all languages. The LAD permits children, once they have sufficient vocabulary, to speak grammatically and comprehend sentences in any language to which they are exposed. Animal research is consistent with this perspective, revealing that a complex language system is unique to humans.
- The broad association of language functions, especially grammatical competence, with left-hemispheric regions of the cerebral cortex is in accord with Chomsky's notion of a brain prepared to process language. Evidence for a sensitive period of language development also supports the nativist view.
- Researchers have challenged the nativist perspective on several grounds, including the difficulty of specifying a universal grammar. Also, children's continuous, gradual mastery of many constructions is inconsistent with the nativist assumption of innately determined grammatical knowledge.
- According to the interactionist perspective, language development results from exchanges between inner capacities and environmental influences. The most influential information-processing accounts are connectionist, or artificial neural network, models, which show that powerful, general cognitive capacities are sufficient to detect certain linguistic patterns. Other evidence confirms that babies identify basic language patterns with the same strategies they use to understand nonlinguistic experiences.
- Social interactionists believe that children's social skills and language experiences combine with native capacity to profoundly affect language development. But debate continues over whether children make sense of their complex language environments by applying general cognitive capacities or capacities specially tuned to language.

Prelinguistic Development: Getting Ready to Talk (p. 368)

Discuss receptivity to language, development of speech sounds, and conversational skills during infancy.

- Newborns are capable of **categorical speech perception** and are sensitive to a wider range of speech categories than exists in their own language. Between 6 and 8 months, infants start to organize speech into the phonemic categories of their native tongue. In the second half of the first year, they have begun to analyze the internal structure of sentences and words. Adults' use of **infant-directed speech** (**IDS**) eases language learning for babies.

© LAURA DWIGHT PHOTOGRAPHY

- Infants begin **cooing** around 2 months, **babbling** around 6 months. Over the first year, the range of babbled sounds expands. Then, as infants get ready to talk, sound and intonation patterns start to resemble those of the child's native language.
- At 10 to 11 months, babies' skill at establishing **joint attention** improves**,** and by the end of the first year they actively engage in turn-taking games and use two communicative gestures, the **protodeclarative** and the **protoimperative,** to influence others' behavior. By the second year, caregiver–child interaction contributes greatly to language progress.

Phonological Development (p. 373)

Describe the course of phonological development.

- First words are influenced partly by the sounds children can pronounce. Because associating new words with their referents taxes toddlers' working memories, they tend to miss the fine details of a new word's sounds, which contributes to early pronunciation errors.
- Young children apply systematic phonological strategies to simplify challenging pronunciations. Gradually, they refine minimal words into full words with correct stress patterns. As the vocal tract matures and preschoolers engage in active problem solving, pronunciation improves greatly. But syllable stress patterns signaling subtle differences in meaning are not mastered until middle childhood or adolescence.

Semantic Development (p. 376)

Summarize the course of semantic development, noting individual differences.

- Language **comprehension** develops ahead of **production.** For most children, rate of word learning increases steadily and continuously from toddlerhood through the preschool years. To build vocabulary quickly, children engage in **fast-mapping.**
- Girls show faster early vocabulary growth than boys, and temperamentally shy or negative toddlers acquire language more slowly. Low-SES children, who experience less verbal stimulation, usually have smaller vocabularies. Most toddlers use a **referential style** of language learning; their early words mainly refer to objects. Some use an **expressive style,** producing more social formulas and pronouns.
- Early vocabularies typically emphasize object words; action and state words appear soon after. When first learning words, children make errors of **underextension** and **overextension.** Their word coinages and metaphors expand the range of meanings they can express.
- Reading contributes enormously to vocabulary growth in middle childhood. School-age children can grasp word meanings from definitions, and comprehension of metaphor and humor expands. Adolescents' ability to reason abstractly leads to an appreciation of irony, sarcasm, and figurative language.

Discuss ideas about how semantic development takes place, including the influence of memory and strategies for word learning.

- A special part of short-term memory, a **phonological store** that permits retention of speech-based information, supports young children's vocabulary growth. After age 5, semantic knowledge also influences how quickly children form phonological traces, and both factors affect word learning.

- Children figure out the meanings of words by contrasting them with words they already know and assigning new words to gaps in their vocabulary. According to one view, children are innately biased to induce word meanings using certain principles, such as a **mutual exclusivity bias** and **syntactic bootstrapping.**
- An alternate perspective is that children build their vocabularies with the same cognitive strategies that they apply to nonlinguistic stimuli. According to the **emergentist coalition model,** children figure out word meanings from a coalition of cues—perceptual, social, and linguistic—which shift in importance with age.

Grammatical Development

(p. 384)

Describe the course of grammatical development.

- Between 1½ and 2½ years, vocabulary reaches 200 to 250 words and two word utterances called **telegraphic speech** appear. These early word combinations do not reflect a consistent, flexible grammar. As children generate three-word sentences, they use grammatical rules in a piecemeal fashion, gradually refining and generalizing structures.
- English-speaking children add **grammatical morphemes** in a consistent order that reflects both structural and semantic complexity. Once children acquire a regular morphological rule, they **overregularize,** extending it to words that are exceptions. Over time, children master expressions based on auxiliary verbs, such as negatives and questions. Between ages 3½ and 6, they add a variety of intricate constructions. Certain forms, such as the passive voice and infinitive phrases, continue to be refined in middle childhood.

Discuss ideas about how grammatical development takes place, including strategies and communicative support for mastering new structures.

- Some experts believe grammar is a product of general cognitive development. According to one view, children engage in **semantic bootstrapping,** relying on word meanings to figure out sentence structure. Others believe that children master grammar through direct observation of the structure of language. Still others agree with the essence of Chomsky's theory. One idea accepts semantic bootstrapping but proposes that grammatical categories are innate. Another speculation is that children have a built-in set of procedures for analyzing language, which supports the discovery of grammatical regularities.
- Adults provide children with indirect feedback about grammatical errors by asking for clarification or by restructuring their speech using **recasts** and **expansions.** However, the impact of such feedback on grammatical development has been challenged.

© ELLEN B. SENISI PHOTOGRAPHY

Pragmatic Development **(p. 390)**

Describe the course of pragmatic development.

- Even 2-year-olds are effective conversationalists. Strategies that help sustain interaction, such as **turnabout** and **shading,** are added in early and middle childhood. Children's understanding of **illocutionary intent** also improves, and they also acquire more effective **referential communication skills.**
- From the preschool to school years, children produce more organized, detailed, and evaluative narratives, which vary widely in form across cultures. The ability to generate clear oral narratives contributes to literacy development. Preschoolers are already sensitive to **speech registers.** Parents tutor young children in politeness routines, emphasizing the importance of adapting language to social expectations.

Development of Metalinguistic Awareness

(p. 394)

Describe the development of metalinguistic awareness and its role in language-related attainments.

- Preschoolers show the beginnings of **metalinguistic awareness.** Their understandings are good predictors of vocabulary and grammatical development and, in the case of phonological awareness, literacy development. Major advances in metalinguistic skills take place in middle childhood.

Bilingualism: Learning Two Languages in Childhood

(p. 394)

How do children become bilingual, and what are the advantages of bilingualism?

- Children who learn two languages in early childhood acquire each according to a typical timetable. When school-age children acquire a second language after mastering the first, they take five to seven years to attain the competence of native-speaking agemates. Bilingual children sometimes engage in **code switching** between the two languages.
- Bilingual children are advanced in cognitive development and metalinguistic awareness—advantages that provide strong justification for bilingual education programs in schools.

CHAPTER

10

“Love of Mother”

Name Unknown, 15 years, Korea

Assertively grasping his mother’s hand, a young child ventures confidently into the wider world. A secure attachment bond with a warm, sensitive caregiver provides children with vital support for exploring and mastering their environment.

Reprinted with permission from the International Collection of Child Art, Milner Library, Illinois State University, Normal, Illinois

Emotional Development

On a spring day, 4-month-old Zach, cradled in his father's arms, arrived at the door of my classroom, which had been transformed into a playroom for the morning. Behind him, led by their mothers, came 13-month-old Emily and 23-month-old Brenda. My students and I spent the next hour watching the three children closely. Especially captivating were the children's emotional reactions to people and objects. Zach grinned gleefully as his dad lifted him in the air, and he responded with an excited giggle to a tickle followed by a lively kiss on the tummy. When I offered Zach a rattle, his brows knit, his face sobered, and he eyed the rattle intently as he mobilized all his energies to reach for it.

Transferred to my arms and then to the laps of several students, Zach remained at ease (although he reserved a particularly broad smile for his father). In contrast, Emily and Brenda were wary. When I offered a toy and coaxed Emily toward it, she pulled back and glanced at her mother, as if to check whether the new adult and tantalizing object were safe to explore. With her mother's encouragement, Emily approached cautiously and accepted the toy. A greater capacity to understand the situation, along with her mother's explanations, helped Brenda adjust, and soon she was engrossed in play. During the hour, Brenda displayed a wide range of emotions, including embarrassment at seeing chocolate on her chin in a mirror and pride as I remarked on the tall block tower she had built.

Emotional development—formerly overshadowed by cognition—is an exciting, rapidly expanding area of research. Our discussion opens with the functions of emotions in all aspects of human activity. Next, we chart age-related gains in children's emotional expression and understanding. We will account for Zach, Emily, and Brenda's expanding emotional capacities as they engage in increasingly complex interactions with their changing physical and social worlds. Our attention then turns to individual differences in temperament and personality. We will examine biological and environmental contributions to these differences and their consequences for future development. Finally, we look at attachment to the caregiver—the infant's first affectionate tie. We will see how the feelings of security that grow out of this bond support the child's exploration, sense of independence, and expanding social relationships. ■

Functions of Emotions

TAKE A MOMENT... Think back over the past day or so. Do you recall feeling happy, sad, fearful, or angry in response to a grade on a test or a conversation with a friend? These events trigger emotion because you care about their outcomes. Your **emotion** is a rapid appraisal of the personal significance of the situation, which prepares you for action. For example, happiness leads you to approach, sadness to passively withdraw, fear to actively move away, and anger to overcome obstacles. An emotion, then, expresses your readiness to establish, maintain, or change your relation to the environment on a matter of importance to you (Campos, Frankel, & Camras, 2004; Saarni et al., 2006).

A number of theorists take a **functionalist approach to emotion,** emphasizing that the broad function of emotions is to energize behavior aimed at attaining personal goals (Barrett & Campos, 1987; Campos, Frankel, & Camras, 2004; Frijda, 2000; Saarni et al.,

▶ Describe the functionalist approach to emotional development.

2006). Events can become personally relevant in several ways. First, you may already have a goal in mind, such as doing well on a test, so the testing situation prompts strong emotion. Second, others' social behavior may alter a situation's significance for you, as when a friend visits and you respond warmly to her friendly greeting. Third, any sensation or state of mind—a sight, sound, taste, smell, touch, memory, or imagining—can become personally relevant and evoke emotion, positive or negative. Your emotional reaction, in turn, affects your desire to repeat the experience.

In each case, emotions arise from ongoing exchanges between the person and the environment, flexibly serving different functions as the individual's circumstances change (Thompson, Winer, & Goodvin, 2011). Functionalist theorists believe that emotions are central in all our endeavors—cognitive processing, social behavior, and even physical health. Let's see how emotions organize and regulate experiences in each domain.

© ELLEN B. SENISI PHOTOGRAPHY

This 17-year-old, an experienced guitarist, is well-prepared for performance. Nevertheless, he reports that high anxiety sometimes interferes, diverting his attention from the cognitive demands of guitar playing.

Emotions and Cognitive Processing

Emotional reactions can lead to learning that is essential for survival. For example, a caregiver's highly charged "No!" is sufficient to keep most newly walking toddlers from touching an electric outlet or careening down a staircase. The toddler need not experience a shock or a fall to avoid these dangers.

The emotion–cognition relationship is evident in the impact of anxiety on performance. Among children and adults, high anxiety impairs thinking, especially on complex tasks, by diverting attention from cognitive processing to task-irrelevant threatening stimuli and worrisome thoughts (Derakshan & Eysenck, 2009). Emotions can also powerfully affect memory. For example, compared to their less stressed agemates, preschool and school-age children who were highly upset by an inoculation at the doctor's office tended to remember the event better, probably because they focused more attention on the threatening experience (Alexander et al., 2002; Goodman et al., 1991).

The relationship between emotion and cognition is bidirectional—a dynamic interplay already under way in early infancy (Lewis, 1999). In one study, researchers taught 2- to 8-month-olds to pull a string to activate pleasurable sights and sounds. As the infants learned the task, they responded with interest, happiness, and surprise. Then, for a short period, pulling the string no longer turned on the attractive stimuli. The babies' emotional reactions quickly changed—mostly to anger but occasionally to sadness. Once the contingency was restored, the infants who had reacted angrily showed renewed interest and enjoyment, whereas the sad babies turned away (Lewis, Sullivan, & Ramsay, 1992). Emotions were interwoven with cognitive processing, serving as outcomes of mastery and as the energizing force for continued involvement and learning.

Emotions and Social Behavior

Children's emotional signals, such as smiling, crying, and attentive interest, powerfully affect the behavior of others. Similarly, the emotional reactions of others regulate children's social behavior.

Careful analyses of caregiver–infant interaction reveal that by 3 months, a complex communication system is in place in which each partner responds in an appropriate and carefully timed fashion to the other's cues (Weinberg et al., 1999). In several studies, researchers disrupted this exchange of emotional signals by having the parent assume either a still-faced, unreactive pose or a depressed emotional state. Two- to 7-month-olds tried facial expressions, vocalizations, and body movements to get the parent to respond again. When these efforts failed, they turned away, frowned, and cried (Moore, Cohn, & Campbell, 2001; Papousek, 2007). This *still-face reaction* occurs only when natural human communication is disrupted (not to a still-faced doll or to the mother wearing a still-faced mask) and is identical in American, Canadian, and Chinese babies, suggesting that it is a built-in withdrawal response to caregivers' lack of communication (Kisilevsky et al., 1998; Legerstee & Markova, 2007). Clearly, when engaged in face-to-face interaction, even young infants expect their partners to be emotionally responsive. To learn more about the impact of parental depression on children's emotional and social adjustment, consult the Biology and Environment box on page 404.

With age, emotional expressions become deliberate means through which infants communicate, and babies monitor the emotional expressions of others to assess their intentions and perspectives. For example, caregivers initiate nearly all positive emotional exchanges with young babies. But by 9 months, infants become initiators, smiling before the caregiver smiles (Cohn & Tronick, 1987). Furthermore, recall from Chapter 9 that by the end of the first year, babies become increasingly skilled at *joint attention*—following the caregiver's line of regard. In these joint attentional episodes, infants and toddlers pick up not only verbal information but also emotional information. Later in this chapter, we will see that when faced with unfamiliar people, objects, or events, older infants pay close attention to their caregiver's affect, using it as a guide for how to respond. Through this checking of others' emotions, called *social referencing*, young children learn how to behave in a great many everyday situations. One 18-month-old, on first witnessing his newborn sister cry, monitored his mother's reaction. On subsequent occasions, he patted the baby and comforted, "No, no, Peach [her nickname], no tears."

Emotions and Health

Much research indicates that emotions influence children's physical well-being. In Chapter 5, we discussed two childhood growth disorders—*growth faltering* and *psychosocial dwarfism*—that involve emotional deprivation. Many other studies indicate that persistent psychological stress, manifested in anxiety, depressed mood, anger, and irritability, is associated with a variety of health difficulties from infancy to adulthood. For example, stress elevates heart rate and blood pressure and depresses the immune response—reactions that may explain its relationship with cardiovascular disease, infectious illness, and several forms of cancer. Stress also reduces digestive activity as blood flows to the brain, heart, and extremities to mobilize the body for action. Consequently, it can lead to gastrointestinal difficulties, including constipation, diarrhea, colitis, and ulcers (Antoni & Lutgendorf, 2007; Ray, 2004). And stress not only induces illness but results from it—a feedback loop that can cause both to worsen over time.

In a dramatic demonstration of the emotion–health relationship, researchers followed children adopted into Canadian homes who had been exposed to chronic stress as a result of at least 8 months of early rearing in extremely depleted Romanian orphanages, where they lacked adult attention and stimulation and suffered from infectious and dietary diseases—most commonly, intestinal parasites, hepatitis, and anemia. Compared with healthy agemates who had been adopted shortly after birth, these physically ill, emotionally deprived children showed extreme reactivity to stress, as indicated by high concentrations of the stress hormone *cortisol* in their saliva—a physiological response linked to persistent illness and learning and behavior problems, including deficits in concentration and control of anger and other impulses. The longer the children spent in orphanage care, the higher their cortisol levels, even six and a half years after adoption (Gunnar et al., 2001; Gunnar & Cheatham, 2003). In other investigations, orphanage children displayed abnormally low cortisol—a blunted physiological stress response that may be the central nervous system's adaptation to earlier, frequent cortisol elevations (Loman & Gunnar, 2010). Extremely low cortisol interferes with release of growth hormone (GH) and, thus, can stunt children's physical growth.

Fortunately, sensitive adult care helps normalize cortisol production in both typically developing and emotionally traumatized infants and young children. Good parenting seems to protect the young brain from the potentially damaging effects of both excessive and inadequate stress-hormone exposure (Gunnar & Quevedo, 2007; Tarullo & Gunnar, 2006). After adoption into caring families, orphanage children's cortisol production moves toward typical levels, and growth and behavior problems lessen (Gunnar & Vasquez, 2001). Nevertheless, as we saw in Chapter 4 and will see again in this chapter, many institutionalized children adopted after spending much of their first year in deprived institutions suffer from serious, lasting adjustment difficulties.

BIOLOGY and ENVIRONMENT

Parental Depression and Child Development

About 8 to 10 percent of women experience chronic depression—mild to severe feelings of sadness, distress, and withdrawal that continue for months or years. Often, the beginnings of this emotional state cannot be pinpointed. In other instances, depression emerges or strengthens after childbirth but fails to subside as the new mother adjusts to hormonal changes in her body and gains confidence in caring for her baby. This is called *postpartum depression*.

Although it is less recognized and studied, fathers, too, experience chronic depression. About 3 to 5 percent of fathers report symptoms after the birth of a child (Madsen & Juhl, 2007; Thombs, Roseman, & Arthurs, 2010). Parental depression can interfere with effective parenting and seriously impair children's development. Genetic makeup increases the risk of depressive illness, but social and cultural factors are also involved.

Maternal Depression

During Julia's pregnancy, her husband, Kyle, showed so little interest in the baby that Julia worried that having a child might be a mistake. Then, shortly after Lucy was born, Julia's mood plunged. She felt anxious and weepy, overwhelmed by Lucy's needs, and angry at loss of control over her own schedule. When Julia approached Kyle about her own fatigue and his unwillingness to help with the baby, he snapped that she was overreacting. Julia's childless friends stopped by just once to see Lucy but did not call again.

Julia's depressed mood quickly affected her baby. In the weeks after birth, infants of depressed mothers sleep poorly, are less attentive to their surroundings, and have elevated levels of the stress hormone cortisol (Field, 1998). The more extreme the depression and the greater the number of stressors in a mother's life (such as marital discord, little or no social support, and poverty), the more the parent–child relationship suffers (Simpson et al., 2003). Julia rarely smiled at, comforted, or talked to Lucy, who responded to her mother's sad, vacant gaze by turning away, crying, and often looking sad or angry herself (Feldman et al., 2009; Field, 2011). Julia, in turn, felt guilty and inadequate, and her depression deepened. By age 6 months, Lucy showed symptoms common in babies of depressed mothers—delays in motor and mental development, an irritable mood, and attachment difficulties (Cornish et al., 2005; McMahon et al., 2006).

© RICHARD NEWTON/ALAMY

This depressed mother appears completely disengaged from her infant. In response, the baby is likely to become negative and irritable, to eventually withdraw, and to develop serious emotional and behavior problems.

When maternal depression persists, the parent–child relationship worsens. Depressed mothers view their infants and children more negatively than independent observers do (Forman et al., 2007). And they use inconsistent discipline—sometimes lax, at other times too forceful. As we will see in later chapters, children who experience these maladaptive parenting practices often have serious adjustment problems. Some withdraw into a depressed mood themselves; others become impulsive and aggressive (Hay et al., 2003). In one study, infants born to mothers who were depressed during pregnancy were four times as likely as babies of nondepressed mothers to have engaged in violent antisocial behavior (such as fighting, bullying, assault with a weapon, and extreme bodily harm) by age 16, after other stressors in the mother's life that could contribute to youth antisocial conduct had been controlled (Hay et al., 2010).

Paternal Depression

Paternal depression is also linked to dissatisfaction with marriage and family life after childbirth and to other life stressors, including job loss and divorce (Bielawska-Batorowicz & Kossakowska-Petrycka, 2006). In a study of a large representative sample of British parents and babies, researchers assessed depressive symptoms of fathers shortly after birth and again the following year. Then they tracked the children's development into the preschool years. Persistent paternal depression was, like maternal depression, a strong predictor of child behavior problems—especially overactivity, defiance, and aggression in boys (Ramchandani et al., 2008).

Paternal depression is linked to frequent father–child conflict as children grow older (Kane & Garber, 2004). Over time, children subjected to parental negativity develop a pessimistic worldview—one in which they lack self-confidence and perceive their parents and other people as threatening. Children who constantly feel in danger are especially likely to become overly aroused in stressful situations, easily losing control in the face of cognitive and social challenges (Sturge-Apple et al., 2008). Although children of depressed parents may inherit a tendency to develop emotional and behavior problems, quality of parenting is a major factor in their adjustment.

Interventions

Early treatment is vital to prevent parental depression from interfering with the parent–child relationship. Julia's doctor referred her to a therapist, who helped Julia and Kyle with their marital problems. At times, antidepressant medication is prescribed.

In addition to alleviating parental depression, therapy that encourages depressed mothers to revise their negative views of their babies and to engage in emotionally positive, responsive caregiving is vital for reducing young children's attachment and other developmental problems (Forman et al., 2007). When a depressed parent does not respond easily to treatment, a warm relationship with the other parent or another caregiver can safeguard children's development (Mezulis, Hyde, & Clark, 2004).

Other Features of the Functionalist Approach

In addition to the vital role of emotions in cognitive, social, and physical development, functionalist theorists point out that emotions contribute to the emergence of self-awareness. For example, the interest and excitement that babies display when acting on novel objects help them forge a *sense of self-efficacy*—confidence in their own ability to control events in their surroundings (Harter, 2006). By the middle of the second year, when self-awareness is sufficiently developed, children begin to experience a new array of emotions with distinct functions. Recall Brenda's expressions of pride and embarrassment—two *self-conscious emotions* that have to do with evaluating the self's goodness or badness in relation to standards for morality, social behavior, and task mastery (Saarni et al., 2006).

Finally, the functionalist approach emphasizes that to adapt to their physical and social worlds, children must gain control over their emotions, just as they do their motor, cognitive, and social behavior. As part of this increasing *emotional self-regulation*, children must master their culture's rules for when and how to convey emotion. As a result, by late childhood, few emotions are expressed as openly and freely as they were in the early years of life. With these ideas in mind, let's chart the course of emotional development.

ASK YOURSELF

Review ■ Using research findings, provide an example of the impact of emotions on children's (1) cognitive processing, (2) social behavior, and (3) physical health.

Connect ■ Does the still-face reaction help us understand infants' responses to parental depressed mood, reviewed in the Biology and Environment box on page 404? Explain.

Apply ■ Recently divorced, Jeannine—mother of 3-month-old Jacob—feels lonely, depressed, and anxious about finances. How might Jeannine's emotional state affect Jacob's emotional and social adjustment? What can be done to help Jeannine and Jacob?

Reflect ■ Using one of your own experiences, illustrate the bidirectional relationship between emotion and cognition.

Development of Emotional Expression

- How does the expression of basic emotions change during infancy?
- Describe the development of self-conscious emotions, emotional self-regulation, and conformity to emotional display rules.

Because infants cannot describe their feelings, determining exactly which emotions they are experiencing is a challenge. Although vocalizations and body movements provide some information, researchers have relied most on facial expressions. Cross-cultural evidence reveals that people around the world associate photographs of different facial expressions with emotions in the same way (Ekman, 2003; Ekman & Friesen, 1972). These findings inspired researchers to analyze infants' facial patterns carefully to determine the range of emotions they display at different ages.

Nevertheless, assuming a close correspondence between a pattern of behavior and an underlying emotional state can lead to error. Infants, children, and adults use diverse responses to express a particular emotion. For example, babies on the visual cliff (see page 159 in Chapter 4) generally do not display a fearful facial expression, though they do show other signs of fear—drawing back and refusing to crawl over the deep side. Recall, also, from Chapter 4 that the emotional expressions of blind babies, who cannot make eye contact, are muted, prompting parents to withdraw (see page 162). When therapists show parents how blind infants express emotions through finger movements, parents become more interactive (Fraiberg, 1971; Saarni et al., 2006). Furthermore, the same general response can express several emotions. Depending on the situation, a smile might convey joy, embarrassment, contempt, or a social greeting.

In line with the *dynamic systems perspective* (see page 30 in Chapter 1), emotional expressions vary with the person's developing capacities, goals, and context (Lewis, 2000, 2008). To infer babies' emotions more accurately, researchers must attend to multiple interacting expressive cues—vocal, facial, and gestural—and see how they differ across situations believed to elicit different emotions.

Basic Emotions

Basic emotions—happiness, interest, surprise, fear, anger, sadness, disgust—are universal in humans and other primates and have a long evolutionary history of promoting survival. Do infants come into the world with the ability to express basic emotions? Although signs of some emotions are present, babies' earliest emotional life consists of little more than two global arousal states: attraction to pleasant stimulation and withdrawal from unpleasant stimulation (Camras et al., 2003; Fox, 1991). Only gradually do emotions become clear, well-organized signals.

The dynamic systems perspective helps us understand how this happens: Children coordinate separate skills into more effective, emotionally expressive systems as the central nervous system develops and the child's goals and experiences change (Camras & Shutter, 2010). Videotaping the facial expressions of her daughter from 6 to 14 weeks, Linda Camras (1992) found that in the early weeks, the baby displayed a fleeting angry face as she was about to cry and a sad face as her crying waned. These expressions first appeared on the way to or away from full-blown distress and were not clearly linked to the baby's experiences and desires. With age, she was better able to sustain an angry signal when she encountered a blocked goal and a sad signal when she could not overcome an obstacle.

According to one view, sensitive, contingent caregiver communication, in which parents selectively mirror aspects of the baby's diffuse emotional behavior, helps infants construct emotional expressions that more closely resemble those of adults (Gergely & Watson, 1999). With age, face, gaze, voice, and posture start to form organized patterns that vary meaningfully with environmental events. For example, by the middle of the first year, babies typically respond to the parent's playful interaction with a joyful face, pleasant babbling, and a relaxed posture, as if to say, "This is fun!" In contrast, an unresponsive parent often evokes a sad face, fussy sounds, and a drooping body (sending the message, "I'm despondent") or an angry face, crying, and "pick me up" gestures (as if to say, "Change this unpleasant event!") (Weinberg & Tronick, 1994; Yale et al., 1999). Gradually, emotional expressions become well-organized and specific—and therefore provide more precise information about the baby's internal state.

Four basic emotions—happiness, anger, sadness, and fear—have received the most research attention. Let's see how they develop.

Happiness

Happiness—expressed first in blissful smiles, later through exuberant laughter—contributes to many aspects of development. When infants achieve new skills, they smile and laugh, displaying delight in motor and cognitive mastery. As the smile encourages caregivers to be affectionate and stimulating, the baby smiles even more (Aksan & Kochanska, 2004). Happiness binds parent and child into a warm, supportive relationship that fosters the infant's developing competencies.

© RADIUS IMAGES/ALAMY IMAGES

A baby's joyous laughter encourages his mother to respond in kind, binding them together in a warm, affectionate relationship that promotes all aspects of development.

During the early weeks, newborn babies smile when full, during REM sleep, and in response to gentle touches and sounds, such as stroking of the skin, rocking, and the mother's soft, high-pitched voice. By the end of the first month, infants smile at dynamic, eye-catching sights, such as a bright object jumping suddenly across their field of vision. And as infants attend to the parent's face, and the parent talks and smiles, babies knit their brows, open their mouths to coo, and move their arms and legs excitedly, gradually becoming more emotionally positive until, between 6 and 10 weeks, the parent's communication evokes a broad grin called the **social smile** (Lavelli & Fogel, 2005; Sroufe & Waters, 1976). These changes parallel the development of infant perceptual capacities—in particular, babies' sensitivity to visual patterns, including the human face (see Chapter 4). And social smiling becomes better organized and stable as babies learn to use it to evoke and sustain pleasurable face-to-face interaction.

Laughter, which appears around 3 to 4 months, reflects faster processing of information than smiling. But as with smiling, the first laughs occur in response to very active stimuli, such as the parent saying playfully, "I'm gonna get you!" and kissing the baby's tummy. As infants understand more about their world, they laugh at events with subtler elements of surprise, such as a silent game of peekaboo (Sroufe & Wunsch, 1972).

Around the middle of the first year, infants smile and laugh more when interacting with familiar people, a preference that strengthens the parent–child bond. Between 8 and 10 months, infants more often interrupt their play with an interesting toy to relay their delight to an attentive adult (Venezia et al., 2004). And like adults, 10- to 12-month-olds have several smiles, which vary with context—a broad, "cheek-raised" smile in response to a parent's greeting; a reserved, muted smile for a friendly stranger; and a "mouth-open" smile during stimulating play (Bolzani et al., 2002; Messinger & Fogel, 2007). By the end of the first year, the smile has become a deliberate social signal.

© KOICHI SAITO/AMANAIMAGES/PHOTOLIBRARY

This 8-month-old knows just what object she wants and who is keeping it from her. Angry reactions increase as babies become capable of intentional behavior and better able to identify obstacles to reaching their goals.

Anger and Sadness

Newborn babies respond with generalized distress to a variety of unpleasant experiences, including hunger, painful medical procedures, changes in body temperature, and too much or too little stimulation (see Chapter 4). From 4 to 6 months into the second year, angry expressions increase in frequency and intensity (Braungart-Rieker, Hill-Soderlund, & Karrass, 2010). Older infants also react with anger in a wider range of situations—when an interesting object or event is removed, an expected pleasant event does not occur, their arms are restrained, the caregiver leaves for a brief time, or they are put down for a nap (Camras et al., 1992; Stenberg & Campos, 1990; Sullivan & Lewis, 2003).

Why do angry reactions increase with age? As infants become capable of intentional behavior (see Chapter 6), they want to control their own actions and the effects they produce and will purposefully try to change an undesirable situation (Alessandri, Sullivan, & Lewis, 1990). They are also more persistent about obtaining desired objects and less easily distracted from those goals (Mascolo & Fischer, 2007). Furthermore, older infants are better at identifying who caused them pain or removed a toy. Their anger is particularly intense when a caregiver from whom they have come to expect warm behavior causes discomfort. The rise in anger is also adaptive. New motor capacities enable angry infants to defend themselves or overcome obstacles (Izard & Ackerman, 2000). Finally, anger motivates caregivers to relieve a baby's distress and, in the case of separation, may discourage them from leaving again soon.

Although expressions of sadness also occur in response to pain, removal of an object, and brief separations, they are less common than anger (Alessandri, Sullivan, & Lewis, 1990). In contrast, sadness occurs often when infants are deprived of a familiar, loving caregiver or when caregiver–infant communication is seriously disrupted (refer again to the Biology and Environment box on page 404).

Fear

Like anger, fear rises during the second half of the first year into the second year (Braungart-Rieker, Hill-Soderland, & Karrass, 2010). Older infants hesitate before playing with a new toy, and newly crawling infants soon back away from heights (see Chapter 4). But the most frequent expression of fear is to unfamiliar adults, a response called **stranger anxiety**. Many infants and toddlers are quite wary of strangers, although the reaction does not always occur. It depends on several factors: temperament (some babies are generally more fearful), past experiences with strangers, and the current situation. When an unfamiliar adult picks up the infant in a new setting, stranger anxiety is likely. But if the adult sits still while the baby moves around and a parent remains nearby, infants often show positive and curious behavior (Horner, 1980). The stranger's style of interaction—expressing warmth, holding out an attractive toy, playing a familiar game, and approaching slowly rather than abruptly—reduces the baby's fear.

LOOK and LISTEN

While observing an 8- to 18-month-old with his or her parent, gently approach the baby, offering a toy. Does the baby respond with stranger anxiety? To better understand the baby's behavior, ask the parent to describe his or her temperament and past experiences with strangers.

© ELLEN B. SENISI PHOTOGRAPHY

Stranger anxiety appears in many infants after 6 months. But this baby, safe in his father's arms, also expresses curiosity, reaching out warily toward an unfamiliar adult who eases his fear by smiling and approaching slowly.

Cross-cultural research reveals that infant-rearing practices can modify stranger anxiety. Among the Efe hunters and gatherers of the Republic of Congo, where the maternal death rate is high, infant survival is safeguarded by a collective caregiving system in which, starting at birth, Efe babies are passed from one adult to another. Consequently, Efe infants show little stranger anxiety (Tronick, Morelli, & Ivey, 1992). In contrast, among infants in Israeli kibbutzim (cooperative agricultural settlements), who live in isolated communities vulnerable to terrorist attacks, wariness of strangers is widespread. By the end of the first year, when infants look to others for cues about how to respond emotionally, kibbutz babies display far greater stranger anxiety than their city-reared counterparts (Saarni et al., 2006).

The rise in fear after age 6 months keeps newly mobile babies' enthusiasm for exploration in check. Once wariness develops, infants use the familiar caregiver as a **secure base,** or point from which to explore, venturing into the environment and then returning for emotional support. As part of this adaptive system, encounters with strangers lead to two conflicting tendencies: approach (indicated by interest and friendliness) and avoidance (indicated by fear). The infant's behavior is a balance between the two.

Eventually, as cognitive development permits toddlers to discriminate more effectively between threatening and nonthreatening people and situations, stranger anxiety and other fears of the first two years decline. This change is adaptive because adults other than caregivers will soon be important in children's development. Fear also wanes as children acquire a wider array of strategies for coping with it, as you will see when we discuss emotional self-regulation.

Self-Conscious Emotions

Besides basic emotions, humans are capable of a second, higher-order set of feelings, including guilt, shame, embarrassment, envy, and pride. These are called **self-conscious emotions** because each involves injury to or enhancement of our sense of self. We feel guilt when we know that we have harmed someone and we want to correct the wrongdoing. When we are ashamed or embarrassed, we have negative feelings about our behavior, and we want to retreat so others will no longer notice our failings. In contrast, pride reflects delight in the self's achievements, and we are inclined to tell others what we have accomplished and to take on further challenges (Saarni et al., 2006).

Self-conscious emotions appear in the middle of the second year, as 18- to 24-month-olds become firmly aware of the self as a separate, unique individual. Toddlers show shame and embarrassment by lowering their eyes, hanging their heads, and hiding their faces with their hands. They show guiltlike reactions, too, like the 22-month-old who returned a toy she had grabbed and patted her upset playmate. Pride also emerges around this time, and envy by age 3 (Barrett, 2005; Garner, 2003; Lewis et al., 1989).

Besides self-awareness, self-conscious emotions require an additional ingredient: adult instruction in *when* to feel proud, ashamed, or guilty. The situations in which adults encourage self-conscious emotions vary from culture to culture. In Western individualistic nations, most children are taught to feel pride over personal achievement—throwing a ball the farthest, winning a game, and (later on) getting good grades. In collectivist cultures such as China and Japan, calling attention to purely personal success evokes embarrassment and self-effacement. And violating cultural standards by failing to show concern for others—a parent, a teacher, or an employer—sparks intense shame (Akimoto & Sanbonmatsu, 1999; Lewis, 1992).

As their self-concepts develop, children become increasingly sensitive to praise and blame or to the possibility of such feedback from parents, teachers, and other adults who matter to them, often viewing their expectations as obligatory rules ("Dad said you're 'posed to take turns"). By age 3, self-conscious emotions are clearly linked to self-evaluation (Lewis, 1995; Thompson, Meyer, & McGinley, 2006). Preschoolers show much more pride when they succeed in difficult rather than easy tasks and much more shame when they fail simple rather than hard tasks (Lewis, Alessandri, & Sullivan, 1992).

Quality of adult feedback influences these early self-evaluative reactions. When parents repeatedly comment on the worth of the child and her performance ("That's a bad job!" "I thought you were a good girl"), children experience self-conscious emotions intensely—more shame after failure, more pride after success. In contrast, when parents focus on how to improve performance ("You did it this way; now try doing it that way"), they induce moderate, more adaptive levels of shame and pride and greater persistence on difficult tasks (Kelley, Brownell, & Campbell, 2000; Lewis, 1998).

Among Western children, intense shame is associated with feelings of personal inadequacy ("I'm stupid"; "I'm a terrible person") and with maladjustment—withdrawal and depression as well as intense anger and aggression toward those who participated in the shame-evoking situation (Lindsay-Hartz, de Rivera, & Mascolo, 1995; Mills, 2005). In contrast, guilt—when it occurs in appropriate circumstances and is neither excessive nor accompanied by shame—is related to good adjustment. Guilt helps children resist harmful impulses, and it motivates a misbehaving child to repair the damage and behave more considerately (Mascolo & Fischer, 2007; Tangney, Stuewig, & Mashek, 2007). But overwhelming guilt—involving such high emotional distress that the child cannot make amends—is linked to depressive symptoms as early as age 3 (Luby et al., 2009).

The consequences of shame for children's adjustment, however, may vary across cultures. In Asian collectivist societies, where people define themselves in relation to their social group, shame is viewed as an adaptive reminder of the importance of others' judgments (Bedford, 2004). Chinese parents, for example, believe that it is important for a misbehaving child to feel ashamed. As early as age 2½, they frequently use shame to teach right from wrong, while mindful that excessive shaming could harm the child's self-esteem (Fung, 1999). Not surprisingly, Chinese children add the word *shame* to their vocabularies by age 3, much earlier than their American counterparts do (Shaver, Wu, & Schwartz, 1992).

© ELLEN B. SENISI PHOTOGRAPHY

A teacher's praise reinforces this 6-year-old's pride in completing a sheet of challenging math problems. But even when no adult is present, school-age children experience pride, guilt, and other self-conscious emotions.

As children develop inner standards of excellence and good behavior and a sense of personal responsibility, the circumstances under which they experience self-conscious emotions change. Unlike preschoolers, school-age children experience pride in a new accomplishment and guilt over a transgression even when no adult is present (Harter & Whitesell, 1989). Also, school-age children no longer report guilt for any mishap, as they did earlier, but only for intentional wrongdoing, such as ignoring responsibilities, cheating, or lying (Ferguson, Stegge, & Damhuis, 1991). These changes reflect the older child's more mature sense of morality, a topic we will take up in Chapter 12.

Emotional Self-Regulation

Besides expressing a wider range of emotions, children learn to manage their emotional experiences. **Emotional self-regulation** refers to the strategies we use to adjust our emotional state to a comfortable level of intensity so we can accomplish our goals. It requires several cognitive capacities that we discussed in Chapter 7—attention focusing and shifting, the ability to inhibit thoughts and behavior, and planning, or actively taking steps to relieve a stressful situation (Eisenberg & Spinrad, 2004; Thompson & Goodvin, 2007). When you remind yourself that an anxiety-provoking event will be over soon, suppress your anger at a friend's behavior, or decide not to see a scary horror film, you are engaging in emotional self-regulation.

Emotional self-regulation requires voluntary, effortful management of emotions. This capacity for *effortful control* improves gradually, as the result of development of the prefrontal cortex and the assistance of caregivers, who help children manage intense emotion and teach them strategies for doing so (Fox & Calkins, 2003; Rothbart, Posner, & Kieras, 2006). Individual differences in control of emotion are evident in infancy and, by early childhood, play such a vital role in children's adjustment that—as we will see later—effortful control is considered a major dimension of temperament. Let's turn now to changes in emotional self-regulation from infancy to adolescence.

Infancy In the early months, infants have only a limited capacity to regulate their emotional states. When their feelings get too intense, they are easily overwhelmed. They depend on the soothing interventions of caregivers—being lifted to the shoulder, rocked, gently stroked, and talked to softly—for distraction and reorienting of attention.

More effective functioning of the prefrontal cortex increases the baby's tolerance for stimulation. Between 2 and 4 months, caregivers build on this capacity by initiating face-to-face play and attention to objects. In these interactions, parents arouse pleasure in the baby while adjusting the pace of their own behavior so the infant does not become overwhelmed and distressed. As a result, the baby's tolerance for stimulation increases further (Kopp & Neufeld, 2003).

By 4 to 6 months, the ability to shift attention and engage in self-soothing helps infants control emotion. Babies who more readily turn away from highly stimulating novel events (a toy fire truck with siren blaring and lights flashing) or engage in self-soothing are less prone to distress (Crockenberg & Leerkes, 2003a). At the end of the first year, crawling and walking enable infants to regulate emotion more effectively by approaching or retreating from various situations. And further gains in attention permit toddlers to sustain interest in their surroundings and in play activities for a longer time (Rothbart & Bates, 2006).

Infants whose parents "read" and respond contingently and sympathetically to their emotional cues tend to be less fussy and fearful, to express more pleasurable emotion, to be more interested in exploration, and to be easier to soothe (Braungart-Rieker, Hill-Soderlund, & Karrass, 2010; Crockenberg & Leerkes, 2004; Volling et al., 2002). In contrast, parents who respond impatiently or angrily or who wait to intervene until the infant has become extremely agitated reinforce the baby's rapid rise to intense distress. This makes it harder for parents to soothe the baby in the future—and for the baby to learn to calm herself. When caregivers fail to regulate stressful experiences for infants who cannot yet regulate them for themselves, brain structures that buffer stress may fail to develop properly, resulting in an anxious, emotionally reactive child who has a reduced capacity for managing emotional problems (Feldman, 2007; Little & Carter, 2005).

Through adult–child conversations that prepare children for difficult experiences, preschoolers learn techniques for regulating emotions. With her mother's reassurance, a 3-year-old is ready for the daily transition to preschool.

© ELLEN B. SENISI PHOTOGRAPHY

In the second year, gains in representation and language lead to new ways of regulating emotion. A vocabulary for talking about feelings—"happy," "love," "surprised," "scary," "yucky," "mad"—develops rapidly after 18 months, but toddlers are not yet good at using language to manage their emotions. Temper tantrums tend to occur because toddlers cannot control the intense anger that often arises when an adult rejects their demands, particularly when they are fatigued or hungry (Mascolo & Fischer, 2007). Toddlers whose parents are emotionally sympathetic but set limits (by not giving in to tantrums), who distract the child by offering acceptable alternatives to the prohibited activity, and who later suggest better ways to handle adult refusals display more effective anger-regulation strategies and social skills during the preschool years (Lecuyer & Houck, 2006).

Patient, sensitive parents also encourage toddlers to describe their internal states. Then, when 2-year-olds feel distressed, they can guide caregivers in helping them. For example, while listening to a story about monsters, one 22-month-old whimpered, "Mommy, scary." Her mother put down the book and gave her a consoling hug.

Early Childhood After age 2, children frequently talk about feelings, and language becomes a major means of actively trying to control them (Cole, Armstrong, & Pemberton, 2010). By age 3 to 4, preschoolers verbalize a variety of emotional self-regulation strategies. For example, they know they can

APPLYING WHAT WE KNOW

Helping Children Manage Common Fears of Early Childhood

FEAR	SUGGESTION
Monsters, ghosts, and darkness	Reduce exposure to frightening stories in books and on TV until the child is better able to distinguish between appearance and reality. Make a thorough "search" of the child's room for monsters, showing him that none are there. Leave a night-light burning, sit by the child's bed until he falls asleep, and tuck in a favorite toy for protection.
Preschool or child care	If the child resists going to preschool but seems content once there, the fear is probably separation. Provide a sense of warmth and caring while gently encouraging independence. If the child fears being at preschool, find out what is frightening—the teacher, the children, or a crowded, noisy environment. Provide extra support by accompanying the child and gradually lessening the amount of time you are present.
Animals	Do not force the child to approach a dog, cat, or other animal that arouses fear. Let the child move at her own pace. Demonstrate how to hold and pet the animal, showing the child that when treated gently, the animal is friendly. If the child is larger than the animal, emphasize this: "You're so big. That kitty is probably afraid of *you!*"
Intense fears	If a child's fear is intense, persists for a long time, interferes with daily activities, and cannot be reduced in any of the ways just suggested, it has reached the level of a *phobia*. Sometimes phobias are linked to family problems, and counseling is needed to reduce them. At other times, phobias diminish without treatment as the child's capacity for emotional self-regulation improves.

blunt emotions by restricting sensory input (covering their eyes or ears to block out an unpleasant sight or sound), talking to themselves ("Mommy said she'll be back soon"), or changing their goals (deciding that they don't want to play anyway after being excluded from a game). Children's use of these strategies means fewer emotional outbursts over the preschool years (Thompson & Goodvin, 2007). As the examples suggest, shifting attention away from sources of frustration continues to be an effective approach to managing emotion. Three-year-olds who can distract themselves when frustrated tend to become cooperative school-age children with few problem behaviors (Gilliom et al., 2002).

By watching adults handle their own feelings and respond to those of others, preschoolers pick up strategies for regulating emotion. Warm, patient parents who use verbal guidance, including suggesting and explaining strategies and prompting children to generate their own, strengthen children's capacity to handle stress (Colman et al., 2006; Morris et al., 2011). Such children are more likely to use private speech (verbal self-guidance) to regulate emotion (Atencio & Montero, 2009). In contrast, when parents rarely express positive emotion, dismiss children's feelings as unimportant, and have difficulty controlling their own anger, children have continuing problems in managing emotion that seriously interfere with psychological adjustment (Hill et al., 2006; Katz & Windecker-Nelson, 2004; Thompson & Meyer, 2007).

As with infants and toddlers, preschoolers who experience negative emotion intensely have greater difficulty shifting their attention away from disturbing events and inhibiting their feelings. They are more likely to be anxious and fearful, respond with irritation to others' distress, react angrily or aggressively when frustrated, and get along poorly with teachers and peers (Chang et al., 2003; Eisenberg et al., 2005a; Raikes et al., 2007). Because these emotionally reactive children become increasingly difficult to rear, they are often targets of ineffective parenting, which compounds their poor self-regulation.

Adult–child conversations that prepare children for difficult experiences also foster emotional self-regulation (Thompson & Goodman, 2010). Parents who discuss what to expect and ways to handle anxiety offer techniques that children can apply. Nevertheless, preschoolers' vivid imaginations and incomplete grasp of the distinction between appearance and reality make fears common in early childhood. Consult Applying What We Know above for ways adults can help young children manage fears.

Middle Childhood and Adolescence Rapid gains in emotional self-regulation occur after school entry, as emotion regulation strategies become more varied, sophisticated, and flexible (Raffaelli, Crockett, & Shen, 2005). Between ages 6 and 8—as they become aware of the difference between feeling an emotion and expressing it—children increasingly reserve the full performance of emotional expressions for communicating with others. When alone—although they report experiencing emotions just as intensely—they abbreviate their emotional expressions, representing them internally, just as they internalize their private speech (see Chapter 6) (Holodynski, 2004). This emergence of a *mental level* of emotional self-communication helps children reflect on their emotions and, therefore, manage them.

At the same time, school-age children face new challenges in regulating negative emotion, prompted by their developing sense of self-worth and expanding knowledge of the wider world. Common fears of the school years include poor academic performance, rejection by classmates, the possibility of personal harm (being robbed or shot), threats to parental health, and media events (wars and disasters) (Gullone, 2000; Weems & Costa, 2005). School-age children's fears are shaped in part by their culture. For example, in China, where self-restraint and compliance with social standards are highly valued, more children mention failure and adult criticism as salient fears than in Australia or the United States. Chinese children, however, are not more fearful overall (Ollendick et al., 1996). The number and intensity of fears they report resemble those of Western children.

By age 10, most children shift adaptively between two general strategies for managing emotion. In **problem-centered coping,** they appraise the situation as changeable, identify the difficulty, and decide what to do about it. If problem solving does not work, they engage in **emotion-centered coping,** which is internal, private, and aimed at controlling distress when little can be done about an outcome (Kliewer, Fearnow, & Miller, 1996; Lazarus & Lazarus, 1994). For example, when faced with an anxiety-provoking test or a friend who is angry at them, older school-age children view problem solving and seeking social support as the best strategies. But when outcomes are beyond their control—for example, after receiving a bad grade—they opt for distraction or try to redefine the situation in ways that help them accept it: "Things could be worse. There'll be another test." School-age children's improved ability to appraise situations and reflect on thoughts and feelings means that, compared with preschoolers, they more often use these internal strategies to manage emotion (Brenner & Salovey, 1997).

Cognitive development, including gains in planning and inhibition, and a wider range of social experiences contribute to flexible, effective coping strategies. When emotional self-regulation has developed well, young people acquire a sense of *emotional self-efficacy*—a feeling of being in control of their emotional experience (Saarni, 2000; Thompson & Goodman, 2010). This fosters a favorable self-image and an optimistic outlook, which help them face further emotional challenges.

LOOK and LISTEN

Ask several school-age children and adolescents how they would manage their emotions in the following situations: (1) a friend is angry with them, and (2) they receive a bad grade on an important test. Do their responses reflect flexible, adaptive coping?

Acquiring Emotional Display Rules

In addition to regulating internal emotional states, children must learn to control what they communicate to others. Young preschoolers have some ability to modify their expressive behavior. For example, when denied a cookie before dinnertime, one 2-year-old paused, picked up her blanket, and walked from the hard kitchen floor to the soft family-room carpet where she could comfortably throw herself down and howl loudly!

At first, children modify emotional expressions to serve personal needs, and they exaggerate their true feelings (as this child did to get attention and a cookie). Soon, they learn to restrain their expressive behavior and substitute other reactions, such as smiling when feeling anxious or disappointed. All societies have **emotional display rules** that specify when, where, and how it is appropriate to express emotions.

As early as the first few months, parents encourage infants to suppress negative emotion by often imitating their expressions of interest, happiness, and surprise and rarely imitating their expressions of anger and sadness. Baby boys get more of this training than girls, in part because boys have a harder time regulating negative emotion (Else-Quest et al., 2006;

Malatesta et al., 1986). As a result, the well-known sex difference—females as emotionally expressive and males as emotionally controlled—is promoted at a tender age. Perhaps because of greater social pressure to suppress emotion, school-age boys are less accurate than girls in describing their emotions. In a Canadian study, after watching an emotionally arousing video, boys were less likely than girls to report feelings that matched their facial expressions (Strayer & Roberts, 1997). This disconnect between boys' public messages (facial expressions) and verbal acknowledgment of feelings probably contributes to the gender difference in intimacy of close relationships, which we examine in Chapter 13.

Although caregiver shaping of emotional behavior begins early, children only gradually gain the ability to conform to display rules. By age 3, capacity for self-regulation predicts children's skill at portraying an emotion they do not feel—for example, reacting cheerfully after receiving an undesirable gift (Kieras et al., 2005). These emotional "masks" are largely limited to positive feelings of happiness and surprise. Children of all ages (like adults) find it harder to act angry, sad, or disgusted than pleased (Lewis, Sullivan, & Vasen, 1987). These trends reflect social pressures: To foster harmonious relationships, most cultures teach children to communicate positive feelings and inhibit unpleasant emotional displays.

Through interacting with parents, teachers, and peers, children learn how to express negative emotion in ways likely to evoke a desired response from others. School-age children increasingly prefer verbal strategies to crying, sulking, or aggression (Shipman et al., 2003). As these findings suggest, children gradually become consciously aware of display rules. Kindergartners typically say they obey the rules to avoid punishment and gain approval from others. By third grade, children understand the value of display rules in ensuring social harmony (Jones, Abbey, & Cumberland, 1998). School-age children who justify emotional display rules by referring to concern for others' feelings are rated as especially helpful, cooperative, and socially responsive by teachers and as better liked by peers (Garner, 1996; McDowell & Parke, 2000).

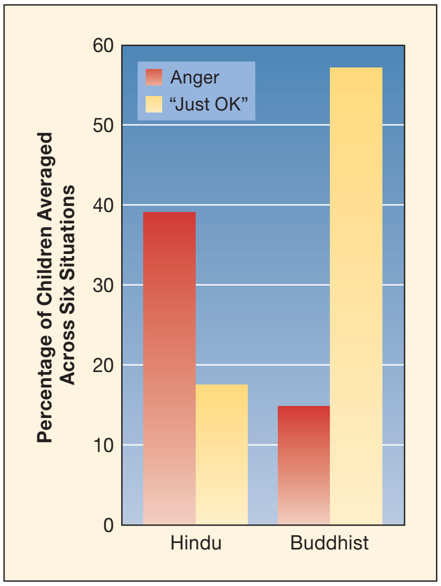

FIGURE 10.1 Hindu and Buddhist children's reports of feeling anger and "just OK" in response to emotionally charged situations. Hindu children reported that they would feel more anger. Buddhist children, whose religion values a calm, peaceful disposition, more often stated that they would feel "just OK." The children sometimes selected other emotions, such as "happy," "sad," or "scared," but these did not differ between the two subcultures and are not shown. (Adapted from Cole & Tamang, 1998.)

Collectivist cultures place particular emphasis on emotional display rules, although they vary in how they teach children to inhibit negative displays. In a striking illustration, researchers studied children in two collectivist subcultures in rural Nepal. In response to stories about emotionally charged situations (such as peer aggression or an unjust parental punishment), Hindu children more often said they would feel angry but would try to mask their feelings. Buddhist children, in contrast, interpreted the situation so that they felt "just OK" rather than angry. "Why be angry?" they explained. "The event already happened" (see Figure 10.1). In line with this difference, Hindu mothers reported that they often teach their children how to control their emotional behavior, whereas Buddhist mothers pointed to the value their religion places on a calm, peaceful disposition (Cole & Tamang, 1998; Cole, Tamang, & Shrestha, 2006). Compared to both Nepalese groups, U.S. children preferred conveying their anger verbally in these situations; for example, to an unjust punishment, they answered, "If I say I'm angry, he'll stop hurting me!" (Cole, Bruschi, & Tamang, 2002). Notice how this response fits with the Western individualistic emphasis on personal rights and self-expression.

ASK YOURSELF

Review ■ Why do many infants show stranger anxiety in the second half of the first year? What factors can increase or decrease wariness of strangers?

Connect ■ Why do children of depressed parents have difficulty regulating emotion (see page 402)? What implications do their weak self-regulatory skills have for their response to cognitive and social challenges?

Apply ■ At age 14 months, Reggie built a block tower and gleefully knocked it down. But at age 2, he called to his mother and pointed proudly to his tall block tower. What explains this change in Reggie's emotional behavior?

Reflect ■ How do you typically manage negative emotion? Describe several recent examples. How might your early experiences, gender, and cultural background have influenced your style of emotional self-regulation?

- Describe the development of emotional understanding from infancy through middle childhood.
- Describe the development of empathy from infancy into adolescence, noting individual differences.

Understanding and Responding to the Emotions of Others

Children's emotional expressiveness is intimately tied to their ability to interpret the emotional cues of others. We have seen that in the first few months, infants match the feeling tone of the caregiver in face-to-face communication. Some researchers claim that young babies respond in kind to others' emotions through a built-in, automatic process of *emotional contagion* (Stern, 1985). Others, however, believe that infants acquire these emotional contingencies through operant conditioning—for example, learning that a smile generally triggers pleasurable feedback and that distress prompts a comforting response (Saarni et al., 2006).

Around 3 to 4 months, infants can match the emotion in a voice with the appropriate face of a speaking person, and they become sensitive to the structure and timing of face-to-face interactions. When they gaze, smile, or vocalize, they now expect their social partner to respond in kind, and they reply with positive vocal and emotional reactions (Markova & Legerstee, 2006; Rochat, Striano, & Blatt, 2002). Within these exchanges, babies become increasingly aware of the range of emotional expressions (Montague & Walker-Andrews, 2001). Recall from Chapter 4 (see page 146) that out of this early imitative communication, infants start to view others as "like me"—an awareness believed to lay the foundation for understanding others' thoughts and feelings (Meltzoff, 2007).

From 5 months on, infants perceive facial expressions as organized patterns (see Chapter 4). Responding to emotional expressions as organized wholes suggests that these signals are becoming meaningful to babies. Between 7 and 12 months, ERPs recorded while infants attend to facial expressions reveal reorganized brain-wave patterns resembling those of adults, suggesting enhanced processing of emotional cues (Grossmann, Striano, & Friederici, 2007).

As skill at establishing joint attention improves, infants realize that an emotional expression not only has meaning but is also a meaningful reaction to a specific object or event (Moses et al., 2001; Tomasello, 1999). Once these understandings are in place, infants actively seek emotional information from trusted caregivers.

Social Referencing

Beginning at 8 to 10 months, when infants start to evaluate unfamiliar people, objects, and events in terms of their own safety and security, they often engage in **social referencing**—relying on another person's emotional reaction to appraise an uncertain situation (Mumme et al., 2007). Many studies show that a caregiver's emotional expression (happy, angry, or fearful) influences whether a 1-year-old will be wary of strangers, play with an unfamiliar toy, or cross the deep side of the visual cliff (de Rosnay et al., 2006; Stenberg, 2003; Striano & Rochat, 2000). The caregiver's voice—either alone or combined with a facial expression—is more effective than a facial expression alone (Kim, Walden, & Knieps, 2010; Vaish & Striano, 2004). The voice conveys both emotional and verbal information, and the baby need not turn toward the adult but, instead, can focus on evaluating the novel event.

As recall memory and language skills improve, and as parents' warnings to their newly walking youngsters become more frequent and intense, babies retain these emotional messages over longer time intervals. At 11 months, they respond appropriately after a delay of a few minutes, at 14 months after a delay of an hour or more (Hertenstein & Campos, 2004). By the middle of the second year, social referencing expands to include indirect emotional signals. After observing an adult react angrily to a second adult's play with a toy, 18-month-olds increased their monitoring of the angry adult's facial expression and reduced their touching of the object (Repacholi & Meltzoff, 2007).

As toddlers begin to appreciate that others' emotional reactions may differ from their own, social referencing allows them to compare their own and others' assessments of events. In one study, an adult showed 14- and 18-month-olds broccoli and crackers. In one condition, she acted delighted with the taste of broccoli but disgusted with the taste of crackers. In the other

LOOK and LISTEN

Observe a toddler and parent at a playground, park, or shopping mall, noting circumstances that trigger social referencing. How does the parent convey emotional information? How does the toddler respond?

condition, she showed the reverse preference. When asked to share the food, 14-month-olds offered only the type of food they themselves preferred—usually crackers. In contrast, 18-month-olds gave the adult whichever food she appeared to like, regardless of their own preferences (Repacholi & Gopnik, 1997).

In sum, in social referencing, toddlers move beyond simply reacting to others' emotional messages. They use those signals to evaluate the safety and security of their surroundings, to guide their own actions, and to gather information about others' intentions and preferences. These experiences, along with cognitive and language development, probably help toddlers refine the meanings of emotions of the same valence—for example, happiness versus surprise, anger versus fear—during the second year (Gendler, Witherington, & Edwards, 2008; Saarni et al., 2006).

A toddler engages in social referencing, concluding from her father's calm, confident manner that it is safe to approach these unfamiliar animals.

Emotional Understanding in Childhood

During the preschool years, children's emotional understanding expands rapidly, as their everyday talk about emotions reveals:

> *Two-year-old: [After father shouted at child, she became angry, shouting back]* I'm mad at you, Daddy. I'm going away. Goodbye.
>
> *Two-year-old: [Commenting on another child who refused to take a nap and cried]* Mom, Annie cry. Annie sad.
>
> *Six-year-old: [In response to mother's comment, "It's hard to hear the baby crying"]* Well, it's not as hard for me as it is for you. *[When mother asked why]* Well, you like Johnny better than I do! I like him a little, and you like him a lot, so I think it's harder for you to hear him cry.
>
> *Six-year-old: [Comforting a small boy in church whose mother had gone up to communion]* She'll be right back. Don't be afraid. I'm here. (Bretherton et al., 1986, pp. 536, 540, 541)

Cognitive Development and Emotional Understanding

As these examples show, early in the preschool years, children refer to causes, consequences, and behavioral signs of emotion, and over time their understanding becomes more accurate and complex (Stein & Levine, 1999). By age 4 to 5, they correctly judge the causes of many basic emotions ("He's happy because he's swinging very high"; "He's sad because he misses his mother"). Preschoolers' explanations tend to emphasize external factors over internal states, a balance that changes with age (Levine, 1995). In Chapter 11, we will see that after age 4, children appreciate that both desires and beliefs motivate behavior. Once these understandings are secure, children's grasp of how internal factors can trigger emotion expands.

Preschoolers can also predict what a playmate expressing a certain emotion might do next. Four-year-olds know that an angry child might hit someone and that a happy child is more likely to share (Russell, 1990). And they realize that thinking and feeling are interconnected—that a person reminded of a previous sad experience is likely to feel sad (Lagattuta, Wellman, & Flavell, 1997). Furthermore, they come up with effective ways to relieve others' negative feelings, such as hugging to reduce sadness (Fabes et al., 1988).

In middle childhood, ability to consider conflicting cues when explaining others' emotions improves. When asked what might be happening in a picture showing a happy-faced child with a broken bicycle, 4- and 5-year-olds tended to rely only on the emotional expression: "He's happy because he likes to ride his bike." By age 8 to 9, children more often reconciled the two cues: "He's happy because his father promised to help fix his broken bike" (Gnepp, 1983; Hoffner & Badzinski, 1989). Similarly, older children are more aware of circumstances likely to spark mixed emotions, each of which may be positive or negative and may differ in intensity (Larsen, To, & Fireman, 2007; Pons et al., 2003). Preschoolers, by contrast, staunchly deny that two emotions can occur at once, much as they do not integrate two variables (height and width) in a Piagetian conservation-of-liquid task (see Chapter 6).

© JIM WEST/ALAMY

The older of these siblings clearly realizes—even if his younger brother doesn't—that it is possible to experience two emotions at once: happiness at getting a Christmas gift but disappointment with the gift itself.

Appreciating mixed emotions helps school-age children realize that people's expressions may not reflect their true feelings (Misailidi, 2006; Saarni, 1999). It also fosters awareness of self-conscious emotions, which are more complex in expression than basic emotions. For example, between ages 6 and 7, children improve sharply in ability to distinguish pride from happiness and surprise (Tracy, Robins, & Lagattuta, 2005). And 8- and 9-year-olds understand that pride combines two sources of happiness—joy in accomplishment and joy that a significant person recognized that accomplishment (Harter, 1999). As with the development of *metacognition* (thinking about thought), discussed in Chapter 7, striking gains in thinking about emotion occur in middle childhood.

Social Experience and Emotional Understanding The more mothers label emotions, explain them, and express warmth and enthusiasm when conversing with preschoolers, the more "emotion words" children use and the better developed their emotional understanding (Fivush & Haden, 2005; Laible & Song, 2006). Maternal prompting of emotional thoughts ("What makes him afraid?") is a good predictor of 2-year-olds' emotion language. For older preschoolers, explanations ("He's sad because his dog ran away") are more important (Cervantes & Callanan, 1998). Does this remind you of the concept of *scaffolding*, discussed in Chapter 6—that to be effective, adult teaching must adjust to children's increasing competence?

Preschoolers whose parents frequently acknowledge their emotional reactions and explicitly teach them about diverse emotions are better able to judge others' emotions when tested at later ages (Denham & Kochanoff, 2002). Discussions in which family members disagree are particularly helpful. In one study, when mothers explained feelings and negotiated and compromised during conflicts with their 2½-year-olds, their children, at age 3, were advanced in understanding emotion and used similar strategies to resolve disagreements (Laible & Thompson, 2002). Such dialogues seem to help children reflect on the causes and consequences of emotion while modeling mature communication skills. Furthermore, 3- to 5-year-olds who have a warm, relaxed relationship with their mothers (a secure attachment bond) better understand emotion. Attachment security is related to warmer and more elaborative parent–child narratives, including discussions of feelings that highlight the emotional significance of events (Laible, 2004; Laible & Song, 2006; Raikes & Thompson, 2006).

As preschoolers learn more about emotion from interacting with adults, they engage in more emotion talk with siblings and friends, especially during make-believe play (Hughes & Dunn, 1998). Make-believe, in turn, contributes to emotional understanding, especially when children play with siblings (Youngblade & Dunn, 1995). The intense nature of the sibling relationship, combined with frequent acting out of feelings, makes pretending an excellent context for early learning about emotions. And when parents intervene in sibling disputes by reasoning and negotiating, preschoolers gain in sensitivity to their siblings' feelings (Perlman & Ross, 1997). They more often refer to their siblings' emotional perspective ("You get mad when I don't share") and engage in less fighting.

Knowledge about emotions helps children greatly in their efforts to get along with others. As early as 3 to 5 years of age, it is related to friendly, considerate behavior; willingness to make amends after harming another; and constructive responses to disputes with agemates (Dunn, Brown, & Maguire, 1995; Garner & Estep, 2001; Hughes & Ensor, 2010). Also, the more preschoolers refer to feelings when interacting with playmates, the better liked they are by their peers (Fabes et al., 2001). Children seem to recognize that acknowledging others' emotions and explaining their own enhance the quality of relationships.

Empathy and Sympathy

In empathy, understanding and expression of emotions are interwoven, since both awareness of the emotions of another and the vicarious experience of those emotions are required for an empathic response. Current theorists agree that **empathy** involves a complex interaction of cognition and affect: the ability to detect different emotions, to take another's emotional perspective, and to feel with that person, or respond emotionally in a similar way. Beginning in the preschool years, empathy is an important motivator of **prosocial,** or **altruistic, behavior**—actions that benefit another person without any expected reward for the self (Eisenberg, Fabes, & Spinrad, 2006; Spinrad & Eisenberg, 2009). Yet in some children, empathizing with an upset adult or peer does not yield acts of kindness and helpfulness but instead escalates into *personal distress*. In trying to reduce these feelings, the child focuses on his own anxiety rather than on the person in need. As a result, empathy does not lead to **sympathy**—feelings of concern or sorrow for another's plight.

Development of Empathy Empathy has roots early in development. Newborn babies tend to cry in response to the cry of another baby (see pages 135–136 in Chapter 4). And earlier we noted young infants' matching of others' emotional expressions. In sensitive, face-to-face communication, infants "connect" emotionally with their caregivers—experiences believed to be the foundation for empathy and concern for others (Zahn-Waxler, 1991).

Like self-conscious emotions, true empathy requires children to understand that the self is distinct from other people. As self-awareness strengthens at the end of the second year, toddlers begin to empathize. With age, they not only sense another's unhappiness but become better at inferring from the situation what might help relieve it (Svetlova, Nichols, & Brownell, 2010). For example, 2- to 2½-year-olds will readily hand a blanket to an adult who is rubbing her arms, shivering, and saying, "Brrrr." And they are likely to respond to their mother's simulated sadness by offering a hug or comforting words, or trying to distract her with a toy (Zahn-Waxler & Radke-Yarrow, 1990). Children of this age even react with concern and consoling behavior to an adult who experiences harm (someone destroys her treasured possession) but who shows no overt emotion (Vaish, Carpenter, & Tomasello, 2009). Older toddlers seem to be able to engage in basic *affective perspective-taking*—inferring how another feels by imagining themselves in that person's place.

As language develops, children rely more on words to console others, indicating a more reflective level of empathy (Bretherton et al., 1986). When a 4-year-old received a Christmas gift that she hadn't included on her list for Santa, she assumed it belonged to another little girl and pleaded with her parents, "We've got to give it back—Santa's made a big mistake. I think the girl's crying 'cause she didn't get her present!"

Empathy increases over the elementary school years as children understand a wider range of emotions and take multiple cues into account in assessing others' feelings (Ricard & Kamberk-Kilicci, 1995). During late childhood and adolescence, advances in perspective taking permit an empathic response not just to people's immediate distress but also to their general life condition (Hoffman, 2000). The ability to empathize with the poor, oppressed, and sick requires an advanced form of perspective taking in which the young person understands that people lead continuous emotional lives beyond the current situation.

© LAURA DWIGHT PHOTOGRAPHY

A preschooler comforts a sad classmate. As children's language and perspective-taking skills expand, empathy increases and, in children who are good at regulating emotion, leads to sympathetic concern and prosocial behavior.

Individual Differences Temperament plays a role in whether empathy occurs and whether it prompts sympathetic, prosocial behavior or a personally distressed, self-focused response. Twin studies reveal that empathy is moderately heritable (Knafo et al., 2009). Children who are sociable, assertive, and good at regulating emotion are more likely than poor emotion regulators to empathize with others' distress, display sympathetic concern, and engage in prosocial behavior, helping, sharing, and comforting others in distress (Bengtson, 2005; Eisenberg et al., 1998; Valiente et al., 2004). Such children are also more likely to empathize with others' positive emotions of joy and happiness (Sallquist et al., 2009).

In contrast, aggressive children's high hostility, weakened capacity to take another's perspective, and impulsive acting out of negative feelings blunt their capacity for empathy and sympathy. Many show a decline—rather than the typical rise—in concern for others during middle childhood (Hastings et al., 2000; Strayer & Roberts, 2004b). And shy children may not display sympathetic concern because they are easily overwhelmed by anxiety when others are distressed (Eisenberg et al., 1996).

Individual differences in empathy and sympathy are evident in children's facial and neurobiological responses. In a series of studies, children watched videotapes of people in need, such as two children lying on the ground crying. Children who reacted with facial or physiological markers of concern—an interested, caring expression or a decrease in heart rate, suggesting orienting and attention—usually behaved prosocially when offered a chance to help. Those who showed facial and physiological evidence of distress—frowning, lip biting, and a rise in heart rate—were less prosocial (Fabes et al., 1994; Miller et al., 1996). Similarly, empathy is related to EEG brain-wave activity—a mild increase in the left hemisphere (which houses positive emotion) among children showing facial signs of empathy. In contrast, children who do not show these empathic signs often display a sharp EEG increase in the right hemisphere (which houses negative emotion)—an indication that they are overwhelmed by negative emotion (Jones, Field, & Davalos, 2000; Pickens, Field, & Nawrocki, 2001).

Parenting profoundly influences empathy and sympathy. When parents are warm, encourage emotional expressiveness, and show sensitive, empathic concern for their youngsters' feelings, their children are likely to react in a concerned way to the distress of others—relationships that persist into adolescence and early adulthood (Koestner, Franz, & Weinberger, 1990; Michalik et al., 2007; Strayer & Roberts, 2004a). Besides modeling sympathy, parents can help children learn to regulate angry feelings, which disrupt empathy and sympathy. They can also teach children the importance of kindness and can intervene when they display inappropriate emotion—strategies that predict high levels of sympathetic responding (Eisenberg, 2003). And parents can provide opportunities for children to show sympathetic concern through charitable giving and community service activities.

In contrast, angry, punitive parenting disrupts empathy and sympathy at an early age—particularly among children who are poor emotion regulators and, therefore, respond to parental hostility with especially high levels of personal distress (Valiente et al., 2004). In one study, physically abused toddlers at a child-care center rarely expressed concern at a peer's unhappiness but, rather, reacted with fear, anger, and physical attacks (Klimes-Dougan & Kistner, 1990). The children's reactions resembled their parents' insensitive responses to others' suffering.

These findings, like others discussed so far, reveal wide variations in children's emotional dispositions. As we turn now to the topic of temperament, we will encounter additional evidence for the joint contributions of heredity and environment to these differences. But first, consult the Milestones table on the following page for an overview of the emotional attainments just considered.

ASK YOURSELF

Review ■ What do preschoolers understand about emotion, and how do cognition and social experience contribute to their understanding?

Connect ■ Why is good emotional self-regulation vital for empathy to result in sympathy and prosocial behavior?

Connect ■ Cite ways that parenting contributes to emotional understanding, self-conscious emotions, empathy, and sympathy. Do you see any patterns? Explain.

Apply ■ When 15-month-old Ellen fell down while running, she looked at her mother, who smiled and exclaimed, "Oh, wasn't that a funny tumble!" How is Ellen likely to respond emotionally, and why?

- What is temperament, and how is it measured?
- Discuss the roles of heredity and environment in the stability of temperament, the relationship of temperament to cognitive and social functioning, and the goodness-of-fit model.

Temperament and Development

When we describe one person as cheerful and upbeat, another as active and energetic, and still others as calm, cautious, persistent, or prone to angry outbursts, we are referring to **temperament**—early-appearing, stable individual differences in reactivity and self-regulation. *Reactivity* refers to quickness and intensity of emotional arousal, attention, and motor action. *Self-regulation*, as we have seen, refers to strategies that modify

Milestones

Emotional Development

AGE	EMOTIONAL EXPRESSIVENESS	EMOTIONAL UNDERSTANDING
Birth–6 months	- Social smile emerges - Laughter appears - Expressions of happiness increase when interacting with familiar people - Emotional expressions gradually become organized signals that are meaningfully related to environmental events	- Detects emotions by matching the caregiver's feeling tone in face-to-face communication
7–12 months	- Anger and fear increase in frequency and intensity - Uses caregiver as a secure base - Regulates emotion by approaching and retreating from stimulation	- Detects the meaning of others' emotional signals - Engages in social referencing
1–2 years	- Self-conscious emotions emerge but depend on monitoring and encouragement of adults - Begins to use language to assist with emotional self-regulation 	- Begins to appreciate that others' emotional reactions may differ from one's own - Acquires a vocabulary of emotional terms - Displays empathy
3–6 years	- Self-conscious emotions are clearly linked to self-evaluation - As representation and language improve, uses active strategies for regulating emotion - Begins to conform to emotional display rules; can pose a positive emotion he or she does not feel	- Understanding of causes, consequences, and behavioral signs of emotion improves in accuracy and complexity - As language develops, empathy becomes more reflective
7–11 years	- Self-conscious emotions are integrated with inner standards of excellence and good behavior - Uses internal strategies for engaging in emotional self-regulation; shifts adaptively between problem-centered and emotion-centered coping - Conformity to and conscious awareness of emotional display rules improve	- Can reconcile conflicting cues when explaining others' emotions - Is aware that people can have mixed feelings and that their expressions may not reflect their true feelings - Empathy increases as emotional understanding and perspective taking improve

Note: These milestones represent overall age trends. Individual differences exist in the precise age at which each milestone is attained.

that reactivity (Rothbart & Bates, 2006). The psychological traits that make up temperament are believed to form the cornerstone of the adult personality.

In 1956, Alexander Thomas and Stella Chess initiated the New York Longitudinal Study, a groundbreaking investigation of the development of temperament that followed 141 children from early infancy well into adulthood. Results showed that temperament can increase a child's chances of experiencing psychological problems or, alternatively, protect a child from the negative effects of a stressful home life. At the same time, Thomas and Chess (1977) discovered that parenting practices can modify children's temperaments considerably.

These findings stimulated a growing body of research on temperament, including its stability, biological roots, and interaction with child-rearing experiences. Let's begin to explore these issues by looking at the structure, or makeup, of temperament and how it is measured.

The Structure of Temperament

Thomas and Chess's model of temperament, consisting of nine dimensions listed in Table 10.1, inspired all others that followed. When detailed descriptions of infants' and children's behavior obtained from parent interviews were rated on these dimensions, certain characteristics clustered together, yielding three types of children:

- The **easy child** (40 percent of the sample) quickly establishes regular routines in infancy, is generally cheerful, and adapts easily to new experiences.
- The **difficult child** (10 percent of the sample) has irregular daily routines, is slow to accept new experiences, and tends to react negatively and intensely.
- The **slow-to-warm-up child** (15 percent of the sample) is inactive, shows mild, low-key reactions to environmental stimuli, is negative in mood, and adjusts slowly to new experiences.

Note that 35 percent of the children did not fit any of these categories. Instead, they showed unique blends of temperamental characteristics.

The difficult pattern has sparked the most interest because it places children at high risk for adjustment problems—both anxious withdrawal and aggressive behavior in early and middle childhood (Bates, Wachs, & Emde, 1994; Ramos et al., 2005; Thomas, Chess, & Birch, 1968). Compared with difficult children, slow-to-warm-up children present fewer problems in the early years. However, they tend to show excessive fearfulness and slow, constricted behavior in the late preschool and school years, when they are expected to respond

TABLE 10.1 Two Models of Temperament

THOMAS AND CHESS		ROTHBART	
Dimension	*Description*	*Dimension*	*Description*
Activity level	Ratio of active periods to inactive ones	***Reactivity***	
Rhythmicity	Regularity of body functions, such as sleep, wakefulness, hunger, and excretion	Activity level	Level of gross-motor activity
Distractibility	Degree to which stimulation from the environment alters behavior—for example, whether crying stops when a toy is offered	Attention span/ persistence	Duration of orienting or interest
Approach/ withdrawal	Response to a new object, food, or person	Fearful distress	Wariness and distress in response to intense or novel stimuli, including time to adjust to new situations
Adaptability	Ease with which child adapts to changes in the environment, such as sleeping or eating in a new place	Irritable distress	Extent of fussing, crying, and distress when desires are frustrated
Attention span and persistence	Amount of time devoted to an activity, such as watching a mobile or playing with a toy	Positive affect	Frequency of expression of happiness and pleasure
Intensity of reaction	Energy level of response, such as laughing, crying, talking, or gross-motor activity	***Self-Regulation***	
Threshold of responsiveness	Intensity of stimulation required to evoke a response	Effortful control	Capacity to voluntarily suppress a dominant, reactive response in order to plan and execute a more adaptive response
Quality of mood	Amount of friendly, joyful behavior as opposed to unpleasant, unfriendly behavior		

actively and quickly in classrooms and peer groups (Chess & Thomas, 1984; Schmitz et al., 1999).

Today, the most influential model of temperament is Mary Rothbart's (refer again to Table 10.1). It combines related traits proposed by Thomas and Chess and other researchers, yielding a concise list of just six dimensions. For example, "distractibility" and "attention span and persistence" are considered opposite ends of the same dimension, which is labeled "attention span/persistence." A unique feature of Rothbart's model is inclusion of both "fearful distress" and "irritable distress," which distinguish between reactivity triggered by fear and reactivity due to frustration. And the model deletes overly broad dimensions, such as "rhythmicity," "intensity of reaction," and "threshold of responsiveness" (Rothbart, Ahadi, & Evans, 2000; Rothbart & Mauro, 1990). A child who is rhythmic in sleeping is not necessarily rhythmic in eating or bowel habits. And a child who smiles and laughs intensely is not necessarily intense in fear, irritability, or motor activity.

Rothbart's dimensions are supported by factor analyses of many measures of children's temperament (see page 321 in Chapter 8 to review the concept of factor analysis). Notice how her dimensions represent the three underlying components included in the definition of temperament: (1) *emotion* ("fearful distress," "irritable distress," "positive affect," and "soothability"), (2) *attention* ("attention span/persistence"), and (3) *action* ("activity level"). According to Rothbart, individuals differ not only in their reactivity on each dimension but also in the self-regulatory dimension of temperament, **effortful control**—the capacity to voluntarily suppress a dominant response in order to plan and execute a more adaptive response (Rothbart, 2003; Rothbart & Bates, 2006). Variations in effortful control are evident in how effectively a child can focus and shift attention, inhibit impulses, and manage negative emotion.

TAKE A MOMENT... Turn back to page 287 in Chapter 7 to review the concept of *inhibition*, and note its strong resemblance to *effortful control*. As we will see later, researchers assess these capacities in similar ways. Their converging concepts, measures, and findings reveal that the same mental activities lead to effective regulation in both the cognitive and emotional/social domains.

Measuring Temperament

Temperament is often assessed through interviews or questionnaires given to parents. Behavior ratings by pediatricians, teachers, and others familiar with the child and laboratory observations by researchers have also been used. Parental reports are convenient and take advantage of parents' depth of knowledge of the child across many situations (Gartstein & Rothbart, 2003). Although information from parents has been criticized as being biased, parental reports are moderately related to researchers' observations of children's behavior (Majdandžić & van den Boom, 2007; Mangelsdorf, Schoppe, & Buur, 2000). And parent perceptions are vital for understanding how parents view and respond to their child.

Observations by researchers in the home or laboratory avoid the subjectivity of parental reports but can lead to other inaccuracies. In homes, observers find it hard to capture all relevant information, especially events that are rare but important, such as infants' response to frustration. And in the unfamiliar lab setting, fearful children who calmly avoid certain experiences at home may become too upset to complete the session if the lab does not permit avoidance (Wachs & Bates, 2001). Still, researchers can better control children's experiences in the lab. And they can conveniently combine observations of behavior with neurobiological measures to gain insight into the biological bases of temperament.

Most neurobiological research has focused on children who fall at opposite extremes of the positive-affect and fearful-distress dimensions of temperament: **inhibited,** or **shy, children,** who react negatively to and withdraw from novel stimuli; and **uninhibited,** or **sociable, children,** who display positive emotion to and approach novel stimuli. As the Biology and Environment box on page 422 reveals, biologically based reactivity—evident in heart rate, hormone levels, and EEG brain waves in the frontal region of the cerebral cortex—differentiates children with inhibited and uninhibited temperaments.

BIOLOGY and ENVIRONMENT

Development of Shyness and Sociability

Two 4-month-old babies, Larry and Mitch, visited the laboratory of Jerome Kagan, who observed their reactions to a variety of unfamiliar experiences. When exposed to new sights and sounds, such as a moving mobile decorated with colorful toys, Larry tensed his muscles, moved his arms and legs with agitation, and began to cry. In contrast, Mitch remained relaxed and quiet, smiling and cooing at the excitement around him.

As toddlers, Larry and Mitch returned to the laboratory, where they experienced several procedures designed to induce uncertainty. Electrodes were placed on their bodies and blood pressure cuffs on their arms to measure heart rate; toy robots, animals, and puppets moved before their eyes; and unfamiliar people entered and behaved in unexpected ways or wore novel costumes. While Larry whimpered and quickly withdrew, Mitch watched with interest, laughed at the strange sights, and approached the toys and strangers.

On a third visit, at age 4½, Larry barely talked or smiled during an interview with an unfamiliar adult. In contrast, Mitch asked questions and communicated his pleasure at each new activity. In a playroom with two unfamiliar peers, Larry pulled back and watched, while Mitch made friends quickly.

In longitudinal research on several hundred Caucasian infants followed into adolescence, Kagan found that about 20 percent of 4-month-old babies were, like Larry, easily upset by novelty; 40 percent, like Mitch, were comfortable, even delighted, with new experiences. About 20 to 30 percent of these extreme groups retained their temperamental styles as they grew older (Kagan, 2003; Kagan & Saudino, 2001; Kagan et al., 2007). But most children's dispositions became less extreme over time. Genetic makeup and child-rearing experiences jointly influenced stability and change in temperament.

Neurobiological Correlates of Shyness and Sociability

Individual differences in arousal of the *amygdala*, an inner brain structure that controls avoidance reactions, contribute to these contrasting temperaments. In shy, inhibited children, novel stimuli easily excite the amygdala and its connections to the cerebral cortex and sympathetic nervous system, which prepares the body to act in the face of threat. In sociable, uninhibited children, the same level of stimulation evokes minimal neural excitation (Kagan & Fox, 2006). In support of this theory, while viewing photos of unfamiliar faces, adults who had been classified as inhibited in the second year of life showed greater fMRI activity in the amygdala than adults who had been uninhibited as toddlers (Schwartz et al., 2003). And additional neurobiological responses known to be mediated by the amygdala distinguish these two emotional styles:

- *Heart rate*. From the first few weeks of life, the heart rates of shy children are consistently higher than those of sociable children, and they speed up further in response to unfamiliar events (Schmidt et al., 2007; Snidman et al., 1995).
- *Cortisol*. Saliva concentrations of the stress hormone cortisol tend to be higher, and to rise more in response to a stressful event, in shy than in sociable children (Schmidt et al., 1997, 1999; Zimmermann & Stansbury, 2004).
- *Pupil dilation, blood pressure, and skin surface temperature*. Compared with sociable children, shy children tend to show greater pupil dilation, rise in blood pressure, and cooling of the fingertips when faced with novelty (Kagan et al., 1999, 2007).

Another physiological correlate of approach–withdrawal to people and objects is the pattern of EEG brain waves in the frontal lobes of the cerebral cortex. Shy infants and preschoolers show greater EEG activity in the right frontal lobe, which is associated with negative emotional reactivity; sociable children show the opposite pattern (Fox et al., 2008; Kagan et al., 2007). Neural activity in the amygdala, which is transmitted to the frontal lobes, probably contributes to these differences. Inhibited children also show greater generalized activation of the cerebral cortex, an indicator of high emotional arousal and monitoring of new situations for potential threats (Henderson et al., 2004).

Child-Rearing Practices

According to Kagan, extremely shy or sociable children inherit a physiology that biases them toward a particular temperamental style. Yet heritability research indicates that genes contribute only modestly to shyness and sociability (Kagan & Fox, 2006). Experience has a powerful impact.

Child-rearing practices affect the chances that an emotionally reactive baby will become a fearful child. Warm, supportive parenting reduces shy infants' and preschoolers' intense physiological reaction to novelty, whereas cold, intrusive parenting heightens anxiety (Coplan, Arbeau, & Armer, 2008; Hane et al., 2008). And if parents overprotect infants and young children who dislike novelty, they make it harder for the child to overcome an urge to retreat. Parents who make appropriate demands for their child to approach new experiences help shy youngsters develop strategies for regulating fear (Rubin & Burgess, 2002).

When inhibition persists, it leads to excessive cautiousness, low self-esteem, and loneliness (Fordham & Stevenson-Hinde, 1999; Rubin, Stewart, & Coplan, 1995). In adolescence, persistent shyness increases the risk of severe anxiety, especially social phobia—intense fear of being humiliated in social situations (Kagan & Fox, 2006). For inhibited children to acquire effective social skills, parenting must be tailored to their temperaments—a theme we will encounter again in this and later chapters.

© LAURA DWIGHT PHOTOGRAPHY

A strong physiological response to novel stimuli prompts this child to cling to his father. With patient, insistent encouragement, parents can help shy children overcome the urge to retreat from unfamiliar events.

Stability of Temperament

Young children who score low or high on attention span, irritability, sociability, shyness, or effortful control tend to respond similarly when assessed again several months to a few years later and, occasionally, even into the adult years (Caspi et al., 2003; Kochanska & Knaack, 2003; Majdandžić & van den Boom, 2007; Rothbart, Ahadi, & Evans, 2000; van den Akker et al., 2010). However, the overall stability of temperament is low in infancy and toddlerhood and only moderate from the preschool years on (Putnam, Samson, & Rothbart, 2000). Some children remain the same, but many others change.

Why isn't temperament more stable? A major reason is that temperament itself develops with age. To illustrate, let's look at irritability and activity level. Recall from Chapter 4 that most babies fuss and cry in the early months. As infants better regulate their attention and emotions, many who initially seemed irritable become calm and content. In the case of activity level, the meaning of the behavior changes. At first, an active, wriggling infant tends to be highly aroused and uncomfortable, whereas an inactive baby is often alert and attentive. Once infants move on their own, the reverse is so! An active crawler is usually alert and interested in exploration, whereas a very inactive baby may be fearful and withdrawn.

These discrepancies help us understand why long-term prediction from early temperament is best achieved after age 3, when children's styles of responding are better established (Roberts & DelVecchio, 2000). In line with this idea, between ages 2½ and 3, children improve substantially and also perform more consistently across a wide variety of tasks requiring effortful control, such as waiting for a reward, lowering their voice to a whisper, succeeding at games like "Simon Says," and selectively attending to one stimulus while ignoring competing stimuli (Kochanska, Murray, & Harlan, 2000; Li-Grining, 2007). Researchers believe that around this time, areas in the prefrontal cortex involved in suppressing impulses develop rapidly (Gerardi-Caulton, 2000; Rothbart & Bates, 2006).

Nevertheless, the ease with which children manage their reactivity in early childhood depends on the type and strength of the reactive emotion involved. Preschoolers who were highly fearful as 2-year-olds score slightly better than their agemates in effortful control as 4-year-olds. In contrast, angry, irritable 2-year-olds tend to be less effective at effortful control at later ages (Bridgett et al., 2009; Kochanska & Knaack, 2003; Kochanska, Murray, & Harlan, 2000).

In sum, many factors affect the extent to which a child's temperament remains stable, including development of the biological systems on which temperament is based, the child's capacity for effortful control, and the success of her efforts, which depend on the quality and intensity of her emotional reactivity. When we consider the evidence as a whole, the low to moderate stability of temperament makes sense. It also confirms that experience can modify biologically based temperamental traits considerably, although children rarely change from one extreme to another—that is, a shy preschooler practically never becomes highly sociable, and irritable children seldom become easy-going. With these ideas in mind, let's turn to genetic and environmental contributions to temperament and personality.

Genetic and Environmental Influences

The word *temperament* implies a genetic foundation for individual differences in personality. Research indicates that identical twins are more similar than fraternal twins across a wide range of temperamental traits (activity level, attention span, shyness/sociability, irritability, and effortful control) and personality measures (introversion/extroversion, anxiety, agreeableness, curiosity and imaginativeness, and impulsivity) (Bouchard, 2004; Bouchard & Loehlin, 2001; Caspi & Shiner, 2006; Roisman & Fraley, 2006; Saudino & Cherny, 2001). In Chapter 3, we noted that heritability estimates derived from twin studies suggest a moderate role for genetic factors in temperament and personality: About half of individual differences have been attributed to differences in genetic makeup.

Nevertheless, genetic influences vary with the temperamental trait and the age of the individual being studied. For example, heritability estimates are higher for expressions of negative emotion than for positive emotion. And the role of heredity is considerably less in infancy than in childhood and later years, when temperament becomes more stable (Wachs & Bates, 2001).

Although genetic influences on temperament are clear, environment is also powerful. For example, persistent nutritional and emotional deprivation profoundly alters temperament, resulting in maladaptive emotional reactivity. Recall from Chapter 5 that even after dietary improvement, children exposed to severe malnutrition in infancy remain more distractible and fearful than their agemates. Also, higher levels of home noise and crowding are linked to withdrawal and irritability in the second year (Matheny & Phillips, 2001; Wachs, 2006). And earlier in this chapter, we noted that children who spent their infancy in deprived orphanages are easily overwhelmed by stressful events. Their poor regulation of emotion results in inattention and weak impulse control, including frequent expressions of anger (see page 197).

Other research shows that child rearing has much to do with whether infants and young children maintain their temperamental traits. In fact, heredity and environment often jointly contribute to temperament, since a child's approach to the world affects the experiences to which she is exposed. To illustrate how this works, let's look closely at ethnic differences in temperament.

© NEVADA WIER/NOMAD/PHOTOLIBRARY

This Japanese grandmother holds her grandchild close while interacting gently and soothingly. These caregiving behaviors contribute to Japanese babies' calm, emotionally restrained temperamental style.

Cultural Variations Compared with North American Caucasian infants, Chinese and Japanese babies tend to be less active, irritable, and vocal; more easily soothed when upset; and better at quieting themselves (Kagan et al., 1994; Lewis, Ramsay, & Kawakami, 1993). Chinese and Japanese babies are also more fearful and inhibited, remaining closer to their mothers in an unfamiliar playroom and displaying more anxiety when interacting with a stranger (Chen, Wang, & DeSouza, 2006). And they are more emotionally restrained, smiling, laughing, and crying less than Caucasian-American babies (Camras et al., 1998; Gartstein et al., 2010).

These variations may have genetic roots, but they are supported by cultural beliefs and practices. Japanese mothers usually say that babies come into the world as independent beings who must learn to rely on their parents through close physical contact. American mothers typically believe just the opposite—that they must wean the baby away from dependency toward autonomy. Consistent with these beliefs, Asian mothers interact gently, soothingly, and gesturally with their babies, whereas Caucasian mothers use a more active, stimulating, verbal approach (Rothbaum et al., 2000b). Also, recall from our discussion of emotional self-regulation that Chinese and Japanese adults discourage babies from expressing strong emotion, which contributes further to their infants' tranquility.

Nonshared Environment In families with several children, an additional influence on temperament is at work. Recall from Chapter 8 that *nonshared environmental influences*—those that make siblings different from one another—play an important role in intelligence. They are also influential in personality development. **TAKE A MOMENT...** Ask several parents to describe each of their children's personalities. You will see that they often emphasize differences between siblings: "She's a lot more active." "He's more sociable." "She's far more persistent." As a result, parents often regard siblings as more distinct than other observers do. In a large study of 1- to 3-year-old twin pairs, parents rated identical twins as resembling each other less in temperament than researchers' ratings indicated. And whereas researchers rated fraternal twins as moderately similar, parents viewed them as somewhat opposite in temperamental style (see Figure 10.2) (Saudino, 2003).

Parents' tendency to emphasize each child's unique qualities affects their child-rearing practices. In a study of 3-year-old identical twins, mothers' differential treatment of each twin predicted differences between twins in psychological adjustment. The pair member who received more warmth and less harshness was more positive in mood and prosocial behavior and less likely to have behavior problems (Deater-Deckard et al., 2001). Each child, in turn, evokes responses from caregivers that are consistent with parental beliefs and the child's developing temperament.

Besides different experiences within the family, siblings have distinct experiences with teachers, peers, and others in their community that affect personality development. And as they get older, siblings often seek ways to differ from one another. For all these reasons, both identical and fraternal twins tend to become increasingly dissimilar in personality with age (Loehlin & Martin, 2001; McCartney, Harris, & Bernieri, 1990). The less contact twins have with each other, the stronger this effect.

Are nonshared factors more important in personality development than *shared environmental influences*—those that affect all siblings similarly? In Chapter 14, we will see that shared factors, such as family stress and child-rearing styles, also affect children's personalities. In sum, we must think of temperament and personality as affected by a complex mix of environmental conditions, some child-specific and others stemming from shared family conditions.

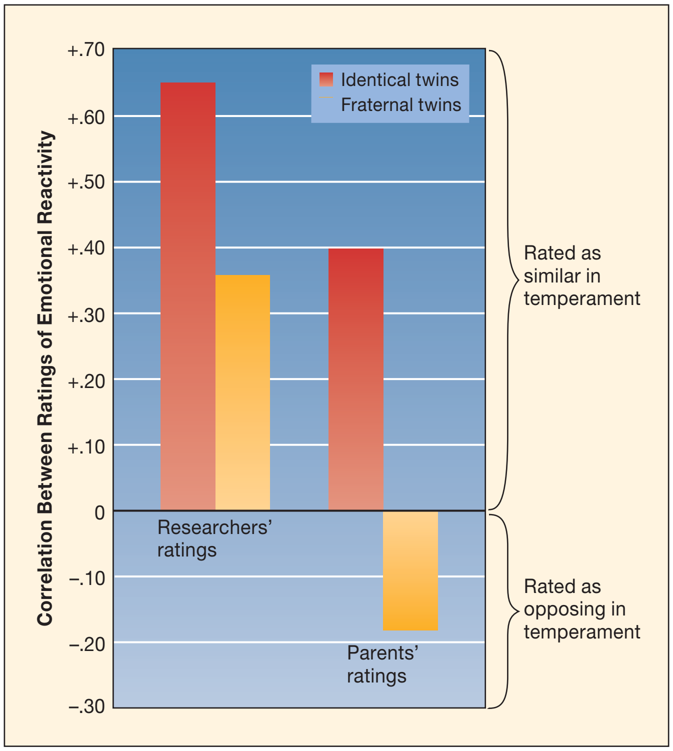

FIGURE 10.2 Temperament correlations for identical and fraternal twin pairs, as rated by researchers and parents. Parents rated 1- to 3-year-old identical twins as resembling each other less in temperament than researchers did. And whereas researchers rated fraternal twins as moderately similar, parents rated them as somewhat opposing in temperament. The correlations depicted here are for emotional reactivity. Activity level, shyness, and attention span/persistence yielded similar findings. (Adapted from Saudino, 2003.)

Temperament as a Predictor of Children's Behavior

Research on temperament provides a powerful illustration of the child's contribution to his or her own development. Children's temperamental traits consistently predict their cognitive and social functioning.

Almost as soon as it can be measured, children's attention span forecasts their learning and cognitive development. For example, persistence during the first year correlates with infant mental test scores and preschool IQ (Matheny, 1989). During early and middle childhood, persistence continues to predict IQ, along with literacy and mathematical progress and grades in school. In contrast, distractibility, high activity level, and difficult temperament are linked to poor school performance (Coplan, Barber, & Lagacé-Séguin, 1999; Martin, Olejnik, & Gaddis, 1994; Strelau, Zawadzki, & Piotrowska, 2001).

Temperament is also related to social behavior. Highly active preschoolers tend to be sociable with peers, but they also become involved in more conflict than their less active agemates. Shy, inhibited children often watch classmates and engage in anxious behaviors that discourage interaction, such as hovering around play activities and rarely speaking (Chen, Wang, & DeSouza, 2006; Henderson et al., 2004). And as we will see in Chapter 12, inhibited children's high anxiety leads to more discomfort after wrongdoing and a greater sense of responsibility to others. As a result, early fearfulness protects children against becoming aggressive. In contrast, irritable, impulsive children are at risk for aggressive and antisocial conduct (Sanson, Hemphill, & Smart, 2004; Vitaro et al., 2006).

In some cases, as with shy children, social behavior seems to be a direct result of temperament. In other instances, it reflects the way people respond to the child's emotional style.

For example, active, impulsive and irritable, anger-prone children often elicit negative interaction, which leads to conflict (Bridgett et al., 2009; van den Akker et al., 2010). As Chapter 12 will make clear, the relationship of early impulsivity and emotional negativity with later aggression and lawbreaking acts has much to do with the inept parenting often evoked by distractible, headstrong children.

Finally, beginning in the preschool years, children's capacity for effortful control is linked to favorable development and adjustment in cultures as diverse as China and the United States (Zhou, Lengua, & Wang, 2009). Positive outcomes include persistence, task mastery, academic achievement, cooperation, moral maturity (such as concern about wrongdoing and willingness to apologize), empathy, sympathy, and prosocial behaviors of sharing and helpfulness (Eisenberg, 2010; Kochanska & Aksan, 2006; Posner & Rothbart, 2007; Valiente, Lemery-Chalfant, & Swanson, 2010). Effortful control is also positively related to children's resistance to stress. For example, it buffers them against the negative impact of parental conflict, perhaps because children high in effortful control can shift attention away from their parents' negative behaviors and their own anxiety to more positive features of their social environments (David & Murphy, 2007). At the same, time, as we will see next, parenting practices can impede or promote children's effortful control, thereby profoundly altering the link between early temperament and development.

© LAURA DWIGHT PHOTOGRAPHY

These fifth graders collaborating on a science project exhibit a high capacity for effortful control—a dimension of temperament that predicts academic achievement and many other favorable outcomes.

Temperament and Child Rearing: The Goodness-of-Fit Model

If a child's disposition interferes with learning or getting along with others, adults must gently but consistently counteract the child's maladaptive style. Thomas and Chess (1977) proposed a **goodness-of-fit model** to explain how temperament and environment together can produce favorable outcomes. Goodness of fit involves creating child-rearing environments that recognize each child's temperament while encouraging more adaptive functioning.

Goodness of fit helps explain why difficult children (who withdraw from new experiences and react negatively and intensely) are at high risk for later adjustment problems. These children frequently experience parenting that fits poorly with their dispositions. As infants, they are less likely to receive sensitive caregiving (van den Boom & Hoeksma, 1994). By the second year, their parents—especially in low-SES families—tend to use angry, punitive discipline, which undermines the development of effortful control. As the child reacts with defiance and disobedience, parents become increasingly stressed (Bridgett et al., 2009; Paulussen-Hoogeboom et al., 2007). As a result, they continue their coercive tactics and also discipline inconsistently, sometimes rewarding the child's noncompliance by giving in to it (Calkins, 2002). These practices sustain and even increase the child's irritable, conflict-ridden style (van Aken et al., 2007; Pesonen et al., 2008).

In contrast, when parents are positive and sensitive, which helps babies regulate emotion, difficultness declines by age 2 to 3 (Feldman, Greenbaum, & Yirmiya, 1999; Raikes et al., 2007). In toddlerhood and childhood, parental sensitivity, support, clear expectations, and limits foster effortful control, reducing the likelihood that difficultness will persist and lead to emotional and social difficulties (Cipriano & Stifter, 2010; Jaffari-Bimmel et al., 2006).

Recent evidence indicates that temperamentally difficult children function much worse than other children when exposed to inept parenting, yet benefit most from good parenting (Pluess & Belsky, 2011). Using molecular genetic analyses, researchers are investigating gene–environment interactions (see page 121 in Chapter 3) that explain this finding. In one study, 2-year-olds with a chromosome 17 gene containing a certain repetition of DNA base pairs (called short 5-HTTLPR), which interferes with functioning of the inhibitory neurotransmitter serotonin (and, thus, greatly increases the risk of negative mood and self-regulation difficulties), became increasingly irritable as their mothers' anxiety about parenting increased (Ivorra et al., 2010). Maternal anxiety had little impact on children without this genetic marker. In another investigation, preschoolers with the short 5-HTTLPR gene benefited, especially, from positive parenting. With parental affection and support, their capacity for self-regulation equaled that of agemates with a low-risk genotype (Kochanska, Philibert, & Barry, 2009).

Effective parenting of challenging children, however, also depends on life conditions—good parental mental health, marital harmony, and favorable economic conditions (Schoppe-Sullivan et al., 2007). In a comparison of the temperaments of Russian and U.S. babies, Russian infants were more emotionally negative, fearful, and upset when frustrated (Gartstein, Slobodskaya, & Kinsht, 2003). At the time of the study, Russia's national economy was severely depressed. Because of financial worries and longer work hours, Russian parents may have lacked time and energy for the patient parenting that protects against difficultness.

© CORBIS

A parent's firm but affectionate approach to child rearing can help temperamentally difficult children gain in self-regulatory capacity.

Cultural values also affect the fit between parenting and child temperament, as research in China illustrates. In the past, collectivist values, which discourage self-assertion, led Chinese adults to evaluate shy children positively. Several studies showed that shy Chinese children of a decade or two ago appeared well-adjusted, both academically and socially (Chen, Rubin, & Li, 1995; Chen et al., 1998). But rapid expansion of a market economy in China, which requires assertiveness and sociability for success, may be responsible for a recent change in Chinese parents' and teachers' attitudes toward childhood shyness (Chen, Wang, & DeSouza, 2006; Yu, 2002). Among Shanghai fourth graders, the association between shyness and adjustment also changed over time. Whereas shyness was positively correlated with teacher-rated competence, peer acceptance, leadership, and academic achievement in 1990, these relationships weakened in 1998 and reversed in 2002, when they mirrored findings of Western research (see Figure 10.3) (Chen et al., 2005). Cultural context makes a difference in whether shy children receive support or disapproval and whether they adjust well or poorly.

An effective match between rearing conditions and child temperament is best accomplished early, before unfavorable temperament–environment relationships produce maladjustment. Both difficult and shy children benefit from warm, accepting parenting that makes firm but reasonable demands for mastering new experiences. With reserved, inactive toddlers, highly stimulating parenting—questioning, instructing, and pointing out objects—fosters exploration. Yet for highly active toddlers, these same parental behaviors are too directive, dampening their play and curiosity (Miceli et al., 1998).

The goodness-of-fit model reminds us that babies have unique dispositions that adults must accept. Parents can neither take full credit for their children's virtues nor be blamed for all their faults. But parents can turn an environment that exaggerates a child's problems into one that builds on the child's strengths. In the following sections, we will see that goodness of fit is also at the heart of infant–caregiver attachment. This first intimate relationship grows out of interaction between parent and baby, to which the emotional styles of both partners contribute.

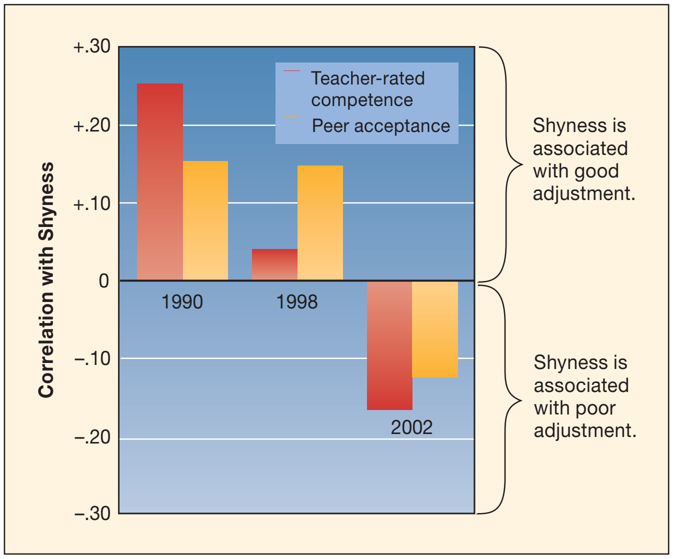

FIGURE 10.3 Changes over time in correlations between shyness and adjustment among Chinese fourth graders. In 1990, shy Chinese children appeared well-adjusted. But as China's market economy expanded and valuing of self-assertion and sociability increased, the direction of the correlations shifted. In 2002, shyness was negatively associated with adjustment. These findings are for teacher-rated competence and peer acceptance. Those for leadership (holding offices in student organizations) and academic achievement changed similarly. (Adapted from Chen et al., 2005.)

- Describe how researchers measure the security of attachment, and discuss the stability of attachment patterns.
- Discuss infants' formation of multiple attachments and the role of early attachment quality in later development.

Development of Attachment

Attachment is the strong, affectionate tie we have with special people in our lives that leads us to experience pleasure and joy when we interact with them and to be comforted by their nearness in times of stress. By the second half of the first year, infants have become attached to familiar people who have responded to their needs.

TAKE A MOMENT... Watch how babies of this age single out their parents for special attention. When the parent enters the room, the baby breaks into a broad, friendly smile. When she picks him up, he pats her face, explores her hair, and snuggles against her. When he feels anxious or afraid, he crawls into her lap and clings closely.

Freud first suggested that the infant's emotional tie to the mother is the foundation for all later relationships. Contemporary research indicates that—although the parent–infant bond is vitally important—later development is influenced not just by early attachment experiences but also by the continuing quality of the parent–child relationship.

Attachment has also been the subject of intense theoretical debate. Recall from Chapter 1 how the *psychoanalytic perspective* regards feeding as the central context in which caregivers and babies build this close emotional bond. *Behaviorism*, too, emphasizes the importance of feeding, but for different reasons. According to a well-known behaviorist explanation, infants learn to prefer the mother's soft caresses, warm smiles, and tender words because these events are paired with tension relief as she satisfies the baby's hunger.

Although feeding is an important context for building a close relationship, attachment does not depend on hunger satisfaction. In the 1950s, a famous experiment showed that rhesus monkeys reared with terry-cloth and wire-mesh "surrogate mothers" clung to the soft terry-cloth substitute, even though the wire-mesh "mother" held the bottle and infants had to climb on it to be fed (Harlow & Zimmerman, 1959). Human infants, too, become attached to family members who seldom feed them, including fathers, siblings, and grandparents. And toddlers in Western cultures who sleep alone and experience frequent daytime separations from their parents sometimes develop strong emotional ties to cuddly objects, such as blankets or teddy bears, that play no role in infant feeding!

Both psychoanalytic and behaviorist accounts of attachment have another problem: They emphasize the caregiver's contribution to the attachment relationship but pay little attention to the importance of the infant's characteristics.

© MARTIN ROGERS/WOODFIN CAMP AND ASSOCIATES

Baby monkeys reared with "surrogate mothers" preferred to cling to a soft terry-cloth "mother" over a wire-mesh "mother" holding a bottle—evidence that parent–infant attachment is based on more than satisfaction of hunger.

Bowlby's Ethological Theory

Today, **ethological theory of attachment,** which recognizes the infant's emotional tie to the caregiver as an evolved response that promotes survival, is the most widely accepted view. John Bowlby (1969), who first applied this idea to the infant–caregiver bond, retained the psychoanalytic idea that quality of attachment to the caregiver has profound implications for the child's feelings of security and capacity to form trusting relationships.

At the same time, Bowlby was inspired by Konrad Lorenz's studies of imprinting (see Chapter 1). Bowlby believed that the human infant, like the young of other animal species, is endowed with a set of built-in behaviors that keep the parent nearby to protect the infant from danger and to provide support for exploring and mastering the environment (Waters & Cummings, 2000). Contact with the parent also ensures that the baby will be fed, but Bowlby pointed out that feeding is not the basis for attachment. Rather, attachment can best be understood in an evolutionary context in which survival of the species—through ensuring both safety and competence—is of utmost importance.

According to Bowlby, the infant's relationship with the parent begins as a set of innate signals that call the adult to the baby's side. Over time, a true affectionate bond forms, supported by new emotional and cognitive capacities as well as by a history of warm, sensitive care. Attachment develops in four phases:

1. *Preattachment phase* (birth to 6 weeks). Built-in signals—grasping, smiling, crying, and gazing into the adult's eyes—help bring newborn babies into close contact with other humans. Babies of this age recognize their own mother's smell, voice, and face (see Chapter 4). But they are not yet attached to her, since they do not mind being left with an unfamiliar adult.
2. *"Attachment-in-the-making" phase* (6 weeks to 6 to 8 months). During this phase, infants respond differently to a familiar caregiver than to a stranger. For example, the baby smiles, laughs, and babbles more freely with the mother and quiets more quickly when she picks him up. As infants learn that their own actions affect the behavior of those around them, they begin to develop a *sense of trust*—the expectation that the caregiver will respond when signaled—but they still do not protest when separated from her.
3. *"Clear-cut" attachment phase* (6 to 8 months to 18 months to 2 years). Now attachment to the familiar caregiver is evident. Babies display **separation anxiety,** becoming upset when their trusted caregiver leaves. Like stranger anxiety (see page 405), separation anxiety does not always occur; it depends on infant temperament and the current situation. But in many cultures, separation anxiety increases between 6 and 15 months, suggesting that infants have developed a clear understanding that the caregiver continues to exist when not in view. Consistent with this idea, babies who have not yet mastered Piagetian object permanence usually do not become anxious when separated from the parent (Lester et al., 1974).

   Besides protesting the parent's departure, older infants and toddlers try hard to maintain her presence. They approach, follow, and climb on her in preference to others. And they use the familiar caregiver as a secure base from which to explore.
4. *Formation of a reciprocal relationship* (18 months to 2 years and on). By the end of the second year, rapid growth in representation and language enables toddlers to understand some of the factors that influence the parent's coming and going and to predict her return. As a result, separation protest declines. Now children negotiate with the caregiver, using requests and persuasion to alter her goals. For example, one 2-year-old asked her parents to read a story before leaving her with a babysitter. The extra time with her parents, along with a better understanding of where they were going ("to have dinner with Uncle Charlie") and when they would be back ("right after you go to sleep"), helped this child withstand her parents' absence.

LOOK and LISTEN

Because this 2-year-old has the language and representational skills to predict his mother's return, separation anxiety declines. He accepts his mother's departure.

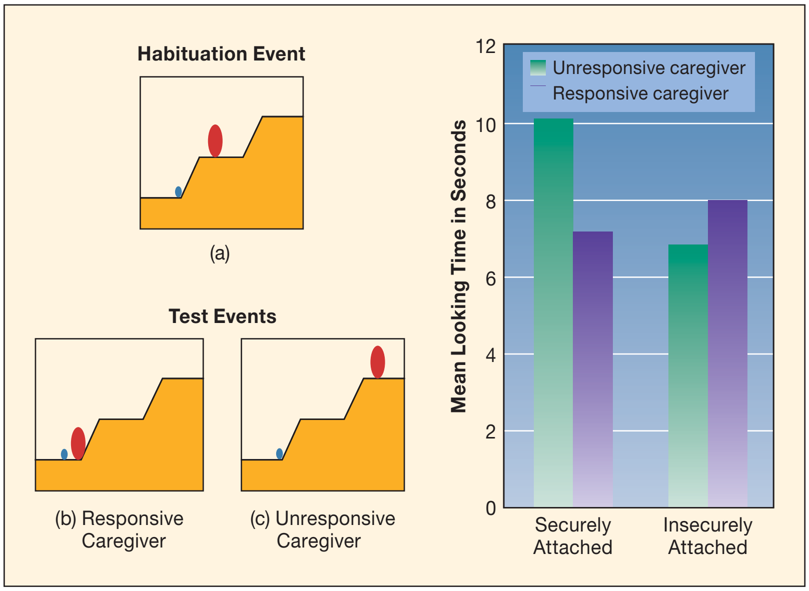

FIGURE 10.4 Testing toddlers for internal working models of attachment. (a) First, 12- to 16-month-olds were habituated to a video of two animated shapes, one large (the "caregiver") and one small (the "child"). The caregiver traveled halfway up an incline to a plateau, and the child began to "cry," depicted by pulsing and bouncing accompanied by an infant cry. Next the researchers presented two test events: (b) In the *responsive-caregiver outcome*, the caregiver returned to the child. (c) In the *unresponsive-caregiver outcome*, the caregiver continued up the slope away from the child. Securely attached toddlers looked longer at the unresponsive outcome, depicting caregiver behavior inconsistent with their attachment-related expectations. Insecurely attached toddlers did not differentiate between the two test events. (Adapted from Johnson, Dweck, & Chen, 2007.)

According to Bowlby (1980), out of their experiences during these four phases, children construct an enduring affectionate tie that they can use as a secure base in the parents' absence. This image serves as an **internal working model,** or set of expectations about the availability of attachment figures, their likelihood of providing support during times of stress, and the self's interaction with those figures. The internal working model becomes a vital part of personality, serving as a guide for all future close relationships (Bretherton & Munholland, 2008).

Consistent with these ideas, as early as the second year, toddlers form attachment-related expectations about parental comfort and support. In two studies, securely attached 12- to 16-month-olds looked longer at a video of an unresponsive caregiver (inconsistent with their expectations) than a video of a responsive caregiver. Insecurely attached toddlers, in contrast, did not distinguish between the two (see Figure 10.4) (Johnson, Dweck, & Chen, 2007; Johnson et al., 2010). With age, children continually revise and expand their internal working model as their cognitive, emotional, and social capacities increase and as they interact with parents and form other close bonds with adults, siblings, and friends.

Measuring the Security of Attachment

Although all family-reared babies become attached to a familiar caregiver by the second year, the quality of this relationship differs from child to child. Some infants appear relaxed and secure in the presence of the caregiver; they know they can count on her for protection and support. Others seem anxious and uncertain.

A widely used laboratory technique for assessing the quality of attachment between 1 and 2 years of age is the **Strange Situation**. In designing it, Mary Ainsworth and her colleagues (1978) reasoned that securely attached infants and toddlers should use the parent as a secure base from which to explore in an unfamiliar playroom. In addition, when the parent leaves, an unfamiliar adult should be less comforting than the parent. The Strange Situation takes the baby through eight short episodes in which brief separations from and reunions with the caregiver occur (see Table 10.2).

Observing infants' responses to these episodes, researchers identified a secure attachment pattern and three patterns of insecurity; a few babies cannot be classified (Ainsworth et al., 1978; Barnett & Vondra, 1999; Main & Solomon, 1990; Thompson, 2006). Although separation anxiety varies among the groups, the baby's reunion responses define attachment quality.

- **Secure attachment.** These infants use the parent as a secure base. When separated, they may or may not cry, but if they do, it is because the parent is absent and they prefer her to the stranger. When the parent returns, they actively seek contact, and their crying is reduced immediately. About 60 percent of North American infants in middle-SES families show this pattern. (In low-SES families, a smaller proportion of babies show the secure pattern, with higher proportions falling into the insecure patterns.)
- **Avoidant attachment.** These infants seem unresponsive to the parent when she is present. When she leaves, they usually are not distressed, and they react to the stranger in much the same way as to the parent. During reunion, they avoid or are slow to greet the parent, and when picked up, they often fail to cling. About 15 percent of North American infants in middle-SES families show this pattern.

TABLE 10.2 Episodes in the Strange Situation

EPISODE	EVENTS	ATTACHMENT BEHAVIOR OBSERVED
1	Researcher introduces parent and baby to playroom and then leaves.	
2	Parent is seated while baby plays with toys.	Parent as a secure base
3	Stranger enters, is seated, and talks to parent.	Reaction to unfamiliar adult
4	Parent leaves room. Stranger responds to baby and offers comfort if baby is upset.	Separation anxiety
5	Parent returns, greets baby, and offers comfort if necessary. Stranger leaves room.	Reaction to reunion
6	Parent leaves room.	Separation anxiety
7	Stranger enters room and offers comfort.	Ability to be soothed by stranger
8	Parent returns, greets baby, offers comfort if necessary, and tries to reinterest baby in toys.	Reaction to reunion

Note: Episode 1 lasts about 30 seconds; each of the remaining episodes lasts about 3 minutes. Separation episodes are cut short if the baby becomes very upset. Reunion episodes are extended if the baby needs more time to calm down and return to play.

Source: Ainsworth et al., 1978.

- **Resistant attachment.** Before separation, these infants seek closeness to the parent and often fail to explore. When the parent leaves, they are usually distressed, and on her return they combine clinginess with angry, resistive behavior, struggling when held and sometimes hitting and pushing. Many continue to cry and cling after being picked up and cannot be comforted easily. About 10 percent of North American infants in middle-SES families show this pattern.
- **Disorganized/disoriented attachment.** This pattern reflects the greatest insecurity. At reunion, these infants show confused, contradictory behaviors—for example, looking away while the parent is holding them or approaching the parent with flat, depressed emotion. Most display a dazed facial expression, and a few cry out unexpectedly after having calmed down or display odd, frozen postures. About 15 percent of North American infants in middle-SES families show this pattern.

Researchers have modified Strange Situation procedures to make them appropriate for preschoolers, looking closely at the child's seeking of physical closeness, eye contact, expressions of emotion, and content and style of parent-directed speech—especially during reunion episodes. The resulting preschool attachment classifications are modestly associated with previously obtained infant assessments (Crittenden, 2000; Main & Cassidy, 1988; Moss et al., 2005b).

An alternative method, the **Attachment Q-Sort,** suitable for children between 1 and 4 years, depends on home observations (Waters et al., 1995). Either the parent or a highly trained observer sorts 90 behaviors—such as "Child greets mother with a big smile when she enters the room," "If mother moves very far, child follows along," and "Child uses mother's facial expressions as a good source of information when something looks risky or threatening"—into nine categories, ranging from "highly descriptive" to "not at all descriptive" of the child. Then a score, ranging from high to low in security, is computed.

Because the Q-Sort taps a wider array of attachment-related behaviors than the Strange Situation, it may better reflect the parent–child relationship in everyday life. However, the Q-sort method is time-consuming, requiring a nonparent informant to spend several hours observing the child before sorting the descriptors, and it does not differentiate between types of insecurity. The Q-Sort responses of expert observers correspond well with babies' secure-base behavior in the

This securely attached 1-year-old actively seeks contact and is calmed by his father's return. An avoidantly attached toddler would be slow to greet the parent; a resistantly attached child would be both clingy and angry.

Strange Situation; more research is needed to verify a correspondence for preschoolers (Posada, 2006). Parents' Q-Sorts, however, show little relationship with Strange Situation assessments (van IJzendoorn et al., 2004). Parents of insecure children, especially, may have difficulty accurately reporting their child's attachment behaviors.

Stability of Attachment

Research on the stability of attachment patterns between 1 and 2 years of age yields a wide range of findings. In some studies, as many as 70 to 90 percent of babies remain the same in their reactions to parents; in others, only 30 to 40 percent do (Thompson, 2000, 2006). A close look at which babies stay the same and which ones change yields a more consistent picture. Quality of attachment is usually secure and stable for middle-SES babies experiencing favorable life conditions. And infants who move from insecurity to security typically have well-adjusted mothers with positive family and friendship ties. Perhaps many became parents before they were psychologically ready but, with social support, grew into the role.

In contrast, in low-SES families with many daily stresses and little social support, attachment generally moves away from security or changes from one insecure pattern to another (Belsky et al., 1996; Fish, 2004; Vondra, Hommerding, & Shaw, 1999; Vondra et al., 2001). In one long-term follow-up of a poverty-stricken sample, many securely attached infants ended up insecure when reassessed in early adulthood. Child maltreatment, maternal depression, and poor family functioning in adolescence distinguished these young people from the few who stayed securely attached (Weinfield, Sroufe, & Egeland, 2000; Weinfield, Whaley, & Egeland, 2004).

These findings indicate that securely attached babies more often maintain their attachment status than insecure babies, whose relationship with the caregiver is, by definition, fragile and uncertain. The exception is disorganized/disoriented attachment—an insecure pattern that is as stable as attachment security: Nearly 70 percent retain this classification over the second year, and the majority remain highly insecure over the long term, continuing to express confused, ambivalent feelings toward parents in early adulthood (Hesse & Main, 2000; Sroufe et al., 2005; Weinfield, Whaley, & Egeland, 2004). As you will soon see, many disorganized/disoriented infants experience extremely negative caregiving, which may disrupt emotional self-regulation so severely that attachment disorganization persists.

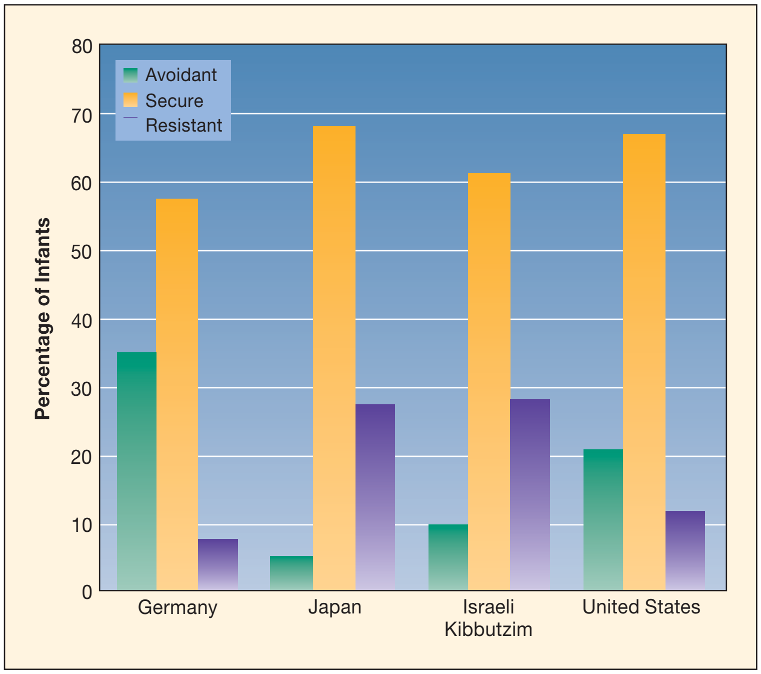

FIGURE 10.5 A cross-cultural comparison of infants' reactions in the Strange Situation. A high percentage of German babies seem avoidantly attached, whereas a substantial number of Japanese and Israeli kibbutz infants appear resistantly attached. Note that these responses may not reflect true insecurity. Instead, they are probably due to cultural differences in child-rearing practices. (Adapted from Sagi et al., 1995; van IJzendoorn & Kroonenberg, 1988; van IJzendoorn & Sagi-Schwartz, 2008.)

Cultural Variations

Cross-cultural evidence indicates that attachment patterns may have to be interpreted differently in certain cultures. For example, as Figure 10.5 reveals, German infants show considerably more avoidant attachment than American babies do. But German parents value independence and encourage their infants to be nonclingy, so the baby's behavior may be an intended outcome of cultural beliefs and practices (Grossmann et al., 1985). In contrast, a study of infants of the Dogon people of Mali, Africa, revealed that none showed avoidant attachment to their mothers (True, Pisani, & Oumar, 2001). Even when grandmothers are primary caregivers (as they are with firstborn sons), Dogon mothers remain available to their babies, holding them close and nursing them promptly in response to hunger and distress.

Japanese infants, as well, rarely show avoidant attachment (refer again to Figure 10.5). Rather, many are resistantly attached, but this reaction may not represent true insecurity. Japanese mothers spend much time in close physical contact with their babies and rarely leave them in others' care, so the Strange Situation probably induces greater stress in them than in infants who experience frequent maternal separations (Takahashi, 1990). Also, Japanese parents expect their babies to be quite upset during reunion in the Strange Situation. They view the attention-seeking that is part of resistant attachment as a normal indicator of infants' efforts to satisfy dependency and security needs (Rothbaum et al., 2000a, 2007). Likewise, infants in Israeli kibbutzim frequently show resistant attachment. For these babies, who can sense the fear of unfamiliar people that is pervasive in their communities (see page 406), the Strange Situation probably induces unusual distress (van IJzendoorn & Sagi, 1999). Despite these and other cultural variations, the secure pattern is still the most common attachment quality in all societies studied to date (van IJzendoorn & Sagi-Schwartz, 2008).

Dogon mothers of Mali, West Africa, stay close to their babies and respond promptly and gently to infant hunger and distress. With their mothers consistently available, none of the Dogon babies show avoidant attachment.

Factors That Affect Attachment Security

What factors might influence attachment security? Researchers have looked closely at four important influences: (1) early availability of a consistent caregiver, (2) quality of caregiving, (3) the baby's characteristics, and (4) family context, including parents' internal working models.

Early Availability of a Consistent Caregiver What happens when a baby does not have the opportunity to establish a close tie to a caregiver? In a series of studies, René Spitz (1946) observed institutionalized infants whose mothers had given them up between 3 and 12 months of age. After being placed in a large ward where each shared a nurse with at least seven others, the babies lost weight, wept, withdrew from their surroundings, and had difficulty sleeping. If a consistent caregiver did not replace the mother, the depression deepened rapidly. These institutionalized babies had emotional problems because they were prevented from forming a bond with one or a few adults (Rutter, 1996).

Another study supports this conclusion. Researchers followed the development of infants in an institution with a good caregiver–child ratio and a rich selection of books and toys. However, staff turnover was so rapid that the average child had 50 different caregivers by age 4½! Many of these children became "late adoptees" who were placed in homes after age 4. Most developed deep ties with their adoptive parents, indicating that a first attachment bond can develop as late as 4 to 6 years of age (Hodges & Tizard, 1989; Tizard & Rees, 1975). But these children were also more likely to display attachment difficulties, including an excessive desire for adult attention, "overfriendliness" to unfamiliar adults and peers, failure to check back with the parent in anxiety-arousing situations, and few friendships.

Children who spent their first year or more in deprived Eastern European orphanages—though also able to bond with their adoptive or foster parents—show elevated rates of attachment insecurity (van den Dries et al., 2009; Smyke et al., 2010). And they, too, are at high risk for emotional and social difficulties. Whereas many are indiscriminately friendly, others are sad, anxious, and withdrawn (Chisholm, 1998; Fisher et al., 1997; O'Connor et al., 2003). These symptoms typically persist and are associated with wide-ranging mental health problems in middle childhood and adolescence, including cognitive impairments, inattention and hyperactivity, depression, and either social avoidance or aggressive behavior (Kreppner et al., 2007, 2010; O'Connor et al., 2003; Rutter et al., 2007, 2010; Zeanah, 2000).

Furthermore, as early as 7 months, institutionalized children show reduced ERP brain waves in response to facial expressions of emotion and have trouble discriminating such expressions—outcomes that suggest disrupted formation of neural structures involved in "reading" emotions (Parker et al., 2005). These problems are still evident in preschoolers adopted during the second year, who find it hard to match appropriate facial expressions with situations in stories (Fries & Pollak, 2004). Consistent with these findings, MRI evidence reveals that in adopted children with longer institutional stays, the volume of the *amygdala*—a brain region devoted to processing emotional information (see page 190 in Chapter 5)—is atypically large (Tottenham et al., 2011). The larger amygdala, the worse adopted children perform on emotion-processing tasks and the poorer their emotion regulation—deficits that contribute to their social-relationship and adjustment problems. Overall, the evidence on orphanage children indicates that fully normal emotional development depends on establishing a close tie with a caregiver early in life.

© GERI ENGBERG/THE IMAGE WORKS

A father and baby engage in a sensitively tuned form of communication called interactional synchrony, in which they match emotional states, especially positive ones. Among Western infants, this style of communication predicts secure attachment.

Quality of Caregiving Dozens of studies report that **sensitive caregiving**—responding promptly, consistently, and appropriately to infants and holding them tenderly and carefully—is moderately related to attachment security in both biological and adoptive mother–infant pairs and in diverse cultures and SES groups (Belsky & Fearon, 2008; DeWolff & van IJzendoorn, 1997; van IJzendoorn et al., 2004). In contrast, insecurely attached infants tend to have mothers who engage in less physical contact, handle them awkwardly or in a “routine” manner, and are sometimes resentful and rejecting, particularly in response to infant distress (Ainsworth et al., 1978; Isabella, 1993; McElwain & Booth-LaForce, 2006; Pederson & Moran, 1996).

Also, in studies of Western babies, a special form of communication called **interactional synchrony** separates the experiences of secure from insecure babies. It is best described as a sensitively tuned “emotional dance,” in which the caregiver responds to infant signals in a well-timed, rhythmic, appropriate fashion. In addition, both partners match emotional states, especially the positive ones (Bigelow et al., 2010; Isabella & Belsky, 1991; Nievar & Becker, 2008). Earlier we saw that sensitive face-to-face play, in which interactional synchrony occurs, increases babies’ sensitivity to others’ emotional messages and helps them regulate emotion. But moderate adult–infant coordination is a better predictor of attachment security than “tight” coordination, in which the adult responds to most infant cues (Jaffee et al., 2001). Perhaps warm, sensitive caregivers use a relaxed, flexible style of communication in which they comfortably accept and repair emotional mismatches, returning to a synchronous state.

Cultures vary in their view of sensitivity toward infants. Among the Gusii people of Kenya, for example, mothers rarely cuddle, hug, or interact playfully with their babies, although they are very responsive to their infants’ needs. Yet most Gusii infants appear securely attached (LeVine et al., 1994). This suggests that security depends on attentive caregiving, not necessarily on moment-by-moment contingent interaction. Puerto Rican mothers, who highly value obedience and socially appropriate behavior, often physically direct and limit their babies’ actions—a style of caregiving linked to attachment security in Puerto Rican culture (Carlson & Horwood, 2003). But in many Western cultures, such physical control and restriction of exploration are viewed as intrusive and predict insecurity (Belsky & Fearon, 2008; Whipple, Bernier, & Mageau, 2011).

Compared with securely attached infants, avoidant babies tend to receive overstimulating care. Their mothers might, for example, talk energetically to them while they are looking away or falling asleep. By avoiding the mother, these infants try to escape from overwhelming interaction. Resistant infants often experience inconsistent care: Their mothers are unresponsive to infant signals. Yet when the baby begins to explore, these mothers interfere, shifting the infant’s attention back to themselves. As a result, the baby is overly dependent as well as angry at the mother’s lack of involvement (Cassidy & Berlin, 1994; Isabella & Belsky, 1991).

Highly inadequate caregiving is a powerful predictor of disruptions in attachment. Child abuse and neglect (topics we will consider in Chapter 14) are associated with all three forms of attachment insecurity. Among maltreated infants, disorganized/disoriented attachment is especially high (van IJzendoorn, Schuengel, & Bakermans-Kranenburg, 1999). Persistently depressed mothers, mothers with very low marital satisfaction, and parents suffering from a traumatic event, such as serious illness or loss of a loved one, also tend to promote the uncertain behaviors of this pattern (Campbell et al., 2004; Madigan et al., 2006; Moss et al., 2005b). And some mothers of disorganized/disoriented infants engage in frightening, contradictory, and unpleasant behaviors, such as looking scared, teasing the baby, holding the baby stiffly at a distance, roughly pulling the baby by the arm, or seeking reassurance from the upset child (Abrams, Rifkin, & Hesse, 2006; Lyons-Ruth, Bronfman, & Parsons, 1999; Moran et al., 2008). Perhaps the baby’s disorganized behavior reflects a conflicted reaction to the parent, who sometimes comforts but at other times arouses fear.

Infant Characteristics Because attachment is the result of a *relationship* that builds between two partners, infant characteristics should affect how easily it is established. In Chapter 3, we saw that prematurity, birth complications, and newborn illness make caregiving more taxing. In families under stress, these difficulties are linked to attachment insecurity. In one study, the *combination* of preterm birth and maternal depression—but not preterm birth alone—increased the likelihood of insecure attachment at 12 months (Poehlmann & Fiese, 2001). Infants with special needs probably require greater sensitivity, which stressed parents often cannot provide. But at-risk newborns whose parents have the time and patience to care for them fare quite well in attachment security (Brisch et al., 2005; Cox, Hopkins, & Hans, 2000).

The role of infant temperament in attachment security has been intensely debated. Some researchers believe that infants who are irritable and fearful may simply react to brief separations with intense anxiety, regardless of the parent's sensitivity to the baby (Kagan, 1998; Kagan & Fox, 2006). Consistent with this view, emotionally reactive, difficult babies are more likely to develop later insecure attachments (van IJzendoorn et al., 2004; Vaughn, Bost, & van IJzendoorn, 2008).

Again, however, other evidence suggests that parental mental health and caregiving are involved. In a study extending from birth to age 2, difficult infants more often had highly anxious mothers—a combination that, by the second year, often resulted in a "disharmonious relationship" characterized by both maternal insensitivity and attachment insecurity (Symons, 2001). Infant difficultness and maternal anxiety seemed to perpetuate each other, impairing caregiving and the security of the parent–infant bond.

Other research focusing on disorganized/disoriented attachment has uncovered gene–environment interactions (Gervai, 2009). In one of these investigations, mothers' experience of unresolved loss of a loved one or other trauma was associated with attachment disorganization only in infants with a chromosome-11 gene having a certain repetition of DNA base pairs (called DRD4 7-repeat), which is linked to deficient self-regulation (see Figure 10.6) (van IJzendoorn & Bakermans-Kranenburg, 2006). Babies with this genetic marker, who face special challenges in managing intense emotion, were more vulnerable to the negative impact of maternal adjustment problems.

If children's temperaments alone determined attachment security, we would expect attachment, like temperament, to be at least moderately heritable. Yet twin comparisons reveal that the heritability of attachment is virtually nil (O'Connor & Croft, 2001; Roisman & Fraley, 2008). In fact, about two-thirds of siblings—whether identical twins, fraternal twins, nontwin siblings, unrelated siblings, or foster infants—establish similar attachment patterns with their parent, although the siblings often differ in temperament (Cole, 2006; Dozier et al., 2001). This suggests that the strongest parental influences on attachment security are *nonshared* experiences, reflecting most parents' efforts to adjust their caregiving to each child's individual needs.

A major reason that children's characteristics do not show strong relationships with attachment quality is that their influence depends on goodness of fit. From this perspective, *many* child attributes can lead to secure attachment as long as caregivers sensitively adjust their behavior to fit the baby's needs (Seifer & Schiller, 1995; Sroufe, 1985).

Interventions that teach parents to interact sensitively with difficult-to-care-for infants are highly successful in enhancing both quality of caregiving and attachment security (Velderman et al., 2006). One program that focused on both maternal sensitivity and effective discipline was particularly effective in reducing stress reactivity (as indicated by lower cortisol levels) and disruptive behavior among toddlers with the DRD4 7-repeat gene, who are at risk for later attention-deficit hyperactivity disorder and externalizing behavior problems (Bakermans-Kranenburg et al., 2008a, 2008b; Bakermans-Kranenburg & van IJzendoorn, 2011). These findings suggest that the DRD4 7-repeat gene makes children more susceptible to the effects of both negative and positive parenting!

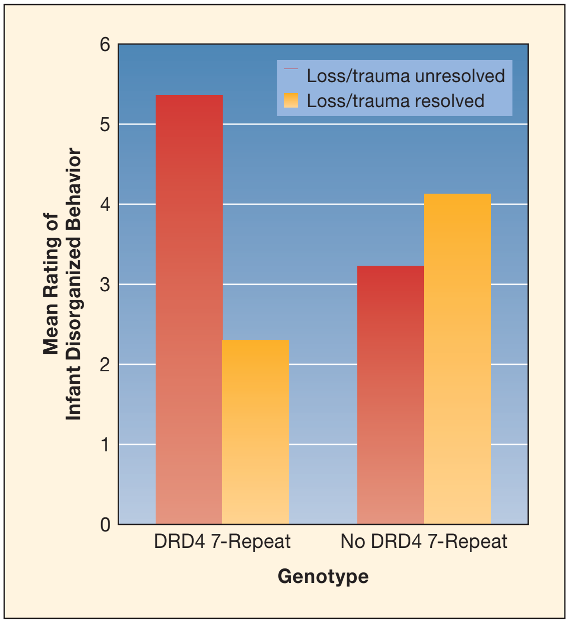

FIGURE 10.6 **The combination of maternal unresolved loss/trauma and infant DRD4 7-repeat gene predicts disorganized/disoriented attachment.** Mothers' experience of unresolved loss or other trauma was associated with disorganized/disoriented attachment only in 1-year-olds with the DRD4 7-repeat gene. (A rating of disorganized behavior in the Strange Situation higher than 5 leads to the attachment classification of disorganized/disoriented.) Family circumstances are linked to attachment quality. Observing her parents' heated quarrels may undermine this child's sense of emotional security.

Family Circumstances As we have indicated in this and previous chapters, quality of caregiving can be fully understood only in terms of the larger context of the parent–child relationship. Job loss, a failing marriage, financial strain, and other stressors can undermine attachment indirectly, by interfering with the sensitivity of parental care. These stressors can also affect babies' sense of security directly by altering the emotional climate of the family (for example, exposing them to angry adult interactions) or by disrupting familiar daily routines (Finger et al., 2009; Raikes & Thompson, 2005).

The arrival of a new sibling illustrates how family circumstances can affect attachment quality. In one study, firstborn preschoolers who declined in attachment security after the birth of a baby had mothers who were depressed, anxious, or hostile before the birth. These symptoms were associated with marital friction (which the firstborns probably sensed) as well as with unfavorable mother–firstborn interaction. When mothers had cooperative marriages, coped well with the second birth, and stayed involved with their older child, preschoolers maintained a secure attachment bond (Teti et al., 1996). The availability of social supports, especially parents with a good relationship who assist each other with caregiving, reduces family stress and predicts greater attachment security (Belsky, 2006; Owen & Cox, 1997).

Parents' Internal Working Models Parents bring to the family context their own history of attachment experiences, from which they construct internal working models that they apply to the bonds they establish with their babies. To assess parents' "state of mind" with respect to attachment, Mary Main and her colleagues devised the *Adult Attachment Interview*, which asks adults to evaluate childhood memories of attachment experiences (Main & Goldwyn, 1998).

As Table 10.3 shows, quality of parents' working models is clearly related to children's attachment security in infancy and early childhood—results replicated in Canada, Germany, Great Britain, Japan, the Netherlands, and the United States. Parents who discuss their childhoods with objectivity and balance tend to have securely attached children. In contrast, parents who dismiss the importance of early relationships or describe them in angry, confused

TABLE 10.3 **Relationship of Parents' Internal Working Models to Infant Attachment Security**

TYPE OF INTERNAL WORKING MODEL	DESCRIPTION	INFANT ATTACHMENT CLASSIFICATION[a]
Autonomous/secure	These parents show objectivity and balance in discussing their childhood experiences, whether these were positive or negative. They neither idealize their parents nor feel angry about the past. Their explanations are coherent and believable. About 58 percent of North American mothers and fathers without psychological disturbance are autonomous/secure.	Secure
Dismissing	These parents devalue the importance of their attachment relationships. They tend to idealize their parents without being able to recall specific experiences. What they do recall is discussed intellectually, with little emotion. About 23 percent of North American mothers and 28 percent of fathers without psychological disturbance are dismissing.	Avoidant
Preoccupied	These parents talk about their childhood experiences with highly charged emotion, sometimes expressing anger toward their parents. They appear overwhelmed and confused about their early attachments and cannot discuss them coherently. About 19 percent of North American mothers and 15 percent of fathers without psychological disturbance are preoccupied.	Resistant
Unresolved	These parents show characteristics of any of the three other patterns. At the same time, they reason in a disorganized and confused way when loss of a loved one or experiences of physical or sexual abuse are discussed. Besides displaying one of the other patterns, about 18 percent of North American mothers and 15 percent of fathers without psychological disturbance are unresolved.	Disorganized/disoriented

[a] Correspondences between type of maternal working model and infant attachment classification hold for 60 to 70 percent of mother–infant pairs.

Source: Bakermans-Kranenburg & van IJzendoorn, 2009; Bretherton & Munholland, 2008.

ways usually have insecurely attached children (Behrens, Hesse, & Main, 2007; Steele, Steele, & Fonagy, 1996; van IJzendoorn, 1995). Caregiving behavior helps explain these associations. Parents with autonomous/secure representations are warmer and more sensitive with their babies. They are also more likely to be supportive and to encourage learning and mastery in their preschoolers, who, in turn, are more affectionate and comfortably interactive with them (Coyl, Newland, & Freeman, 2010; Pederson et al., 1998; Slade et al., 1999).

But we must not assume any direct transfer of parents' childhood experiences to quality of attachment with their own children. Internal working models are *reconstructed memories* affected by many factors, including relationship experiences over the life course, personality, and current life satisfaction. Longitudinal research reveals that negative life events can weaken the link between an individual's own attachment security in infancy and a secure internal working model in adulthood. And insecurely attached babies who become adults with insecure internal working models often have lives that, based on adulthood self-reports, are filled with family crises (Waters et al., 2000; Weinfield, Sroufe, & Egeland, 2000).

In sum, our early rearing experiences do not destine us to become either sensitive or insensitive parents. Rather, the way we *view* our childhoods—our ability to come to terms with negative events, to integrate new information into our working models, and to look back on our own parents in an understanding, forgiving way—appears to be much more influential in how we rear our children than the actual history of care we received (Bretherton & Munholland, 2008).

Multiple Attachments

As we have indicated, babies develop attachments to a variety of familiar people—not just mothers but also fathers, grandparents, siblings, and professional caregivers. Although Bowlby (1969) believed that infants are predisposed to direct their attachment behaviors to a single special person, especially when they are distressed, his theory allowed for these multiple attachments.

Fathers An anxious, unhappy 1-year-old who is permitted to choose between the mother and the father as a source of comfort and security will usually choose the mother. But this preference typically declines over the second year. And when babies are not distressed, they approach, vocalize to, and smile equally often at both parents, who in turn are equally responsive to their infant's social bids (Bornstein, 2006; Parke, 2002).

Fathers' sensitive caregiving and interactional synchrony with infants, like mothers', predict attachment security (Lundy, 2003; van IJzendoorn et al., 2004). But as infancy progresses, mothers and fathers in many cultures, including Australia, Canada, Germany, India, Israel, Italy, Japan, and the United States, tend to interact differently with their babies: Mothers devote more time to physical care and expressing affection, fathers to playful interaction (Freeman & Newland, 2010; Roopnarine et al., 1990).

Mothers and fathers also play differently. Mothers more often provide toys, talk to infants, and gently play conventional games like pat-a-cake and peekaboo. In contrast, fathers—especially with their infant sons—tend to engage in highly arousing physical play with bursts of excitement and surprise that increase as play progresses (Feldman, 2003). As long as fathers are also sensitive, this stimulating, startling play style helps babies regulate emotion in intensely arousing situations and may prepare them to venture confidently into active, unpredictable contexts, including novel physical environments and play with peers (Cabrera et al., 2007; Hazen et al., 2010; Paquette, 2004). In a German study, fathers' sensitive, challenging play with preschoolers predicted favorable emotional and social adjustment from kindergarten to early adulthood (Grossmann et al., 2008).

Play is a vital context in which fathers build secure attachments (Newland, Coyl, & Freeman, 2008). It may be especially influential in cultures where long work hours prevent most fathers from sharing in infant caregiving, such as Japan (Hewlett, 2004; Shwalb et al., 2004). In many Western nations, however, a strict division of parental roles—mother as caregiver, father as playmate—has changed over the past several decades in response to women's workforce participation and to cultural valuing of gender equality.

LOOK and LISTEN

Observe parents at play with infants at home or a family gathering. Describe both similarities and differences in mothers' and fathers' behaviors. Are your observations consistent with research findings?

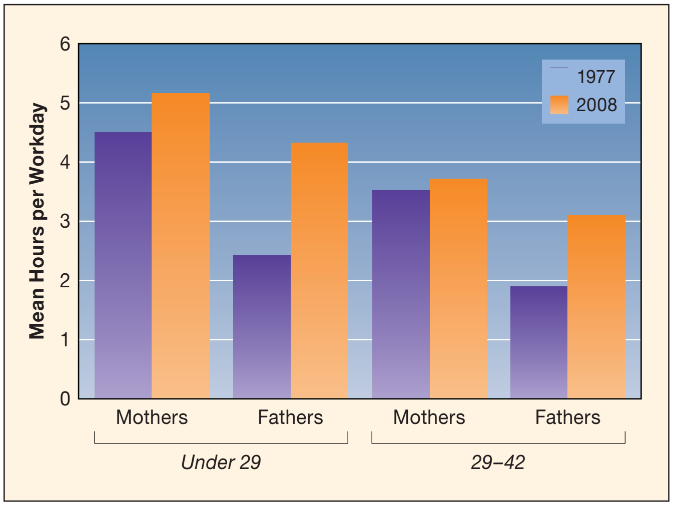

FIGURE 10.7 Average amount of time per workday U.S. employed mothers and fathers reported spending with their children (age 12 and younger) in 1977 and 2008. In national surveys of several thousand employed parents, mothers' time with children remained fairly stable from 1977 to 2008; fathers' time increased substantially. (Adapted from Galinsky, Aumann, & Bond, 2009.)

A recent U.S. national survey of several thousand employed workers indicated that U.S. fathers under age 29 devote about 85 percent as much time to children as mothers do—on average, just over 4 hours per workday, nearly double the hours young fathers reported three decades ago. Although fathers age 29 to 42 spend somewhat less time with children, their involvement has also increased substantially (see Figure 10.7). Today, nearly one-third of U.S. employed women say that their spouse or partner shares equally in or takes most responsibility for child-care tasks (Galinsky, Aumann, & Bond, 2009). Paternal availability to children is fairly similar across SES and ethnic groups, with one exception: Hispanic fathers spend more time engaged, probably because of the particularly high value that Hispanic cultures place on family involvement (Cabrera & García-Coll, 2004; Parke et al., 2004a).

Mothers in dual-earner families tend to engage in more playful stimulation of their babies than mothers who are at home full-time (Cox et al., 1992). But fathers who are primary caregivers retain their arousing play style (Lamb & Oppenheim, 1989). These highly involved fathers are less gender-stereotyped in their beliefs; have sympathetic, friendly personalities; often had fathers who were more involved in rearing them; and regard parenthood as an especially enriching experience (Cabrera et al., 2000; Levy-Shiff & Israelashvili, 1988).

Fathers' involvement with babies occurs within a complex system of family attitudes and relationships. When both parents believe that men are capable of nurturing infants, fathers devote more time to caregiving (Beitel & Parke, 1998). A warm marital bond promotes both parents' sensitivity and involvement with babies, but it is particularly important for fathers (Lamb & Lewis, 2004). See the Cultural Influences box on the following page for cross-cultural evidence documenting this conclusion—and also highlighting the powerful role of paternal warmth in children's development.

Grandparent Primary Caregivers

Nearly 2.4 million U.S. children—4 to 5 percent of the child population—live with their grandparents but apart from parents, in so-called *skipped-generation families* (U.S. Census Bureau, 2011b). The number of grandparents rearing grandchildren has increased over the past two decades. The arrangement occurs in all ethnic groups, though more often in African-American, Hispanic, and Native-American families than in Caucasian families. Although grandparent caregivers are more likely to be women than men, many grandfathers participate. Grandparents generally step in when parents' troubled lives—as a result of substance abuse, child abuse and neglect, domestic violence, mental illness, imprisonment, or adolescent parenthood—threaten children's well-being (Fuller-Thomson & Minkler, 2005, 2007; Minkler & Fuller-Thomson, 2005). Often these families take in two or more children.

© ELLEN B. SENISI PHOTOGRAPHY

Despite stressful family conditions, grandparents who provide long-term physical and emotional care form deep attachments with their grandchildren.

As a result, grandparents tend to assume the parenting role under highly stressful life circumstances. Unfavorable child-rearing experiences have left their mark on children, who show high rates of learning difficulties, depression, and antisocial behavior. Absent parents' adjustment difficulties strain family relationships. Parents may interfere by violating the grandparents' behavioral limits, taking grandchildren away without permission, or making promises to children that they do not keep. These youngsters also introduce financial burdens into households that often are already low-income (Mills, Gomez-Smith, & De Leon, 2005; Williamson, Softas-Nall, & Miller, 2003). And grandparent caregivers, at a time when they anticipated having more time for spouses, friends, and leisure, instead have less. Many report feeling emotionally drained, depressed, and worried about what will happen to the children if their own health fails (Hayslip et al., 2002; Kolomer & McCallion, 2005).

CULTURAL INFLUENCES

The Powerful Role of Paternal Warmth in Development

Research in diverse cultures demonstrates that fathers' warmth contributes to children's long-term favorable development. In studies of many societies and ethnic groups around the world, researchers coded paternal expressions of love and nurturance—evident in such behaviors as cuddling, hugging, comforting, playing, verbally expressing love, and praising the child's behavior. Fathers' sustained affectionate involvement predicted later cognitive, emotional, and social competence as strongly as did mothers' warmth—and occasionally more strongly (Rohner & Veneziano, 2001; Veneziano, 2003). And in Western cultures, paternal warmth and secure attachment are associated with children's mature social behavior and a reduction in a wide range of difficulties, including childhood emotional and behavior problems and adolescent substance abuse and delinquency (Grant et al., 2000; Michiels et al., 2010; Nelson & Coyne, 2009; Tacon & Caldera, 2001).

Fathers who devote little time to physical caregiving express warmth through play. In a German study, fathers' play sensitivity—accepting toddlers' play initiatives, adapting play behaviors to toddlers' capacities, and responding appropriately to toddlers' expressions of emotion—predicted children's secure internal working models of attachment during middle childhood and adolescence (Grossmann et al., 2002). Through play, fathers seemed to transfer to young children a sense of confidence about parental support, which may strengthen their capacity to master many later challenges.

What factors promote paternal warmth? Cross-cultural research reveals a consistent relationship between the amount of time fathers spend near infants and toddlers and their expressions of caring and affection (Rohner & Veneziano, 2001). Consider the Aka hunters and gatherers of Central Africa, where fathers spend more time in physical proximity to their babies than in any other known society. Observations reveal that Aka fathers are within arm's reach of infants more than half the day. They pick up, cuddle, and play with their babies at least five times as often as fathers in other hunting-and-gathering societies. Why are Aka fathers so involved? The bond between Aka husband and wife is unusually cooperative and intimate. Throughout the day, couples share hunting, food preparation, and social and leisure activities. The more time Aka parents are together, the greater the father's loving interaction with his baby (Hewlett, 1992).

In Western cultures as well, happily married fathers whose partners cooperate with them in parenting spend more time with and interact more effectively with infants. In contrast, marital dissatisfaction is associated with insensitive paternal care (Brown et al., 2010; Lundy, 2002; Sevigny & Loutzenhiser, 2010). Clearly, fathers' warm relationships with their partners and their babies are closely linked. Evidence for the power of fathers' affection, reported in virtually every culture and ethnic group studied, is reason to encourage more men to engage in nurturing care of young children.

© BLEND IMAGES/GETTY IMAGES

In diverse cultures, fathers' warmth predicts long-term favorable cognitive, emotional, and social development.

Nevertheless, because they provide physical and emotional care for an extended time and are invested in the child's well-being, grandparent caregivers forge significant attachment relationships with their grandchildren (Poehlmann, 2003). Warm grandparent–grandchild bonds help protect children from worsening adjustment problems, even under conditions of great hardship. Interviews reveal that children often feel loved, cared for, and optimistic about their futures (Hicks & Goedereis, 2009; Sands, Goldberg-Glen, & Shin, 2009). Still, grandparent caregivers have a tremendous need for social and financial support and intervention services for their at-risk grandchildren.

Attachment and Later Development

According to psychoanalytic and ethological theories, the inner feelings of affection and security that result from a healthy attachment relationship support all aspects of psychological development. Consistent with this view, an extended longitudinal study by Alan Sroufe and his collaborators found that preschoolers who were securely attached as babies were rated by their teachers as higher in self-esteem, social skills, and empathy than were their insecurely attached counterparts, who displayed more behavior problems. When studied again at age 11 in summer camp, children who had been secure infants had more favorable relationships with peers, closer friendships, and better social skills, as judged by camp counselors. And as these well-functioning school-age children became adolescents and young adults, they continued to benefit from more supportive social networks, formed more stable and gratifying romantic relationships, and attained higher levels of education (Elicker, Englund, & Sroufe, 1992; Sroufe, 2002; Sroufe et al., 2005).

For some researchers, these findings seem to indicate that secure attachment in infancy causes improved cognitive, emotional, and social competence in later years. Yet contrary evidence exists. In other longitudinal studies, secure infants generally fared better than insecure infants, but not always (Fearon et al., 2010; McCartney et al., 2004; Schneider, Atkinson, & Tardif, 2001; Stams, Juffer, & van IJzendoorn, 2002). Disorganized/disoriented attachment, however, is an exception: It is consistently related to internalizing problems (fear and anxiety) and externalizing problems (anger and aggression) during the preschool and school years. Disorganized children also show inappropriate role reversals: In an apparent effort to compensate for their parent's confused communication, they use either exaggerated comforting or hostility to try to control the parent's behavior (Lyons-Ruth, 1996; Lyons-Ruth, Easterbrooks, & Cibelli, 1997; Moss et al., 2004, 2006; Moss, Cyr, & Dubois-Comtois, 2004).

© MYRLEEN FERGUSON CATE/PHOTOEDIT

Parental sensitivity—not just in infancy but throughout childhood—likely contributed to these teenagers' social confidence and capacity for friendship.

What accounts for the inconsistency in research findings on the consequences of early attachment quality? Mounting evidence indicates that *continuity of caregiving* determines whether attachment security is linked to later development (Lamb et al., 1985; Thompson, 2006). Children whose parents respond sensitively not just in infancy but also in later years are likely to develop favorably. In contrast, children whose parents react insensitively or who, over a long period, are exposed to a negative family climate tend to establish lasting patterns of avoidant, resistant, or disorganized behavior and are at greater risk for developmental difficulties.

A close look at the relationship between parenting and children's adjustment in the first few years supports this interpretation. Recall that parents of disorganized/disoriented infants tend to have serious psychological problems or engage in highly maladaptive caregiving—conditions that usually persist and that are strongly linked to poor adjustment in children (Lyons-Ruth, Bronfman, & Parsons, 1999). And when more than 1,000 children were tracked from age 1 to 3 years, those with histories of secure attachment followed by sensitive parenting scored highest in cognitive, emotional, and social outcomes. Those with histories of insecure attachment followed by insensitive parenting scored lowest, while those with mixed histories of attachment and maternal sensitivity scored in between (Belsky & Fearon, 2002). Specifically, insecurely attached infants whose mothers became more positive and supportive in early childhood showed signs of developmental recovery.

Does this trend remind you of our discussion of *resilience* in Chapter 1? A child whose parental caregiving improves or who has other compensating affectionate ties outside the immediate family can bounce back from adversity. In contrast, a child who experiences tender care in infancy but lacks sympathetic ties later on is at risk for problems.

Turn back to the evidence on page 428, which indicates that as early as the second year, toddlers have formed attachment-related expectations about parental comfort and support. With cognitive development and continuing experiences with caregivers, this rudimentary internal working model expands into a broader, more complex representation. Recall from page 414 that parents of securely attached preschoolers converse with them in more elaborative ways, especially about emotion. Some researchers believe that these narratives facilitate children's construction of a coherent image of the self in relation to attachment figures (Fivush, 2006; Thompson 2008). Then, as children encounter new attachment-related experiences, they refine and "update" their internal working model.

Although a secure attachment in infancy does not guarantee continued good parenting, it does launch the parent–child relationship on a positive path that is likely to continue.

Much research shows that an early warm, positive parent–child tie, sustained over time, promotes many aspects of children's development: a more confident and complex self-concept, more advanced emotional understanding, stronger emotional self-regulation, more favorable relationships with teachers and peers, more effective social skills, a stronger sense of moral responsibility, and higher motivation to achieve in school (Thompson, 2006, 2008). But the effects of early attachment security are *conditional*—dependent on the quality of the child's future relationships. Finally, as our discussion has already revealed and as you will see again in future chapters, attachment is just one of the complex influences on children's psychological development.

ASK YOURSELF

Review ■ What factors explain stability in attachment pattern for some children and change for others? Are these factors also involved in the link between attachment in infancy and later development? Explain.

Connect ■ Review research on emotional self-regulation on page 408. How do the caregiving experiences of securely attached infants promote the development of emotional self-regulation?

Apply ■ In evaluating her childhood attachment experiences, Monica recalls her mother as tense and distant. Is Monica's newborn daughter likely to develop an insecure attachment? Explain, using research on adults' internal working models.

Reflect ■ How would you characterize your internal working model? What factors, in addition to your early relationship with your parents, might have influenced it?

Attachment, Parental Employment, and Child Care

▶ Discuss the implications of parental employment and child care for attachment security and early psychological development.

Over the past three decades, women have entered the labor force in record numbers. Today, more than 60 percent of U.S. mothers with a child under age 2 are employed (U.S. Census Bureau, 2011b). In response to this trend, researchers and laypeople alike have raised questions about the impact on the attachment bond of child care and daily separations of infant from parent.

The Social Issues: Health box on page 442 reviews the current controversy over whether child care threatens young children's development. As you will see, the weight of evidence suggests that *quality of care* is crucially important. Infants and young children exposed to long hours of mediocre to poor nonparental care, regardless of whether they come from middle- or low-SES homes, score lower on measures of cognitive and social skills (Belsky et al., 2007; Hausfather et al., 1997; NICHD Early Child Care Research Network, 2000b, 2001a, 2003b, 2006). In contrast, good child care can reduce the negative impact of a stressed, poverty-stricken home life, and it sustains the benefits of growing up in an economically advantaged family (Lamb & Ahnert, 2006; McCartney et al., 2007; NICHD Early Child Care Research Network, 2003b).

TAKE A MOMENT... Visit several child-care settings, and take notes on what you see. In contrast to most European countries and to Australia and New Zealand, where child care is nationally regulated and funded to ensure its quality, reports on U.S. child care raise serious concerns. Standards are set by the individual states and vary widely. In studies of quality, only 20 to 25 percent of child-care centers and family child-care settings (in which a caregiver cares for children in her home) provided infants and toddlers with sufficiently positive, stimulating experiences to promote healthy psychological development. Most settings offered substandard care (NICHD Early Child Care Research Network, 2000a, 2004b).

Unfortunately, many U.S. children from low-income families experience inadequate child care (Brooks-Gunn, 2004). But U.S. settings providing the very worst care tend to serve middle-SES families. These parents are especially likely to place their children in for-profit centers, where quality tends to be lowest. Low-SES children more often attend publicly subsidized, nonprofit centers, which have smaller group sizes and better teacher–child ratios (Lamb & Ahnert, 2006). Still, child-care quality for low-SES children varies widely.

SOCIAL ISSUES: HEALTH

Does Child Care Threaten Infant Attachment Security and Later Adjustment?

Are infants who experience daily separations from their employed parents and early placement in child care at risk for attachment insecurity and developmental problems? Some researchers think so, but others disagree. Let's look closely at the evidence.

Attachment Quality

Some studies suggest that babies placed in full-time child care before 12 months of age are more likely to display insecure attachment in the Strange Situation (Belsky, 2001, 2005). But the best current evidence—from the U.S. National Institute of Child Health and Development (NICHD) Study of Early Child Care, the largest longitudinal investigation to date, including more than 1,300 infants and their families—confirms that use of nonparental care by itself does not affect attachment quality (NICHD Early Child Care Research Network, 1997, 2001b). Rather, the relationship between child care and emotional well-being depends on both family and child-care experiences.

Family Circumstances

We have seen that family conditions affect children's attachment security and later adjustment. Findings of the NICHD Study confirmed that parenting quality, assessed using a combination of maternal sensitivity and HOME scores (see page 344 in Chapter 8), exerted a more powerful impact on children's adjustment than did exposure to child care (NICHD Early Childhood Research Network, 1998: Watamura et al., 2011).

For employed parents, balancing work and caregiving can be stressful. Mothers who are fatigued and anxious because they feel overloaded by work and family pressures may respond less sensitively to their babies, thereby risking the infant's security. And as paternal involvement in caregiving has risen (see page 436), many more U.S. fathers in dual-earner families also report work–family-life conflict (Galinsky, Aumann, & Bond, 2009).

Quality and Extent of Child Care

Nevertheless, poor-quality child care may contribute to a higher rate of insecure attachment. In the NICHD Study, when babies were exposed to combined home and child-care risk factors—insensitive caregiving at home along with insensitive caregiving in child care, long hours in child care, or more than one child-care arrangement—the rate of attachment insecurity increased. Overall, mother–child interaction was more favorable when children attended higher-quality child care and also spent fewer hours in child care (NICHD Early Child Care Research Network, 1997, 1999).

Furthermore, when children reached age 3, a history of higher-quality child care predicted better social skills (NICHD Early Child Care Research Network, 2002b). However, at age 4½ to 5, children averaging more than 30 child-care hours per week displayed more behavior problems, especially defiance, disobedience, and aggression. For those who had been in child-care centers as opposed to family child-care homes, this outcome persisted through elementary school (Belsky et al., 2007; NICHD Early Child Care Research Network, 2003a, 2006).

But these findings do not necessarily mean that child care causes behavior problems. Rather, heavy exposure to substandard care, which is widespread in the United States, may promote these difficulties, especially when combined with family risk factors. A closer look at NICHD participants during the preschool years revealed that those in both poor-quality home and child-care environments fared worst in social skills and problem behaviors, whereas those in both high-quality home and child care environments fared best. In between were preschoolers in high-quality child care but poor-quality homes (Watamura et al., 2011). These children benefited from the *protective influence* of high-quality child care.

Evidence from other industrialized nations confirms that full-time child care need not harm children's development. In Australia, for example, infants who spend full days in government-funded, high-quality child-care centers have a higher rate of secure attachment than infants informally cared for by relatives, friends, or babysitters. And amount of time in child care is unrelated to Australian preschoolers' behavior problems (Love et al., 2003).

Still, some children may be particularly stressed by long child-care hours. Many infants, toddlers, and preschoolers attending child-care centers for full days show a mild increase in saliva concentrations of cortisol across the day—a pattern that does not occur on days they spend at home. In one study, children rated as highly fearful by their caregivers experienced an especially sharp increase in cortisol levels (Watamura et al., 2003). Inhibited children may find the constant company of large numbers of peers particularly stressful.

Conclusions

Taken together, research suggests that some infants may be at risk for attachment insecurity and later adjustment problems due to inadequate child care, long hours in such care, and the joint pressures their parents experience from full-time employment and parenthood. But it is inappropriate to use these findings to justify a reduction in child-care services. When family incomes are limited or mothers who want to work are forced to stay at home, children's emotional security is not promoted.

Instead, it makes sense to increase the availability of high-quality child care and to relieve work–family-life conflict by providing parents with paid employment leave (see page 119 in Chapter 3) and opportunities for part-time work. In the NICHD study, part-time (as opposed to full-time) employment during the baby's first year was associated with greater maternal sensitivity and a higher-quality home environment, which yielded more favorable development in early childhood (Brooks-Gunn, Han, & Waldfogel, 2010).

Finally, for child care to foster attachment security, the professional caregiver's relationship with the baby is vital. When caregiver–child ratios are generous, group sizes are small, and caregivers are educated about child development and child rearing, caregivers' interactions are more positive and children develop more favorably—cognitively, emotionally, and socially (McCartney et al., 2007; NICHD Early Child Care Research Network, 2000a, 2002a, 2006). Child care with these characteristics can become part of an ecological system that relieves parental and child stress, thereby promoting healthy attachment and development.

© ELLEN B. SENISI PHOTOGRAPHY

High-quality child care, with generous caregiver–child ratios, small group sizes, and knowledgeable caregivers, can be part of a system that promotes all aspects of child development, including attachment security.

APPLYING WHAT WE KNOW

Signs of Developmentally Appropriate Infant and Toddler Child Care

PROGRAM CHARACTERISTIC	SIGNS OF QUALITY
Physical setting	Indoor environment is clean, in good repair, well-lighted, and well-ventilated. Fenced outdoor play space is available. Setting does not appear overcrowded when children are present.
Toys and equipment	Play materials are appropriate for infants and toddlers and are stored on low shelves within easy reach. Cribs, highchairs, infant seats, and child-sized tables and chairs are available. Outdoor equipment includes small riding toys, swings, slide, and sandbox.
Caregiver–child ratio	In child-care centers, caregiver–child ratio is no greater than 1 to 3 for infants and 1 to 6 for toddlers. Group size (number of children in one room) is no greater than 6 infants with 2 caregivers and 12 toddlers with 2 caregivers. In family child care, caregiver is responsible for no more than 6 children; within this group, no more than 2 are infants and toddlers. Staffing is consistent, so infants and toddlers can form relationships with particular caregivers.
Daily activities	Daily schedule includes times for active play, quiet play, naps, snacks, and meals. It is flexible rather than rigid, to meet the needs of individual children. Atmosphere is warm and supportive, and children are never left unsupervised.
Interactions among adults and children	Caregivers respond promptly to infants' and toddlers' distress; hold, talk to, sing to, and read to them; and interact with them in a manner that respects the individual child's interests and tolerance for stimulation.
Caregiver qualifications	Caregiver has some training in child development, first aid, and safety.
Relationships with parents	Parents are welcome anytime. Caregivers talk frequently with parents about children's behavior and development.
Licensing and accreditation	Child-care setting, whether a center or a home, is licensed by the state. Voluntary accreditation by the National Academy of Early Childhood Programs *(www.naeyc.org/accreditation)*, or the National Association for Family Child Care *(www.nafcc.org)* is evidence of an especially high-quality program.

Source: Copple & Bredekamp, 2009.

See Applying What We Know above for signs of high-quality child care for infants and toddlers, based on standards for **developmentally appropriate practice.** These standards, devised by the U.S. National Association for the Education of Young Children, specify program characteristics that meet the developmental and individual needs of young children, based on both current research and consensus among experts. When child care meets standards for developmentally appropriate practice, children's learning opportunities and the warmth, sensitivity, and stability of their caregivers are especially high.

Child care in the United States is affected by a macrosystem of individualistic values and weak government regulation and funding. Furthermore, many parents think that their children's child-care experiences are higher in quality than they really are. Unable to identify good care, they do not demand it (Helburn, 1995). In recent years, recognizing that child care is in a state of crisis, the U.S. federal government and some states have allocated additional funds to subsidize its cost, primarily for low-income families. Though far from meeting the need, this increase in resources has had a positive impact on child-care quality and accessibility (Children's Defense Fund, 2009).

Good child care is a cost-effective means of supporting the development of all children. For children whose development is at risk, it can serve as effective early intervention, much like the programs we discussed in Chapter 8. We will revisit the topics of parental employment and child care in Chapter 14, when we focus on their consequences for development during childhood and adolescence.

ASK YOURSELF

Review ■ Cite evidence that high-quality infant and toddler child care supports development, whereas poor-quality care undermines it.

Apply ■ Randi and Mike are worried that placing their 6-month-old baby, Lucinda, in child care may disrupt Lucinda's sense of security. List steps that Randi and Mike can take to ensure that Lucinda's experiences—at home and in child care—support her emotional and social development.

SUMMARY

Functions of Emotions (p. 401)

Describe the functionalist approach to emotional development.

- The **functionalist approach** emphasizes that the broad function of **emotions** is to energize behavior aimed at attaining personal goals. Emotions are central in cognitive processing, social behavior, and physical health. Emotions also contribute to the emergence of self-awareness, which makes possible new, self-evaluative emotions. Gradually, children gain voluntary control over their emotions.

Development of Emotional Expression (p. 405)

How does the expression of basic emotions change during infancy?

- During the first six months, **basic emotions** gradually become clear, well-organized signals. The **social smile** appears between 6 and 10 weeks, laughter around 3 to 4 months. Happiness strengthens the parent–child bond and reflects and promotes motor and cognitive mastery.

© RADIUS IMAGES/ALAMY IMAGES

- Anger and fear (especially in the form of **stranger anxiety**) increase from the second half of the first year into the second year, as infants' cognitive and motor capacities improve. Newly mobile babies use the familiar caregiver as a **secure base** from which to explore.

Describe the development of self-conscious emotions, emotional self-regulation, and conformity to emotional display rules.

- During toddlerhood, self-awareness and adult instruction provide the foundation for **self-conscious emotions:** guilt, shame, embarrassment, envy, and pride. With age, these emotions become more internally governed.
- **Emotional self-regulation** emerges as the prefrontal cortex develops and as caregivers sensitively assist infants in adjusting their emotional reactions. With motor, cognitive, and language development and warm parental guidance, children acquire more effective self-regulatory strategies. Children who experience negative emotion intensely find it harder to inhibit feelings and shift attention away from disturbing events.
- By age 10, most children can shift adaptively between **problem-centered** and **emotion-centered coping** in regulating emotion. Emotionally well-regulated children are optimistic and cooperative and have positive relationships with teachers and peers.
- Young preschoolers start to conform to their culture's **emotional display rules.** From infancy on, parents encourage children—especially boys—to suppress negative emotion. In middle childhood, children understand the value of display rules in ensuring social harmony.

Understanding and Responding to the Emotions of Others (p. 414)

Describe the development of emotional understanding from infancy through middle childhood.

- Around the middle of the first year, infants respond to emotional expressions as organized, meaningful wholes. Beginning at 8 to 10 months, they engage in **social referencing,** seeking emotional information from caregivers in uncertain situations. By the middle of the second year, toddlers realize that others' emotional reactions may differ from their own.
- Preschoolers understand many causes, consequences, and behavioral signs of emotion. The capacity to consider conflicting cues when explaining others' feelings improves in middle childhood, along with an appreciation of mixed emotions. Warm parental conversations about emotions and interactions with siblings and friends, especially make-believe play, are excellent contexts for learning about emotions.

Describe the development of empathy from infancy into adolescence, noting individual differences.

- As toddlers develop self-awareness, they begin to empathize. During childhood and adolescence, gains in language, emotional understanding, and perspective taking support an increase in **empathy,** which motivates **prosocial,** or **altruistic, behavior.**
- Children who are sociable, assertive, and good at regulating emotion are more likely than poor emotion regulators to move from empathy to sympathetic, prosocial behavior. Warm parents who encourage emotional expressiveness, show empathic concern, and help their child regulate angry feelings promote development of empathy and sympathy. Angry, punitive parenting disrupts these capacities.

Temperament and Development (p. 418)

What is temperament, and how is it measured?

- Children vary widely in **temperament**—early-appearing, stable individual differences in reactivity and self-regulation. The New York Longitudinal Study identified three patterns: the **easy child,** the **difficult child,** and the **slow-to-warm-up child.** The most influential model of temperament, devised by Rothbart, includes dimensions representing emotion, attention, and action, along with **effortful control,** the ability to regulate one's reactivity.
- Temperament is assessed through parental reports, behavior ratings by others familiar with the child, and laboratory observations. Most neurobiological research has focused on distinguishing **inhibited,** or **shy, children** from **uninhibited,** or **sociable, children.**

Discuss the roles of heredity and environment in the stability of temperament, the relationship of temperament to cognitive and social functioning, and the goodness-of-fit model.

- Long-term prediction from early temperament is best achieved after age 3, when styles of responding are better established. Although temperament is moderately heritable, both shared environmental influences and nonshared influences—evident in parents' tendency to emphasize each child's unique qualities—contribute.
- Children's temperamental traits consistently predict their cognitive and social functioning. Effortful control is linked to generally favorable development and adjustment.
- The **goodness-of-fit model** describes how a child's temperament and environment work together to affect later development. Parenting practices that fit well with the child's temperament help children achieve more adaptive functioning.

Development of Attachment (p. 428)

What are the unique features of ethological theory of attachment?

- The most widely accepted perspective on development of **attachment** —our strong affectionate tie with special people in our lives—is **ethological theory,** which recognizes the infant's emotional tie to the caregiver as an evolved response that promotes survival.
- Around 6 to 8 months, **separation anxiety** and use of the parent as a secure base indicate the existence of a true attachment bond. Separation anxiety declines as representation and language develop, enabling preschoolers to better understand the parent's coming and going. From early caregiving experiences, children construct an **internal working model** that serves as a guide for all future close relationships.

Describe how researchers measure the security of attachment, and discuss the stability of attachment patterns.

- Researchers using the **Strange Situation** to measure the quality of attachment between ages 1 and 2 have identified four attachment patterns: **secure, avoidant, resistant,** and **disorganized/disoriented.** The **Attachment Q-Sort**, based on home observations of children between ages 1 and 4 years, yields a score ranging from high to low in security.
- Securely attached babies in middle-SES families with favorable life conditions more often maintain their attachment pattern than insecure babies. However, the disorganized/disoriented pattern is highly stable. Cultural conditions must be considered in interpreting the meaning of attachment patterns.
- Attachment security is influenced by early availability of a consistent caregiver, quality of caregiving, the fit between the baby's temperament and parenting practices, and family circumstances. **Sensitive caregiving** is moderately related to secure attachment. In Western cultures, **interactional synchrony** characterizes the experiences of securely attached babies.

© AFRIPICS.COM/ALAMY

- Parents' internal working models are good predictors of children's attachment security, but parents' childhood experiences do not transfer directly to quality of attachment with their own children.

Discuss infants' formation of multiple attachments and the role of early attachment quality in later development.

- Infants develop strong affectionate ties to fathers, who tend to engage in more exciting, physical play with babies than do mothers. Sensitive, stimulating play is a vital context in which fathers and babies build secure attachments, predicting favorable emotional and social adjustment.
- Grandparents who serve as primary caregivers for grandchildren in skipped-generation families forge significant attachment ties that help protect children with troubled family lives from adjustment problems.
- Secure attachment in infancy launches the parent–child relationship on a positive path. But continuity of caregiving determines whether attachment security is linked to later development. If caregiving improves, children can recover from an insecure attachment history.

Attachment, Parental Employment, and Child Care (p. 441)

Discuss the implications of parental employment and child care for attachment security and early psychological development.

- Research indicates that quality of care is crucially important. Spending many hours in mediocre to poor-quality child care, especially when combined with family risk factors, predicts insecure attachment and less favorable cognitive, emotional, and social development.
- When child-care settings meet professionally accepted standards for **developmentally appropriate practice,** children's learning opportunities and the warmth, sensitivity, and stability of their caregivers are especially high. Good child care can also serve as effective early intervention for children whose development is at risk.

CHAPTER 11

“Hand in Hand”

Shing Nok Man, 11 years, Hong Kong

As young people construct a self-concept, they see themselves as distinct individuals with unique abilities, accomplishments, and aspirations but also as vitally connected to others.

Reprinted with permission from the International Museum of Children’s Art, Oslo, Norway

Self and Social Understanding

“Grandpa, look at my new shirt!” exclaimed 4-year-old Ellen at her family’s annual reunion. “See, it’s got a ladybug on it, and a yellow flower, and . . .”

Ellen’s voice trailed off as she realized that all eyes were on her 1-year-old cousin, who was about to take his first steps. As little David tottered forward, the grownups laughed and cheered. No one—not even Grandpa, who was usually so attentive and playful—took note of Ellen and her new shirt.

Ellen retreated to the bedroom, where she threw a blanket over her head. Arms outstretched, she peered through the blanket’s loose weave and made her way back to the living room. “Here I come, the scary ghost,” announced Ellen, deliberately bumping into David, who toppled over and burst into tears.

Pulling off the blanket, Ellen caught her mother’s disapproving glance and protested, “I couldn’t see him, Mom!”

Ellen’s mother insisted that Ellen apologize and help David up. But she couldn’t help marveling at Ellen’s skillful capacity for trickery.

This chapter addresses the development of **social cognition**, or how children come to understand their multifaceted social world. Like our discussion of cognitive development in Chapters 6 and 7, this chapter is concerned with how children think about and interpret experience. The experience of interest, however, is no longer the child’s physical surroundings but the self and other people.

Researchers interested in social cognition seek answers to questions like these: When do infants discover that they are separate beings, distinct from other people and objects? How does children’s understanding of their own and others’ mental lives change with age? (For example, what new realizations underlie Ellen’s creative act of deception?) When children and adolescents are asked to describe their own and others’ characteristics, what do they say?

As we answer these and other questions, you will see that the trends identified for cognitive development also apply to children’s social understanding:

- Social-cognitive development proceeds *from concrete to abstract.* Children start by noticing observable characteristics—their own and others’ appearance and behavior. Soon after, they become aware of internal processes—the existence of desires, beliefs, intentions, abilities, and attitudes.
- Social cognition becomes *better organized* with age as children integrate separate behaviors into an appreciation of their own and others’ personalities and identities.
- Children revise their ideas about the causes of behavior—from *simple, one-sided explanations* to *complex, interacting relationships* between person and situation.
- Social cognition moves toward *metacognitive understanding.* With age, children’s thinking extends beyond social reality to reflections on their own and other’s social thoughts.

Although nonsocial and social cognition share many features, social cognition is more complex. Movements of things—for example, a rolling ball—can be fully explained by the physical forces that act on objects. In contrast, a person’s behavior is affected not only by others’ actions but also by inner states that we cannot observe directly.

In view of this complexity, we might expect social cognition to develop more slowly than nonsocial cognition. Surprisingly, it does not. Unique features of social experience

are probably responsible. First, because people are animated beings and objects of deep emotional investment, they are especially interesting to think about. Second, social experience constantly prompts children to revise their social cognitions by presenting them with discrepancies between the behaviors they expect and those that occur. Finally, because we are all human beings, with the same basic nervous system and a background of similar experiences, interpreting behavior from the self's viewpoint often helps us understand others' actions. When it does not, humans are equipped with a powerful capacity—*perspective taking*—that enables us to infer others' thoughts and feelings.

Our discussion is organized around three broad aspects of development: thinking about the self, thinking about other people, and understanding conflict, including how to solve social problems. We have already considered some social–cognitive topics—for example, referential communication skills in Chapter 9 and emotional understanding in Chapter 10. Research on moral reasoning and on understanding of gender, also social–cognitive topics, is so extensive that each merits a chapter of its own. We will consider them in Chapters 12 and 13. ■

- ▶ Describe the development of self-awareness in infancy and toddlerhood, along with the emotional and social capacities it supports.
- ▶ Describe the development of the categorical, remembered, and enduring selves.
- ▶ Discuss theory-of-mind development from early to middle childhood, citing social consequences and contributing factors.
- ▶ Discuss the development of self-concept from early childhood through adolescence, noting cognitive, social, and cultural influences.

Emergence of Self and Development of Self-Concept

Infancy is a rich formative period for development of both physical and social understanding. In Chapter 6, you learned that infants develop an appreciation of the permanence of objects. And in Chapter 10, we saw that over the first year, infants recognize and respond appropriately to others' emotions and distinguish familiar from unfamiliar people. That both objects and people achieve an independent, stable existence for infants implies that knowledge of the self as a separate, permanent entity is also emerging. Self-development begins with the dawning of self-awareness in infancy and gradually evolves into a rich, multifaceted, organized view of the self's characteristics and capacities during childhood and adolescence.

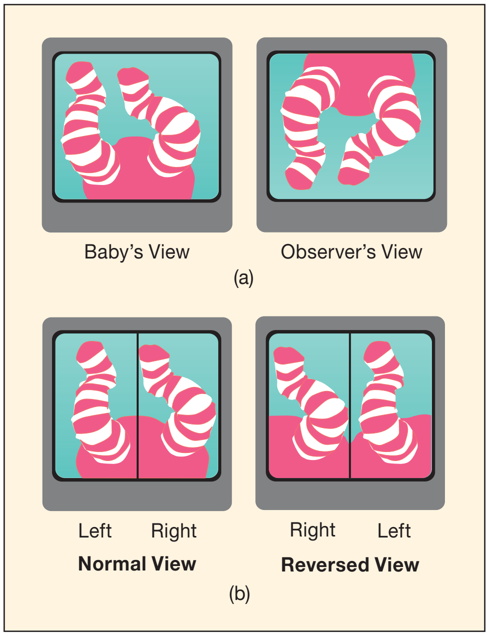

FIGURE 11.1 Three-month-olds' emerging self-awareness, as indicated by reactions to video images. (a) When shown two side-by-side views of their kicking legs, babies looked longer at the novel, observer's view than at their own view. (b) When shown a normal view of their leg positions alongside a reversed view, infants looked longer at the novel, reversed view. (Adapted from Rochat, 1998.)

Self-Awareness
